About the online resources

www.orthopaedicmedicineonline.com

The website that accompanies this book includes several complementary resources:

1. **Additional chapters** (please refer to the Contents) not contained in the book which includes those covering **applied anatomy**. These chapters now showcase a large number of illustrations from Elsevier's key anatomy books such as *Gray's Anatomy*, *Sobotta – Atlas of Anatomy* and *Human Anatomy* by Gosling et al.
2. **Over 100 video clips of examination and treatment techniques** described in the text. The techniques demonstrated on the website are marked in the book by the following symbol .
3. **Lists of references** for the book and online text with direct links to the abstracts on Medline.

Source publications

The online resources include figures taken from the following publications:

The index

The index covers entries taken from the chapters which occur within the book itself. To find entries which occur across the online resources, please use the Search facility on the website, www.orthopaedicmedicineonline.com.

Preface to the third edition

Since its first publication, almost two decades ago, *A System of Orthopaedic Medicine* has proven to be a reliable guide and a dependable working tool for many physicians and therapists working in the field of orthopaedic medicine. During these two decades we have witnessed a quite astonishing advance in technology that has made it possible to see even the slightest anatomical changes. Computed tomography, magnetic resonance imaging, sonography and arthroscopy have changed the practice of medicine to an unbelievable degree. So have new surgical techniques that address the restoration of anatomical defects. Despite the great progress that these procedures represent, they are not an unmixed blessing. There is an almost irresistible tendency to overuse them. This not only plays an important part in escalating the cost of medical practice, but may also result in an unnecessary hazard to the health of the patient. Another danger of the booming technology is that physicians who rely too much on easy-to-order tests are in danger of losing their clinical ability to diagnose and think. In the end, looking substitutes for thinking, which is not without danger if one considers the huge number of asymptomatic anatomical changes that exist in a normal population.

The outline of this third edition remains unchanged. The book still focuses mainly on clinical reasoning and diagnosis to counterbalance the massive present-day emphasis that is given to technical investigation. The 'System' relies first of all on a systematic clinical assessment of the joints involved. Interpretation of the results obtained then groups the disorders and conditions into clinical syndromes. Finally, the natural history and the conservative treatment of each condition are discussed. For this third edition, each chapter has been revised completely and the references fully adapted. This new edition also contains a huge online resource that consists of (a) Over 100 video clips of examination and treatment techniques, (b) all the references with access to the abstracts on Medline, (c) all the applied anatomy chapters, illustrated with artwork from Elsevier anatomy books, and (d) less important chapters taken out from the book.

Ludwig Ombregt
2013

Preface to the first edition

This book is based entirely on the Cyriax approach to orthopaedic medicine. James Cyriax (1904–1985), the 'father' of orthopaedic medicine, devoted his whole life to developing a logical system of clinical examination designed to elicit accurate diagnoses of locomotor disorders. His system is founded on a few elementary theories: *referred pain* and *selective tension* – an injured structure hurts when tension is put on its fibres. A detailed clinical examination using these simple principles outlines clinical patterns that can be interpreted on the basis of the known facts of applied anatomy and physiology. Logical conclusions can then be drawn regarding diagnosis, treatment and spontaneous recovery.

The authors of this book were all trained by Dr Cyriax and subsequently taught with him until his death in 1985. Ever since, they have continued his work, and as far as possible improved it. The fact that they are all practitioners, using the system in their daily clinical work, has helped to add considerable complementary clinical experience.

Orthopaedic medicine has traditionally been a grossly neglected area of medical education, despite the large number of patients suffering from non-surgical orthopaedic conditions. Any family practitioner will confirm that between a fifth and a quarter of his/her work consists of patients complaining of musculoskeletal pain. This combination of inadequate education and a high incidence of disorders leads to a large number of patients for whom there is no clear diagnosis nor proper treatment. Chronicity, neurosis and compensation claims are, then, in many cases, inevitable consequences.

In recent years another trend has had a major impact on orthopaedic medicine. Outstanding advances such as computed axial tomography (CAT), magnetic resonance imaging (MRI), arthroscopy and echography have undoubtedly enhanced the clinician's ability to see detailed anatomical images and structures. However, these procedures have brought mixed blessings. Too often they are employed unquestioningly before a good clinical diagnosis has been established and may contribute needlessly to the escalating costs of health care. More importantly, the 'lesions' these investigations reveal are often not the real cause of the problem and may seriously mislead the examiner, resulting in either inappropriate or potentially harmful treatment for the patient. Technology has become, in too many cases, a substitute for clinical skills, and the ability to diagnose and think remains poor.

An accurate clinical diagnosis is the first and most important obligation for every orthopaedic doctor and therapist. Since these skills are not formally taught, the purpose of this book is to provide a systematic approach to clinical examination which can lead to accurate diagnosis. The method described is logical and consists of assessing in turn the function of each moving tissue, the positive and negative responses forming a pattern. These patterns are then translated into clinical syndromes. The system relies entirely on basic clinical skills and requires none of the diagnostic apparatus found only in hospitals. For this reason, it will be of particular value to family doctors, physiotherapists, rheumatologists, orthopaedic surgeons and particularly those working in sports medicine. Especial emphasis is given to differential diagnosis. Warning signs are highlighted to alert both examiner and therapist to possible pitfalls and therapeutic dangers.

Most of the treatments described were devised by Cyriax. They are: injections, infiltrations and deep transverse friction for muscular, tendinous and ligamentous lesions; manipulation for some ligamentous disorders and for reducing displaced fragments of cartilage in the different joints; traction for some types of lumbar disorders and capsular stretching for some capsular disorders. Although there may be many alternative equally effective treatments practised by others, the authors have confined themselves to those with which they have considerable personal experience. The techniques described here are simple and have, through time, confirmed their effectiveness. For any treatment to be successful, accurate diagnosis must be followed by carefully focused therapy to the affected area. For this reason, considerable detail is given on the correct performance of each therapeutic technique, supported by numerous clear, explanatory photographs and diagrams.

Finally we wish to stress the importance of close cooperation between physician and (physio)therapist. The system of orthopaedic medicine promoted in this book requires teamwork. Both doctor and therapist examine the patient in the same way, speak the same language and share their assessments and diagnoses. As to treatment, some disorders will respond better to physical treatment and others will require a medical approach, but both professions need to be fully aware of the possibilities, modalities and potential results.

Definition of pain

Pain is the presenting symptom in almost every orthopaedic patient. A complaint of pain is always indicative of some variety or degree of dysfunction[1] and results from a combination of physical and psychological causes, although sometimes one or the other predominates. All pain must be regarded as real. Pain entirely devoid of somatic cause is labelled 'psychogenic pain': although no peripheral tissue damage exists, the pain is just as distressing as somatic pain[2] (see Section 16).

The taxonomy committee of the International Association for the Study of Pain defined pain as: 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage'.[3] Pain is thus not a 'primary sensation' in the sense that smell, taste, touch, vision and hearing are, but is an 'emotional state', like sorrow, love or hate. The consequence is that it is extremely difficult to explain one's pain to another person. This is reflected in the numerous words that patients use to describe intensity and quality of pain: twinge, ache, distress, discomfort, soreness, cramp, suffering, misery, agony, torment, anguish.[4] The fact that pain is always a subjective experience provides the first difficulty in its use in diagnosis. The language used is not always easy to understand, and the examiner usually needs a high level of competence and understanding to translate patients' subjective descriptions into more objective and useful statements.

However, unlike the other affective states, pain is always felt in some particular *part* of the body. Having said this, the localization of the pain very often lacks precision, and it is often experienced at some distance from its source – 'referred pain'. This constitutes the second problem in using the symptom of pain as a diagnostic aid.

Perception and modulation of pain

The intensity of pain does not depend only on the intensity of irritation of the peripheral nociceptive system (receptors and their afferents). Centripetal transmission of peripheral nociceptive stimulation is subject to varying degrees of facilitatory and inhibitory modulation at different synapses during its course to the cerebral cortex. An important modulation site, of major concern to the orthopaedic physician, is the gateway synapse in the basal spinal nucleus, but there are also

modulation systems in the spinal grey matter, in the thalamus and in the cerebral cortex itself.[5]

Peripheral nociceptive system

Nociceptive receptors are defined as nerve endings that are sensitive to noxious or potentially noxious (mechanical and chemical) stimuli. The perceptual aspect of the nociceptive system consists of unmyelinated free nerve endings, distributed three dimensionally throughout skin, subcutaneous and adipose tissue, fasciae, aponeuroses, ligaments, tendons, muscles, periosteum and bone.[6,7] Clinically, three distinct areas of pain perception may be considered: the skin (superficial somatic pain); the locomotor system (deep somatic pain); and the viscera (visceral pain). Of these, only the skin is adapted to localize pain exactly in the region of injury. Deep somatic and visceral pain are often felt in unusual locations (see Referred pain, p. 6).

In normal circumstances, this nociceptive receptor system remains largely inactive. The unmyelinated free nerve endings are depolarized only by the application of mechanical forces sufficient to deform or damage the tissue that contains them or after exposure to sufficient concentrations of irritating chemical substances (lactic acid, serotonin, prostaglandins and histamine), released from local inflammatory cells and from the peripheral terminals of the primary afferent fibres themselves.[8–10]

Another important influence on nociceptor sensitivity is the pH of the tissue. High local concentrations of protons are known to occur in inflammation and the consequent reduction in pH contributes to the sensitization of nociceptors.[11,12]

Afferent nociceptive system

Nerve impulses generated at the nociceptive receptor system are delivered into the spinal cord by small myelinated and unmyelinated nerve fibres (5 μm or less in diameter), that mainly belong to the Ad and C groups of afferent nerve fibres (Fig. 1.1). Their cell bodies are located in the dorsal root ganglia of the spinal nerves. The very small diameter of the C nerves explains their slow conduction velocity (1 m/s), and their extreme sensitivity to blockade by local anaesthetic drugs. The myelinated Ad fibres are slightly larger and have a faster conduction velocity (10 m/s).[13]

The nociceptive afferents enter the spinal cord, where they divide into short ascending and descending branches, before they terminate at synapses on various groups of relay neurones in the dorsal horn of the spinal grey matter. Most of the connections are to the neurones in the basal spinal nucleus (at the base of the dorsal horn).[14,15]

The efferents of these cross the cord obliquely to turn upwards on the contralateral side and form the anterolateral spinal tract, which connects the basal spinal nucleus with the thalamic nuclei and has therefore traditionally been called the 'spinothalamic tract'. Most of the fibres in this tract, however, do not directly ascend to the thalamus without interruption, but instead synapse with neurones in the brainstem reticular system, while others re-enter the spinal grey matter to synapse

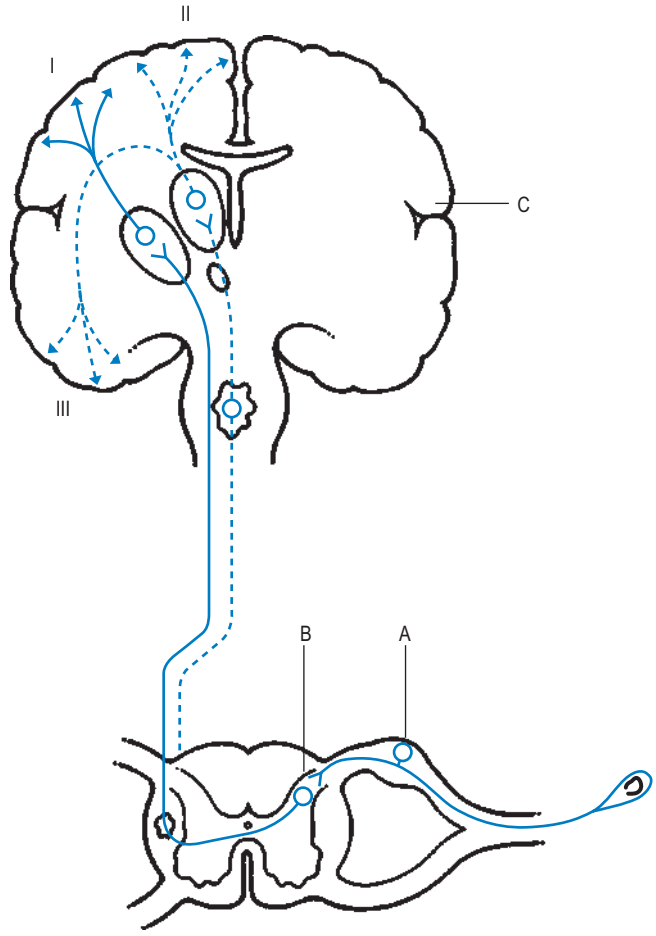

Fig 1.1 • The afferent nociceptive systems. Projection areas: I, perceptual area; II, emotional area; III, memory storage. Three levels of sensory neurone: A, primary sensory neurone; B, dorsal horn cell (gateway synapse); C, thalamic relay.

with internuncial neurones.[16] However, the majority of the ascending nociceptive inputs terminate (sometimes after crossing several synapses) in the thalamic nuclear relay sites.[17] It should be emphasized that not only do the neurones in the thalamic centres respond to peripheral noxious stimulation but they can also be activated by mechanoreceptor peripheral stimulation (see Pain modulation systems below).

The axons of the thalamic nuclei then ascend to the neurones of the cerebral cortex. Three thalamocortical projections can be defined: those responsible for perception; those related to the emotional experience; and those responsible for memory.[18]

The first project to the superior paracentral region of the cerebral cortex and seem to contribute to the so-called '*perceptual component*' of pain – the patient's ability to perceive whereabouts (in which segment of his body) the pain is localized.[19]

The activation of the second thalamocortical projection system, projections that pass from the medial and anterior thalamic nuclei to the frontal lobes, evokes the *emotional disturbances* related with pain.[20] Thus, a stimulus 'hurts' only when the nociceptive afferent projections arrive at the frontal cortex.

A third thalamocortical projection system links some of the medial thalamic nuclei to the cortex of the ipsilateral temporal lobe. Here the recent and *long-term memory storage systems* of the brain are located.[21,22]

A fourth projection system exists which relates some thalamic nuclei to subjacent hypothalamic nuclei in the ventral diencephalon. It is very probable that this thalamohypothalamic system provides the means whereby nociceptive afferent activity entering the brain evokes the complex of *visceral reflex* (cardiovascular and gastrointestinal) *effects* and hormonal changes that are so often associated with the experience of pain.[23]

In conclusion, activity of nociceptive receptors distributes pain into four different projecting systems in the brain, each contributing to a specific component of the global experience 'pain'. However, the projection of pain from a peripheral receptor to the brain is not via a straight-line system. The intensity of pain is not only determined by the intensity of peripheral stimulation but also depends largely on peripheral and central modulation systems at the various synaptic stages in the course of the afferent pathway within the central nervous system. These modulation systems account for the large variation in the intensity of pain experienced. Patients with apparently comparable pathological lesions undergo widely different degrees of suffering; even in an individual patient, the intensity of experience of pain varies widely with the prevailing emotional mood, with concentration on the problem or with suggestions from others.

Pain modulation systems

There are both peripheral and central pain modulation systems.

Peripheral modulation of pain

One of the most important sites at which a synaptic modulation operates from both the peripheral and central sources is at the synapses in the basal spinal nucleus. In 1965, Melzack and Wall,[24] basing their theory mainly on the work of Noordenbos,[25] published an article entitled: 'Pain mechanism: a new theory'. They called their concept of peripheral pain modulation the *gate control theory* (Fig. 1.2), which is based on three premises:

- Afferent nerves contain two types of fibres: small fibres (P), as described above, and large-diameter afferents (M), which are derived from the various mechanoreceptors in the articular capsule, ligaments and muscle spindles. These fibres produce information about static joint position, pressure changes in the joints, joint movement and stresses that develop in the joint at the extremes of movement. The fibres of mechanoreceptor transmission have a lower stimulation threshold and a faster conduction velocity than the smaller and mostly unmyelinated fibres of the nociceptive system.
- In the substantia gelatinosa (SG) of the dorsal horn, both afferent systems converge and interrelate, with the overall effect that the large-diameter afferents have an inhibitory effect on the relay neurones located in the basal spinal nucleus. This inhibition is presynaptic and is reduced only when there is a massive input from the small nociceptive afferent fibres. The latter thus facilitates central transmission of pain. The interaction between both systems is gate control: impulses travelling along the larger fibres close the gate, and those in the small fibres open the gate so that impulses to thalamus and cortex can pass through.
- The activity of the gate is not only modulated by impulses from nociceptive and mechanoreceptor systems but also receives a descending and regulating feedback from the reticular system, the thalamus and the cerebral cortex.

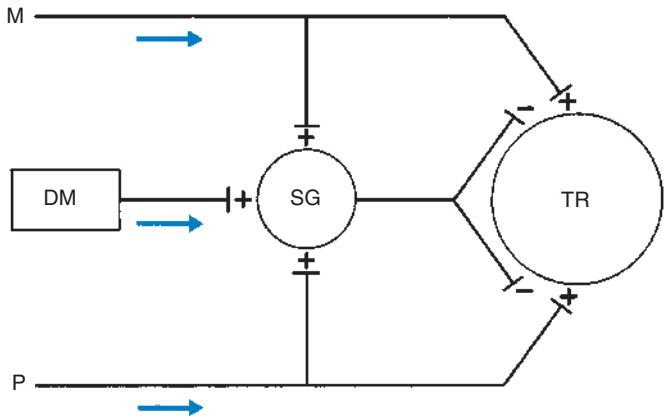

Fig 1.2 • Gate control theory (after Melzack and Wall[24]): P, small nociceptive fibres (pain); M, large mechanoreceptive fibres; TR, transmission cells (relay neurones in the basal spinal nucleus); DM, descending modulation; SG, substantia gelatinosa; +, excitatory effect; –, inhibitory effect.

This peripheral modulation of pain has considerable clinical importance. It indicates that centripetal projection into the central nervous system of afferent activity from the nociceptive receptor systems is not passed straight to any 'pain centre' in the brain but receives constant modulation at its synaptic portal of entry into the neural axis at the level of the basal spinal nucleus. The modulation stems from the concurrent activity of the mechanoreceptors located in the same tissues, and from feedback through projection systems descending from the brainstem and cerebral cortex. This effect is one of the reasons why movement and selective stimulation of mechanoreceptors can cause inhibition of pain.

Central modulation of pain

Awareness of pain is also modulated at the central projection systems.

At the reticular formation

A modulation system at the reticular formation in the brainstem exerts a continuous inhibitory effect on the projection neurones in the spinal nucleus ganglion via the reticulospinal tract, which is discharging continuously at varying frequencies throughout life.[26] The inhibitory effect on nociceptive afferent transmission is augmented when the attention of the patient is distracted from the site of pain. This is what occurs when

another painful site elsewhere in the body is stimulated (counter-irritation), when the patient concentrates on work or other activities or when hypnosis is induced.[27] The inhibitory effect of this reticular system also increases when the blood concentration of catecholamines is very high, as can be the case in states of great emotional tension.[28] Also some drugs (chlorpromazine, diazepam and morphine) may selectively increase the activity of the reticular neurones that operate this inhibitory system.[29]

Inhibitory reticular activity is depressed and pain is enhanced when attention is concentrated on the painful site, or following the administration of barbiturates, caffeine or theophylline.[30]

The cerebral cortex

The cerebral cortex, especially the sectors located in the frontal and paracentral regions, in turn regulates the activity of the reticular formation. Reticular activity is increased, and perception of pain thus inhibited during rest and sleep and after the ingestion of alcohol. Conversely, depression of reticular activity is seen during increasing cortical activity, for example with anxiety, uncertainty and fear.

Referred pain

Introduction

When the skin is pricked with a pin, the patient can exactly pinpoint the injury. This ability to localize the pain is limited to skin and does not apply when the source of the pain is in deep tissue. Deep somatic pain and visceral pain are often felt far from their point of source. In consequence, the examiner needs to know the patterns of pain reference so as not to be misled about where to search for the seat of the trouble. Diagnosis of orthopaedic lesions often rests entirely on history and clinical examination and is therefore almost impossible if the rules and conditions relevant to referred pain are not clearly understood.

Those who originally studied pain reference soon noted that although it appeared erroneous and anarchic, some rules of presentation did exist. For instance, pain from specific structures is always referred to the same parts of the body: colic from a ureteral stone to groin and testicle, diaphragmatic disorders typically to the shoulder, angina pectoris to one or both arms, and the pain caused by arthritis of a hip very often to the ipsilateral knee. Also pain is, in the main, referred distally and its localization depends in a certain way on the severity of the lesion.

In 1905, Sir Henry Head described referred pain in the abdominal wall caused by a visceral disease.[31] Using the dermatological appearances in herpes zoster, he constructed schemes of segmental innervation of the skin.[32] He also described dermatomic zones that became painful in the event of provocation of a related visceral structure. His theory of pain reference was built on the concept of the segmental organization of the human body and its nociceptive system. Further experiments in this sphere were conducted by Sir Thomas Lewis in 1936.[33] In 1938 and 1939, Kellgren published the results of a systematic examination of the phenomena of referred pain, demonstrating segmental radiation and failure to cross the midline.[34,35]

His experiments were confirmed by others.[36–38] Later, the concept of segmental reference of pain was refined[39,40] and exact borders of the different dermatomes mapped out.[41–44]

Possible mechanisms

The fact that referred pain is an error in perception was first pointed out by John Hunter in 1835 (cited by Cyriax).[45] It was obvious that if pain is felt elsewhere than at its true site, the nociceptive mechanism is reacting inappropriately. However, since there seems to be logical consistency in the way the errors are made (pain from specific lesions is always referred to the same areas), there must also be a logical explanation for 'failures'. (If a machine always makes the same mistake, a structural or functional disorder must exist.) The basis for the inadequacy must therefore be sought in a miscalculation in the pain mechanism. Theoretically, the defect can lie anywhere along the afferent pathway, from the peripheral receptors to the synapses in the spinal cord and the reticular area and projection zones in the sensory cortex.

During the last century, numerous investigators have studied referred pain. Two main hypotheses have been put forward:

- *Error at the level of the spinal cord*. Most authors have opted for this hypothesis. Mackenzie described an 'irritable focus' in the grey matter of the spinal cord as being responsible for the phenomenon.[46] Also Livingston[47] placed the basis of the error at synapses in the dorsal horns. Wedell *et al*[48,49] and Pomeranz[50] accepted a double origin for the sensitive neurone – afferent fibres of a somatic structure, and those coming from a related visceral structure synapse with the same spinal ganglion. Taylor *et al*[51] and Wells *et al*[52] also made a plea for the spinal explanation of referred pain. Their view is that separate peripheral sensory nerves (deep somatic, skin and visceral) converge on to the same cell in the dorsal horn of the spinal cord (Fig. 1.3).
- *Failure at the sensory cortex*. A number of authors have proposed that the misinterpretation is at the projection area of the sensory cortex rather than at the spinal level.[33,53,54] The concept was clinically elaborated by Cyriax who based his theory on a number of premises:
  - Referred pain is a pain experience felt elsewhere than at its true site of origin.
  - Skin is an organ adapted to localize the pain accurately.
  - Pain is experienced in the sensory cortex, which is organized dermatome by dermatome.
  - The skin is represented accurately in the sensory cortex.
  - A memory storage system is located in the sensory cortex. This is fed by constant input from the skin. Input from deeper somatic structures is very rare in a normal and healthy individual.

As pointed out previously, pain is experienced at three different locations in the cerebral cortex. Perception – of the site of

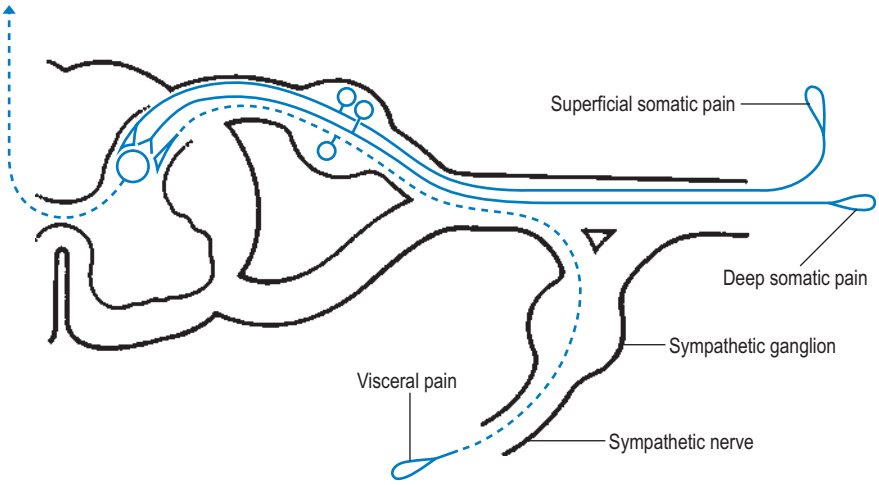

Fig 1.3 • Separate peripheral sensory nerves converge onto the same cell in the dorsal horn of the spinal cord.

pain – is located in the superior paracentral cortex. The frontal lobes evoke the emotional disturbances related to pain, and the memory store is in the temporal lobes.

The ability to localize pain in the region of injury is limited to skin and does not apply when the source of the pain is in deep tissue. In due course, a certain pain memory is built up in the temporal lobes, and achieves a high degree of anatomical precision. The efficacy of the long-term memory storage system is not simply a function of the intensity of the painful experience but also relates to the length of time a painful experience lasts or to the frequency with which it is repeated.[55,56] Since the frequency of painful stimuli coming from the skin is much higher than the frequency of stimuli coming from deeper structures, it will be obvious that pain memory will centre around painful experiences from the skin. When the same cortical cells receive a painful message arriving from a deep-seated structure, the memory will interpret it on the basis of past experience; in that the sensory cortex is arranged segmentally, the pain will be ascribed to the correct segment but the system will fail to localize it accurately at the site of the lesion. The brain therefore 'places' it in the tissue it has a reference for – the skin. Pain is thus felt under the surface area connected with the particular cells that belong to the same segment as the tissue from which the nociceptive afferents originate. The pain is felt deep to the skin of the relevant dermatome and not accurately in the skin.

Clinical consequences

The concept of referred pain is extremely important to the orthopaedic physician, who has to deal daily with the problem. If the principles of erroneous localization by the cortex are clearly understood, the examiner can turn a misleading phenomenon to diagnostic advantage. In the Cyriax concept, referred pain obeys certain rules. The inadequacy in the sensory cortex is structural and therefore can easily be accommodated. To a certain degree, referred pain can be compared with the refraction of light when it falls on a water surface. The observer does not see objects under the water surface at their exact localization. However, since the error of perception is structural and obeys particular physical rules and laws, it is easy to correct what is seen (provided the observer knows the correction formula) and so locate the object accurately. The same applies to referred pain. The examiner must constantly ask if the localization of the pain is also the exact localization of the disorder and, if the answer is negative, what corrections must be made to arrive at the exact localization.

Before this discussion of referred pain is continued, it should be stressed that root pain reference does not necessarily mean that a nerve is involved. The false idea that wide radiation of pain is evidence of involvement of nerves is still strongly held by some and is usually the most important obstacle to a logical understanding of referred pain. To approach the problem of referred pain with an open mind, the reader must constantly remember that referred pain is an *error of perception*. Although the nerve supply to these peripheral structures is distributed on a segmental basis, it does not indicate that referred pain 'runs down' a somatic nerve. For instance, pain at the anterior aspect of the leg does not necessarily mean that a nerve structure (L3, femoral nerve or peripheral branches of the femoral nerve) is involved. Although inflammation of the dural sleeve of the L3 nerve root does of course lead to pain extending in the L3 dermatome, the same pain can be provoked by a lesion in any other tissue belonging to the L3 segment (e.g. hip joint or psoas bursa). There will not be any difference in the nature and extent of the pain. The only distinction between pain as the result of a compressed and inflamed nerve root and pain originating from trauma to other structures is the appearance of paraesthesia (see Pressure on nerves, Ch. 2).

Rules of referred pain (Box 1.1)

The first rule – reference of pain within the borders of the skin area that belongs to the same segment as the tissue lesion that causes pain – follows directly from the premise that the nociceptive mechanism is organized on a segmental basis. Nociceptors, afferent fibres and the sensory cortex are all arranged segmentally. Afferents from skin, deep somatic structures and visceral organs from the same segment relay on the same dorsal neurones and project to the same area in the sensory cortex. Pain reference is therefore confined to, and remains within, the borders of the cutaneous area (or dermatome) that belongs

embryologically to the same segment as the tissue from which the pain is arising.

To understand the segmental organization of the nociceptive mechanism, it is necessary to reconsider embryogenesis (Fig. 1.4).

Embryogenesis

Primitive body

When a fetus is between 4 and 6 weeks old, 42 pairs of somites develop: four occipital, eight cervical, 12 thoracic, four to six lumbar, five sacral and eight to 10 coccygeal.[57] The first two and the last seven or eight pairs disappear early in development. The ventral aspect of each somite differentiates into the *sclerotome* which, together with the chorda around the neural tube, forms the origin of the axial skeleton. The other part of the somite becomes the *myotome*, covered by the *dermatome*. Each pair of somites develops its own segmental innervation which later leads to the development of the spinal ganglion and spinal nerve.

In due course, the dermatome differentiates into skin and subcutaneous tissue, the myotome into muscles, tendons, ligaments, capsules and bursae, and the sclerotome into bone and fibrous septa. Although the original form of most segments is modified as the limbs are formed, their segmental innervation remains constant throughout life. The projection area in the cerebral cortex also remains segmentally organized.

Limb formation

After the first month of intra-uterine life, two pairs of buds originate at the lateral sides of the fetus. The proximal papules appear first at the base of the neck, followed by the formation of two distal buds in the caudal area. These extensions gradually project from the cylindrical fetal segments from which they originate. As the limbs grow further and further laterally, some dermatomes become totally disconnected from the trunk (Fig. 1.5).

For the upper limb, the dermatomes C5, C6, C7, C8 and T1 leave the trunk completely to form the covering of the arm. T2, although also present at the inner aspect of the upper arm, connects with the trunk again, and borders with C4.

In the lower limb, parts of L2, L3 and the whole dermatomes L4–L5 and S1 withdraw from the trunk to form the lower limb. S2 is present partly in the limb and partly in the buttock, where it borders with L3.

During limb formation, some muscles undergo centripetal migration and others centrifugal. As a rule, however, dermatomes distally project further than myotomes, and sometimes a muscle becomes completely dissociated from the covering dermatome. An example of dermatome migration is

Box 1.1

Rules of referred pain

- The pain radiates segmentally and does not cross the midline
- The pain is usually felt deeply
- The pain is referred distally within the dermatome
- The pain does not necessarily cover the area of the causative lesion
- The pain is felt anywhere in the dermatome but not necessarily in the whole dermatome

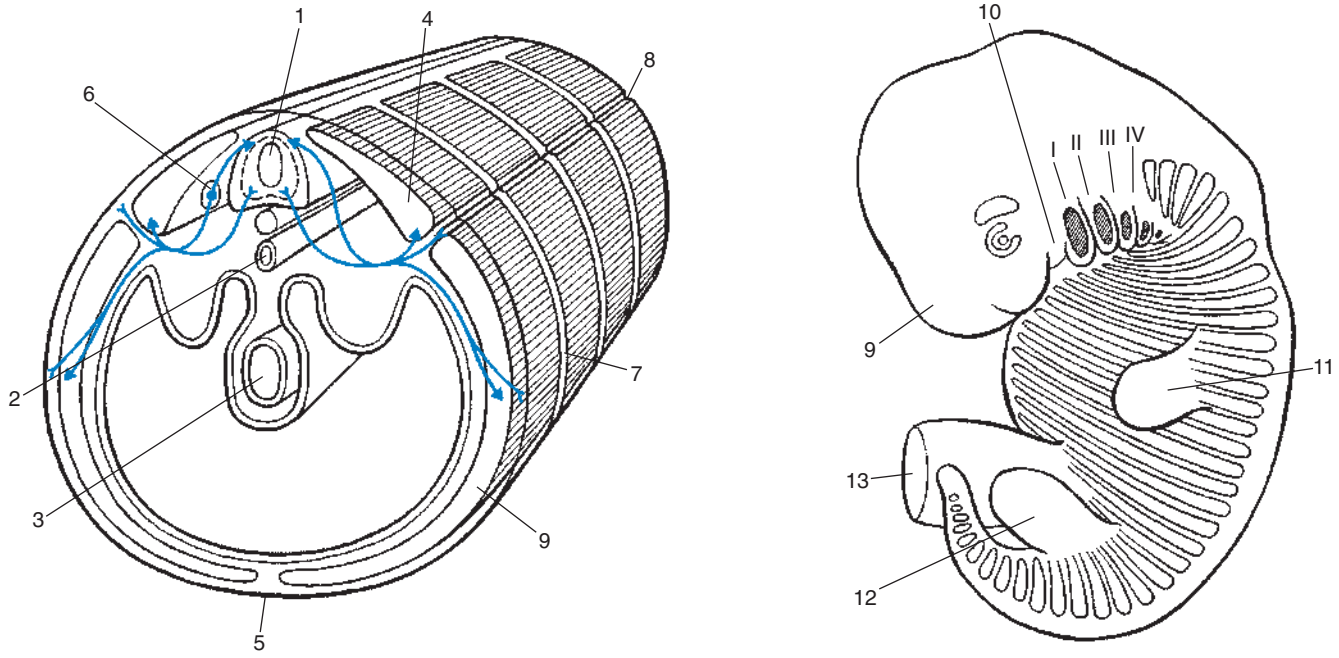

Fig 1.4 • Embryogenesis: 1, neural tube; 2, aorta; 3, intestine; 4, myotome; 5, dermatome; 6, primitive spinal ganglion and spinal nerves; 7, myoseptum between the segments; 8, horizontal septum; 9, frontal knob; 10, maxillar knob; 11, cranial limb bud; 12, caudal limb bud; 13, umbilical cord; I–IV, gill arches.

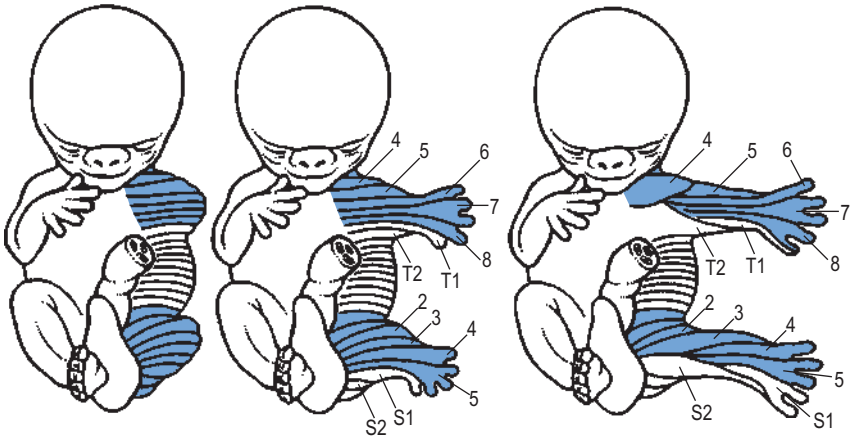

Fig 1.5 • Limb formation. As the limbs grow further and further laterally, some dermatomes become anatomically disconnected from the trunk.

the C5 segment in the upper limb: the myotome does not extend beyond the elbow, but the fifth cervical dermatome descends to the radial styloid. An example of centrifugal dissociation between a muscle and its relevant dermatome is the diaphragm, which has a C4 origin: the C4 dermatome ends at the scapular spine and under the clavicle, and is therefore completely separated from the thoracic localization of the muscle. Another instance of muscle migration is the latissimus dorsi muscle (C7–C8) which shifts its origin to the iliac crest. The dermatomes of the seventh and eighth cervical segment, however, do not occupy the trunk, so dissociating the muscle almost completely from its corresponding dermatomes.

Because of these muscle migrations, with overlaps and discontinuous areas, it is very difficult to draw accurate maps of the myotomes. However, in the appropriate chapters of this book, we will indicate to which segment each of the structures under discussion belongs.

Dermatomes

The cutaneous area supplied by one spinal nerve is a dermatome. The first clinicians to draw dermatomic maps were Head and Campbell.[58] Their diagrams are the basis for the classical drawings in standard neurological textbooks. However, they did not take into consideration the significant degree of variability and overlap in dermatomic borders.[57,58] Later investigators such as Keegan and Garrett, and Fukui *et al*[59,60] have demonstrated that dermatomes of adjacent spinal nerves overlap markedly.

An example of this is pain at the anterior aspect of the thigh, which can be of second or third lumbar origin. The second lumbar dermatome spreads from the groin, down the front of the thigh, to the patella. Pain of third lumbar origin again spreads along the anterior aspect of the thigh and the patella but it can continue down the anterior aspect of the leg, to just above the ankle. Pain at the anterior aspect of the thigh therefore can be of second or third lumbar origin but if it spreads further down below the patella then its origin is third lumbar.

Another example of overlap between dermatomes is referred pain in the hand and fingers: C6 pain refers to the dorsal aspect of the hand, the thumb and the index finger, whereas C7 refers also to the dorsum of the hand and the index finger, as well as to the long and ring fingers. In a patient complaining of pain at the back of the forearm or at the dorsum of the hand and the index finger, it is difficult to decide whether the pain is of sixth or seventh cervical origin.

We use the charts drawn by Foerster[41] in 1933 and corrected by Cyriax in 1982,[45] in order to give the broadest possible information about the area to which pain from a particular segment may refer. The extreme importance of accurate localization of pain in orthopaedic medicine requires the physician to use a map of dermatomes that is as close as possible to clinical reality. The figures showing the dermatomes are based on Foerster,[41] Cole *et al*,[61] Cyriax,[45] Conesa,[62] Wakasugi,[63] and Mitta.[64]

Cervical and thoracic dermatomes

C1 to C4 occupy the scalp (C1), the back of the neck and the temporal area, the upper half of the ear and the upper half of the face (C2), the neck, lower mandibular area and chin (C3), and the lower half of the neck, shoulder area, front of the upper chest and the area above the spina scapulae (C4) (Fig. 1.6).

C5 to T2 are projected from the trunk to form the covering of the upper limb (Figs 1.7 and 1.8).

C5 covers the deltoid area and the outer aspect of the arm up to the base of the thumb.

C6 is the anterolateral aspect of the arm, the thenar eminence, thumb, dorsum of hand and index finger.

C7 comprises the back of the arm and hand, together with index, long and ring fingers.

C8 is the inner aspect of the forearms, the hypothenar area and palm, together with the three ulnar fingers.

T1 includes the inner aspect of the forearm as far as the hypothenar eminence.

T2 is Y-shaped and overlies the inner aspect of the upper arm and the axilla, where it divides into an anterior and a posterior component. This latter part of the dermatome borders with the inferior aspect of the C4 dermatome.

If the upper limb is held outstretched horizontally with the thumb pointing upwards, the original position of the embryological bud is recreated, and one can reconstruct the way the dermatomes project from the trunk. This is a good way to

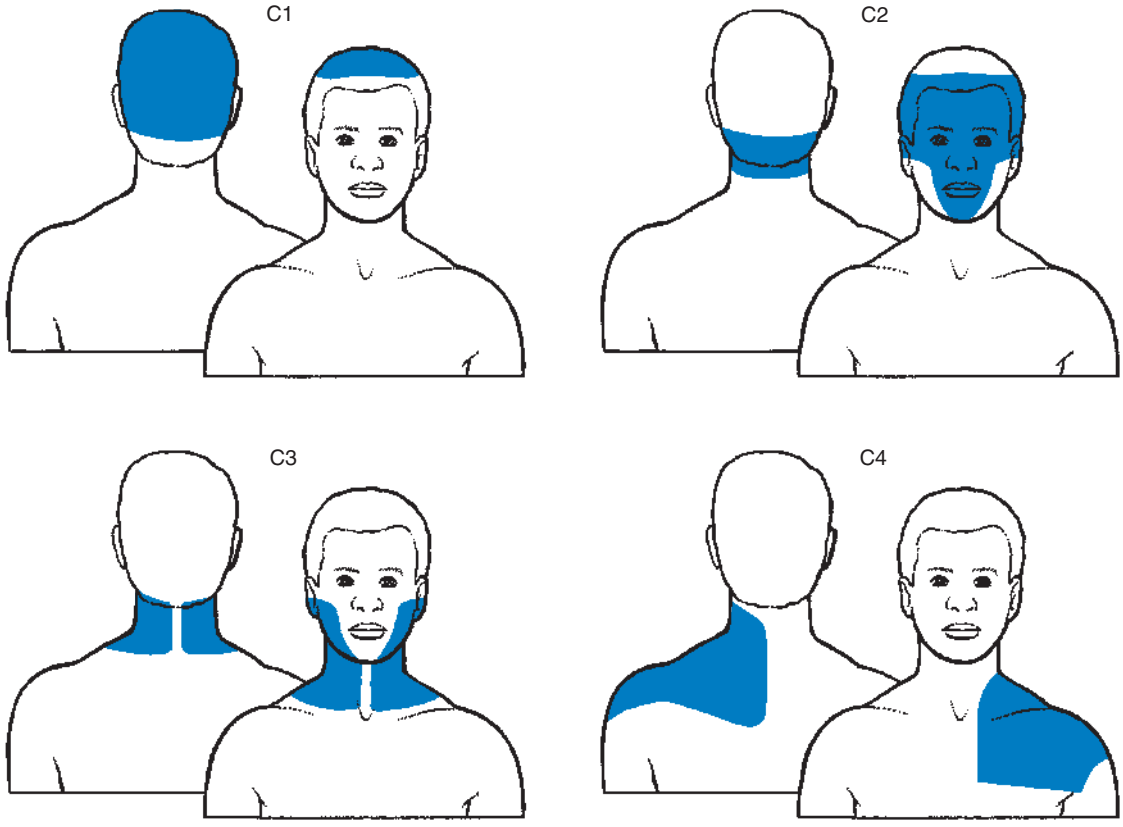

Fig 1.6 • C1 to C4 dermatomes.

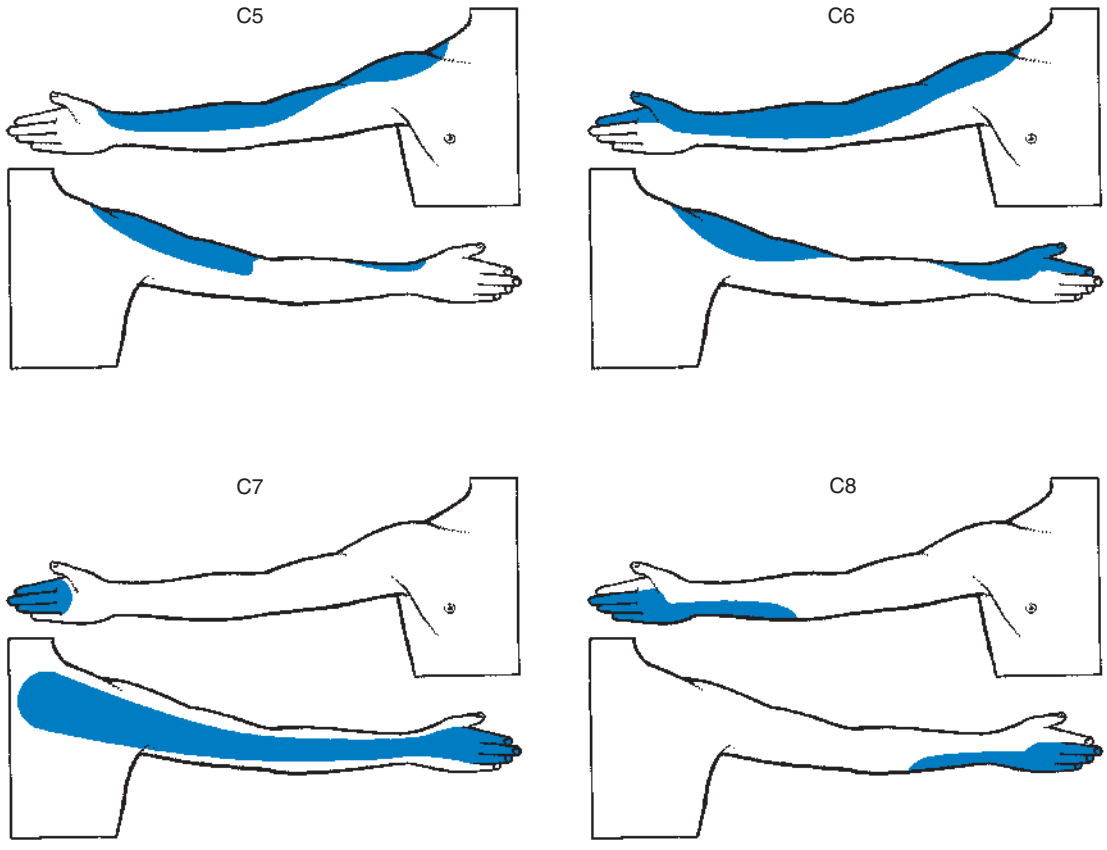

Fig 1.7 • C5 to C8 dermatomes.

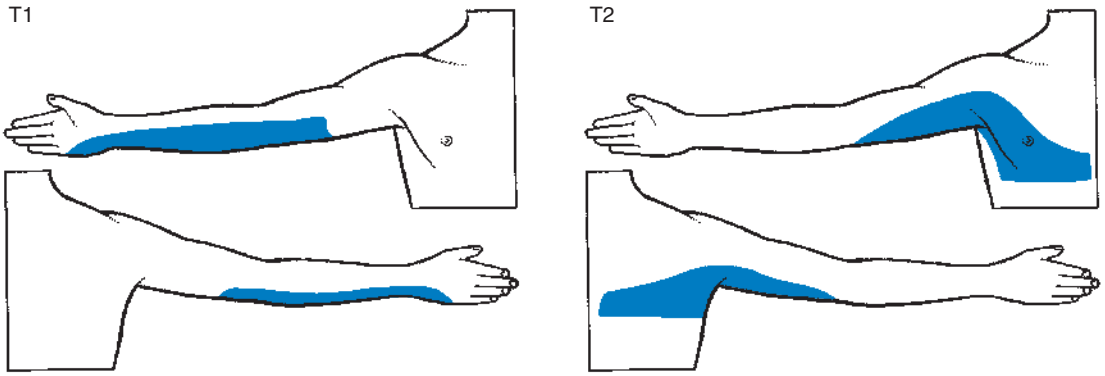

Fig 1.8 • T1 and T2 dermatomes.

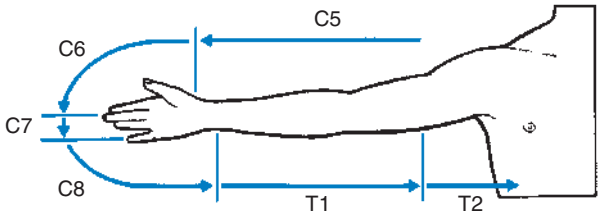

Fig 1.9 • Outstretched arm with arrows showing the dermatomes.

memorize the position of the separate dermatomes in the upper limb (see Fig. 1.9).

From T4 to T12, the dermatomes encircle the trunk, more or less following the original segmental construction of the embryo (Fig. 1.10).

T4 constitutes the axilla and a patch on the front of the chest.

T4 encircles the trunk at the level of the nipple.

T7 reaches the lower costal margin and covers the xiphoid process.

T10 is level with the umbilicus, and T12 reaches to the groin, and probably also the area between the femoral trochanter and iliac crest.

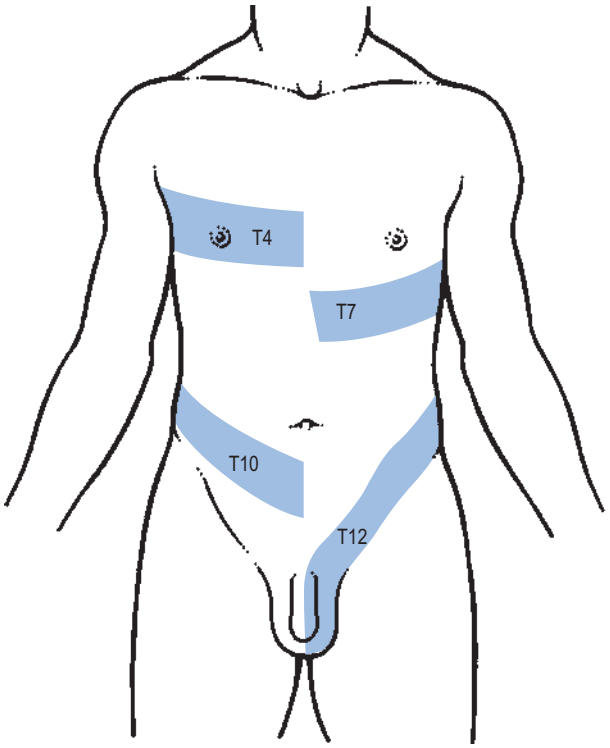

Fig 1.10 • T4, T7, T10 and T12 dermatomes.

Lumbar and sacral dermatomes

L1 is also more or less circular (Fig. 1.11). It comprises the lumbar region from the second to the fourth lumbar vertebrae, and runs along the upper aspect of the buttock and the iliac crest to the lower abdomen and the groin.

L2 and L3 are two discontinuous areas, one in the lower lumbar region and upper buttock, and one in the leg (Fig. 1.12). The areas in the buttock largely overlap. Also, in the leg, there is considerable overlap between L2 and L3: L2 involves the whole front of the thigh, from the groin to the patella. L3 also takes in the anterior aspect of the thigh, but spreads further down, as far as the anterior and medial aspects of the ankle.

L4, L5 and S1 are completely disconnected from the trunk, overlying the surface of the leg and foot (Figs 1.13 and 1.14).[64] In consequence, the third lumbar dermatome lies adjacent to the upper border of the second sacral dermatome at the lower buttock.

L4 occupies the lateral aspect of the thigh, crosses the leg above the ankle, and ends at the medial malleolus, the inner border of the foot and the big toe.

L5 consists of the outer aspect of the leg and crosses the ankle above the lateral malleolus, to end on the dorsum of the foot. L5 also comprises the big, second and third toes, and the inner half of the sole.

S1 includes the calf, the heel, the lateral malleolus and foot, the two outer toes and the whole sole of the foot (Fig. 1.15). Sicard and Leca[65] demonstrated that the fifth lumbar and first sacral dermatomes also comprise a small vertical band at the

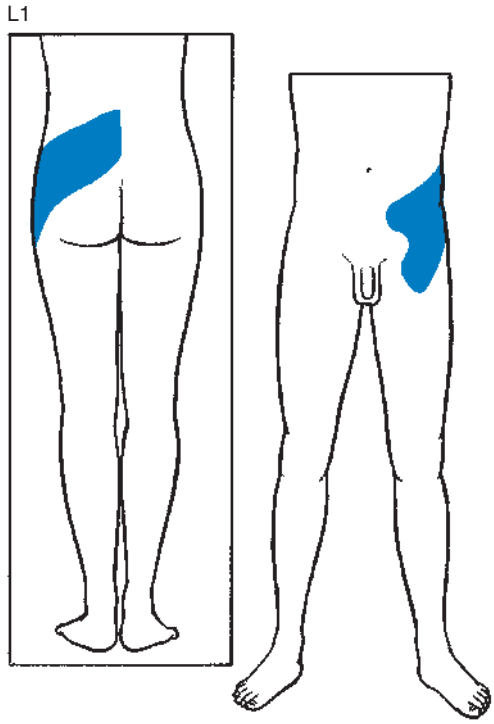

Fig 1.11 • L1 dermatome.

posterior aspect of the thigh, which could account for the thigh pain commonly described by patients suffering from L5 or S1 sciatica.

S2 is large and comprises the plantar aspect of the heel, the calf, the back of the whole thigh and the lower buttock. In the buttock, it borders with the lumbar part of L3 (Fig. 1.15).

S3 is a narrow zone at the inner side of the thigh, where it borders with L2 anteriorly and S2 posteriorly (Fig. 1.16). The tip ends just proximal to the knee. The upper extent reaches the inguinal ligament where it adjoins the 12th thoracic and first and second lumbar dermatomes. It follows that the groin is a confluence of dermatomes, and pain, apart from that of local origin, may be referred from a 12th thoracic, a first or second lumbar, or a third sacral origin. The groin is also a common site for extrasegmental dural pain reference.

S4 comprises the saddle area, anus, perineum, and scrotum and penis or labia and vagina.

S5 is the coccyx.

As in the upper limb, the original position of the distal embryological bud can be reconstructed by abducting the thigh to 90°, and by lateral rotation until the big toe points upwards. This position demonstrates the way the dermatomes were projected from the trunk and also constitutes a good way of memorizing the position of the various dermatomes in the lower limb (Fig. 1.17). Proximally to distally and then turning proximally again, the following are encountered: L2 at the

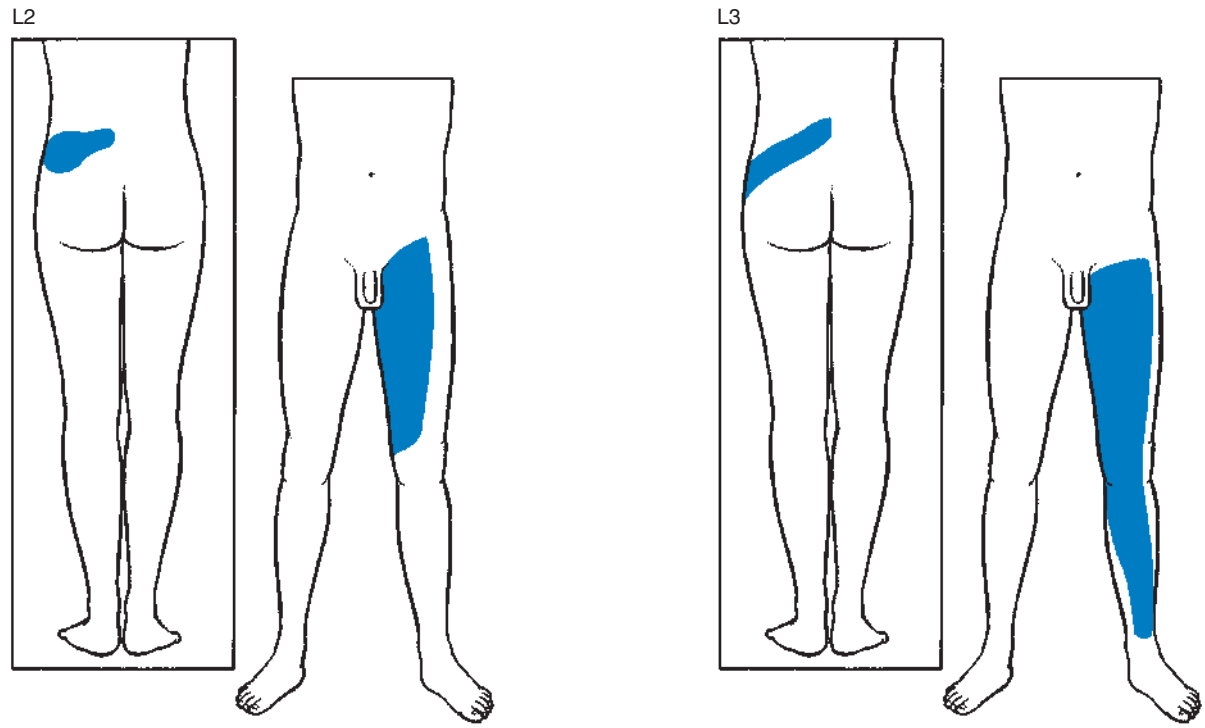

Fig 1.12 • L2 and L3 dermatomes.

anterior thigh, L3 at thigh and leg, L4 at the lateral aspect of the leg, anterior aspect of ankle and inner border of foot up to the big toe, L5 at the dorsum of the foot and the three inner toes, S1 at the lateral aspect of the foot, outer malleolus and calf, S2 at the posterior aspect of the leg; turning back to the trunk in the gluteal area, the boundary zone in the perineum, between leg and trunk is comprised of S3 and S4.

Discrepancies between dermatomes and myotomes

We have mentioned already that, as the outcome of embryological development, dermatomes do not always precisely cover the underlying myotomes. Cyriax described eight areas in the human body where the skin and the structure it covers have completely different embryological derivations (Cyriax[45]). These are the head, scapular and pectoral region, hand, intrathoracic and intra-abdominal region, buttock and scrotum.

Head

The skull, head and face are derived from the two remaining occipital somites, originally situated at the back of the neck. During development, a pair of frontal knobs and two mandibular arches form and fold forwards to create the skeleton and soft tissues around the buccal cavity. The skin of the head and face, however, are formed from the upper two cervical segments.

Scapular region

The growth of the protuberances that are to become the upper limbs draws some segments out from the cylindrical cervical and thoracic structures. At the same time, the scapula and its muscles, together with the latissimus dorsi (C5–C7) move centripetally between the skin of the thorax (circularly arranged thoracic dermatomes) and the underlying ribs and intercostal muscles (circularly arranged thoracic sclerotomes and myotomes). Therefore, pain in the scapular area can have both scapular (cervical) and thoracic origins.

Pectoral region

During the growth of the upper limb bud, the same phenomenon as occurs in the scapular region takes place at the pectoral region. The pectoral muscles, derived from cervical segments (C6–C7) move centripetally between the thoracic dermatomes and their myotomes.

The hand

The thenar muscles form part of the eight cervical and first thoracic myotomes, but the skin is formed from the fifth and sixth cervical dermatomes. The interosseus muscles are C8 and T1, but the skin of the dorsum of the hand, except at the ulnar border which is also C8, is derived from the C6 and C7 segments.

Intrathoracic region

It is obvious that there are numerous discrepancies in origin between the thoracic cage and its content. The diaphragm, for instance, is derived from the third and fourth cervical segments

and thereafter descends. Hence a lesion of the diaphragm may cause pain felt in the neck and at the upper scapular and pectoral region, even though it lies at the lower thoracic level. The heart is derived from C8 to T4. Therefore myocardial pain may radiate to the chest, the shoulder and the inner aspect of the arm, as far as the ulnar border of the hand. It is presumed that a small part of the myocardium, probably the auricles, has a third cervical origin, which could explain the well-known clinical fact that the pain of angina often radiates to the neck anteriorly. The oesophagus is T4–T6 and the lungs have a T2–T5 origin.

Intra-abdominal region

The abdominal wall has a more or less circular construction, from T7 at the xiphoid process, over T10 at the umbilicus, to L1 at the iliac crest, inguinal ligament and groin. In the abdominal wall, the dermatomes exactly overlie the myotomes.

Most of the intra-abdominal content also has a mid- and lower thoracic origin. The embryological derivation of the stomach and duodenum (T6–T10), liver (T7–T9 right), gall bladder (T6–T10 right),[66] pancreas (T7–T8) and small intestine (T9–T10), fit very well with their actual localization in the abdominal cavity, and therefore pain derived from these organs approximates with their surface representation. Structures of lower thoracic, lumbar or even sacral origin, however, show a more complicated pattern of referred pain. The kidney and ureter, for instance, have a T11–L1 derivation and, although they are localized high up in the abdomen, referred pain can reach the inguinal fossa and the groin (T12–L1). The colonic flexure is from L2 to L3, which allows the pain not only to radiate to the lower back but also to the front of the thigh. The sigmoid colon and rectum have S3–S5 origin. Hence, in diseases of the sigmoid and the rectum, pain can be felt in the iliac fossa, perineum, penis, vulva and inner aspect of the thigh.

The buttock

The skin of the lower lumbar area and the outer buttock is derived from L1. At the upper buttock, there is considerable overlap with the lumbar patches of the L2 and L3 segments (Fig. 1.18). The skin of the lower buttock is derived from S2.

The gluteal muscles forming the buttocks are derived from the fourth lumbar to the first sacral segments. Consequently, the dermatomes descend further distally than the myotomes they cover.

Scrotum

The testicles are derived from T11–T12 and L1. The epididymis has a T10 origin. The scrotum, however, belongs to the S4 dermatome. A trauma to the testicle therefore may cause not only local pain but also pain spreading along the iliac crest posteriorly and up to the lower thoracic region. Testicular disease frequently produces pain in one or the other iliac fossa.

Referred pain in visceral diseases

It is important to emphasize that referred pain is not a phenomenon of orthopaedic medicine only. As described earlier, many visceral diseases also cause referred pain. For the convenience of practitioners often faced with thoracic or abdominal pain, a list of the segmental derivations of the viscera, based on the work of Cyriax[45] (see his p. 30), William and Warwick,[67] Lindsay *et al*[68] and Guyton (cited by Van Cranenburgh[69] is given in Box 1.2).

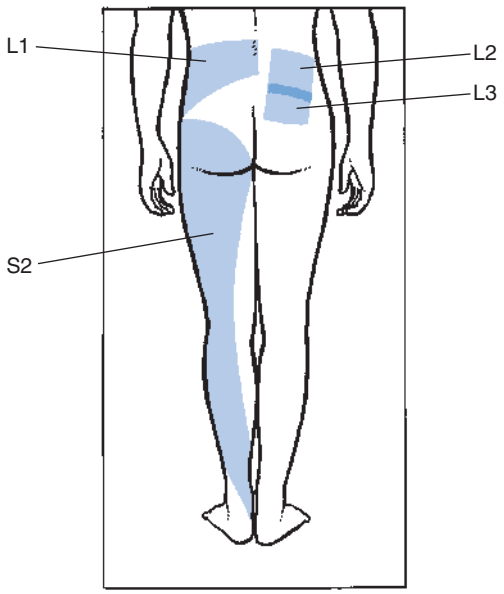

Fig 1.18 • Overlap of the dermatomes at the back and the buttock.

Box 1.2

Referred pain in visceral diseases

Heart (auricles?)	C8–T4 (C3?)
Lungs	T2–T5
Oesophagus	T4–T6
Diaphragm	C3–C4
Stomach and duodenum	T6–T10
Liver and gall bladder	T7–T9 right
Spleen	T7–T10 left
Pancreas	T8
Small intestine	T9–T10
Appendix	T10–L1
Kidney	T10–T12 (L1)
Ureter	T11–T12
Suprarenal glands	T11–L1
Ovary and testis	T11–T12 (L1)
Epididymis	T10
Colon: ascending	T10–L1
flexure	L2–L3
sigmoid	S3–S5
Rectum	S3–S5

Referred pain is felt deeply and distally in the dermatome

An important difference between local pain and referred pain is that in the latter the pain is felt deeply and vaguely. The

patient thus does not point to a localized and precise area, but outlines an approximate one and tends to describe it as 'deep'.

That pain – with some exceptions – is always referred distally, remains a purely empirical clinical observation and has hitherto not been explained on neurophysiological grounds. The fact that pain that arises from the proximal part of a segment can be felt distally in the dermatome but a distal lesion is not referred proximally within this same segment, remains an inconsistency that is hard to rationalize. However, this clinical observation is very important to the clinician confronted with referred pain, for the lesion must never be sought in a structure that is localized distally of the painful area. Pain at the distal aspect of the L3 dermatome (knee and lower limb) can have a proximal origin (spine, hip), but pain only in the hip or the groin, cannot be caused by a lesion at the knee or the thigh.

Segmentally referred pain does not cross the midline

The segments in the body are arranged in pairs, each of which has its own segmental innervation and its own projection area in the cerebrum. Hence it is obvious that the cerebral cortex will easily differentiate between a left-side or a right-side pain, and no one will question that a C5 pain on the left side has a left-side origin and vice versa. The fact that pain stemming from a unilateral structure does not cross the midline, becomes important in the interpretation of more or less centrally localized pain, for instance in aches in the neck or back. It is evident that a lesion of a unilateral facet joint will not cause pain radiating all over the lower back. Only centrally localized structures (vertebral body, longitudinal ligaments, intra- and supraspinal ligaments and dura mater) can theoretically be responsible for a bilaterally radiating pain at both sides of the midline. A pain felt centrally or bilaterally must originate from a central structure, or from two bilateral structures (two facet joints or two sacroiliac joints) but it can never be the result of a lesion in a unilateral structure.

Dura mater an 'exception' to segmental reference

Pain originating from the dura mater has a rather peculiar behaviour. First, in that the dura is a midline structure, it is innervated from both sides, so that pain refers bilaterally. Second, pain stemming from the dura has a very broad reference and seems to cover several consecutive dermatomes. For instance, pressure of a lumbar disc on the dura at the L5 level can cause pain in the back which radiates to the abdomen and groins, down to the anterior and posterior aspect of both thighs and legs, and upwards to the back of the lower chest. This type of pain reference is inexplicable in terms of segments. We therefore call it '*extrasegmental reference*' of pain. Because in orthopaedic medicine, the dura is the exclusive source of this type of pain radiation, it is also called *dural reference*. Pain of this nature can be very difficult to interpret if it is felt in a part or parts of the possible reference area. As in purely segmental reference, dural reference can be to only a part of the respective dermatomes. Thus, instead of the broad radiation to the whole back, both glutei and both legs, dural pain sometimes only affects a small part, for instance one groin, or one buttock or the whole posterior aspect of the thigh. The differential diagnosis from a more segmental pain, for instance as the result of a nerve root compression, is then difficult.

A common clinical finding in a cervical disc protrusion that impacts on the dura is unilateral interscapular pain or pain in the trapezius or pectoral area. In the latter instance, suspicion of angina pectoris may then easily arise. Also the removal of an appendix for dural pain of lumbar origin referred extrasegmentally into the iliac fossa and groin is not at all exceptional.

A possible explanation for the misleading pain reference of the dura may lie in its multisegmental origin, which is reflected in the great overlap between the fibres of the consecutive sinuvertebral nerves innervating its anterior aspect.[70–73] More recent researchers describe division of the nerves into ascending and descending branches which ramify variously, to give off longitudinally and transversely orientated branches.[74,75] In a recent study that used the very sensitive acetylcholinesterase method, more ramifications between the nerve branches were demonstrated (Fig. 1.19).[76] Ascending branches up to four segments cranial to the level of entry into the dural nerve plexus and also descending branches extending up to four segments caudally were observed. In addition, many vertical and horizontal interconnections between the various ascending and descending branches were seen. The conclusion is that dural nerves may spread over *eight segments* and that a great overlap exists between adjacent and contralateral dural nerves.

These findings may form an anatomical explanation for the clinical observations of Cyriax on the limits of extrasegmental reference of dural pain.[77] Upwards, pain originating in the lower cervical part of the dura may spread to the occiput, skull and forehead (Fig. 1.20). Downwards it can descend to T7 which corresponds with the lower angles of the scapulae. Anteriorly the pain can occupy the whole pectoral area. Extrasegmental pain does not extend beyond the upper half of the arms.

A middle thoracic disc lesion can cause dural extrasegmental pain that may radiate to the base of the neck, and downwards to the whole abdomen and to the upper lumbar region (Fig. 1.21).

Dural extrasegmental reference from a low lumbar level may reach the lower thorax posteriorly, the lower abdomen deep to the umbilicus, the groins, the buttocks, and the sacrum and coccyx (Fig. 1.22). Unlike the cervical dura – which does not radiate far into the arms – extrasegmental reference from a lumbar origin may also involve the legs, both the anterior and the posterior aspects, and descend to the ankles.

Referred tenderness

There seems to be more to referred pain than just mislocation by the patient. Within or near the area of referred pain, it is often possible to find small *trigger points* which are exquisitely

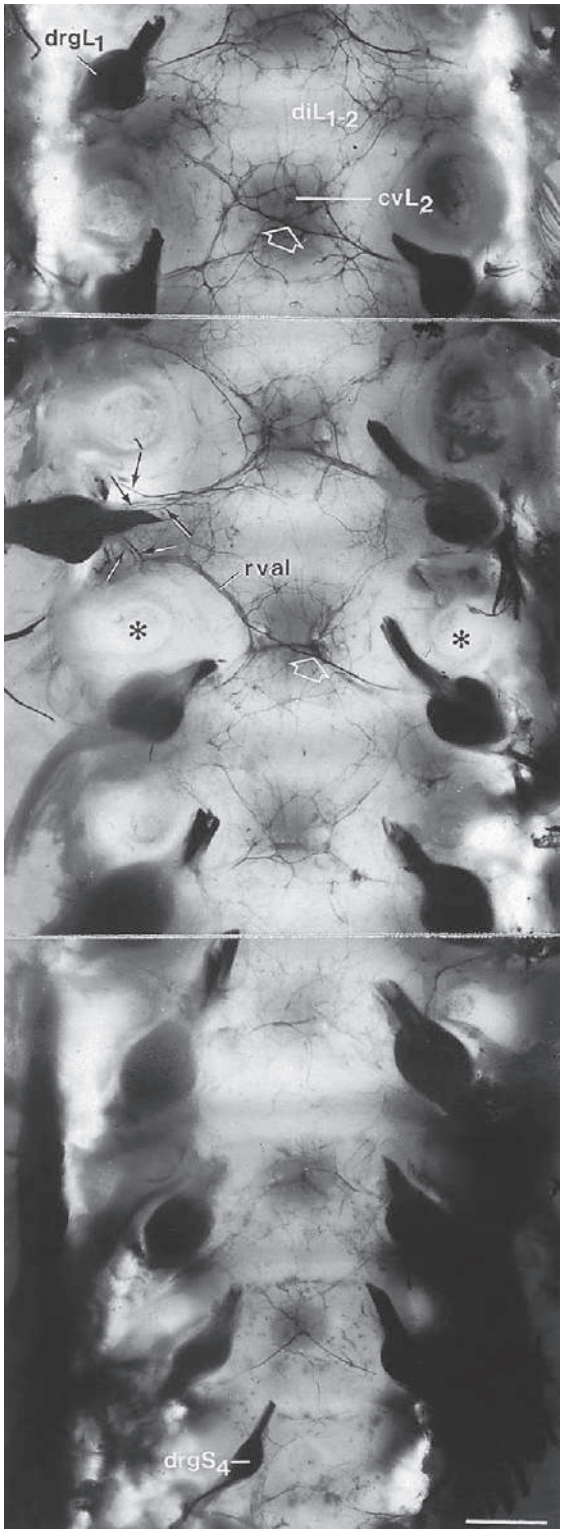

Fig 1.19 • The nerve plexus of the lumbosacral posterior longitudinal ligament (L1 to S4). Fig 1.20 • Limits of dural multisegmental pain of cervical origin.

sensitive. Pressure on one of these immediately produces a deep and radiating tenderness which is identified by most patients as the source of their symptoms. Classic localizations of these tender spots are:

- In cervical dural compression, the upper border of the trapezius, the scapular muscles or the base of the neck.
- In lower lumbar dural involvement, the sacroiliac region and the upper part of the buttocks.

If the tender area is palpated without the prior conduct of a proper functional examination of the neck or lumbar spine, the tenderness is regarded as the primary lesion, the more so because the patient insists that it is the apparent origin of the pain. It is no wonder then that 'fibrositis', 'myofibrositis' or 'myofascial pain' syndromes have long been regarded as primary lesions. The 'fibrositis' concept has been used to explain the cause of lumbago.[78] Lewis[33] was the first to recognize that trigger points and myalgic spots were not primary lesions and that the painful area, although tender to the touch, did not contain a focus.

Cyriax considered that the localized tender area is a secondary effect of pressure on the dura mater.[79,80] He derived his theory from the simple clinical observation that the tender spot shifted from place to place over a few seconds after a successful manipulation and that, when a full and painless range of motion had been restored, the tenderness disappeared.

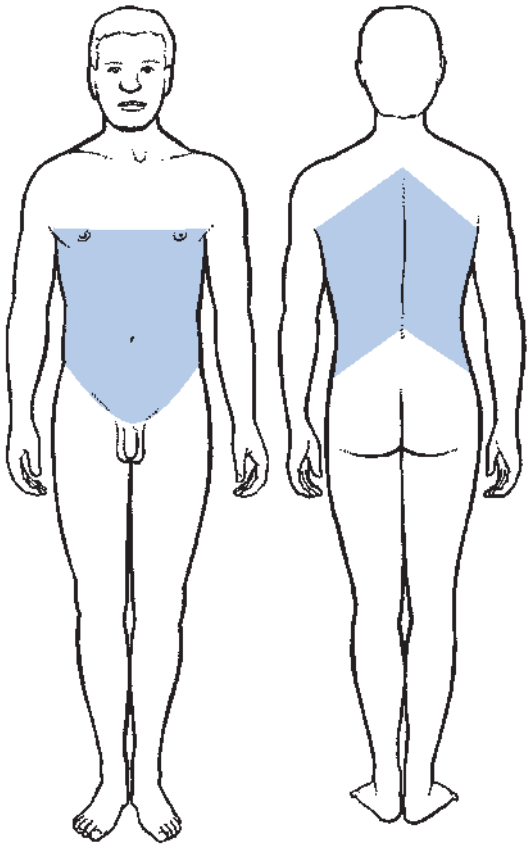

Fig 1.21 • Limits of dural multisegmental pain of thoracic origin.

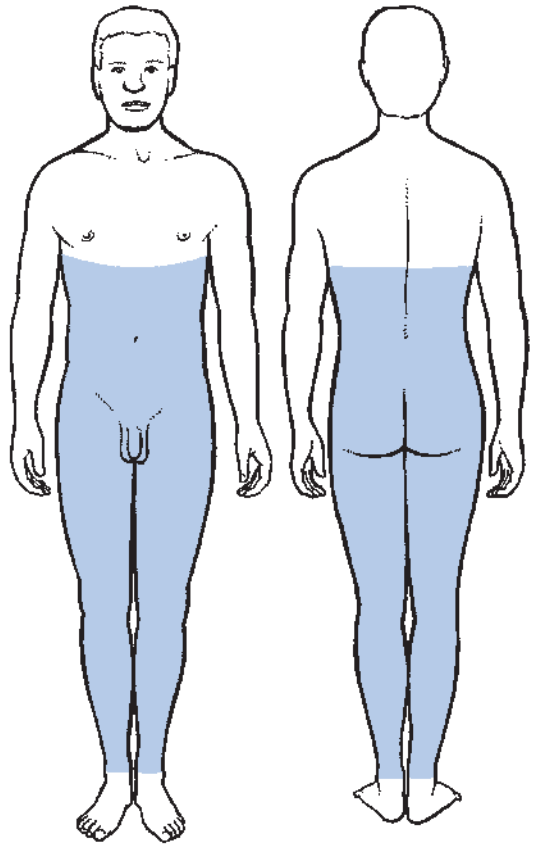

Fig 1.22 • Limits of multisegmental pain of lumbar origin.

However, referred tenderness has also been demonstrated in muscular and fibrous tissue lesions,[81] in visceral lesions such as ischaemic heart attacks[82] and in pathological viscera. The phenomena are not completely understood as yet but it is reasonable to assume that trigger points are caused by summation mechanisms which can be understood in terms of gate-control mechanisms.[79]

Summation – the excitatory effect of converging inputs – is an important pain mechanism. Pain may be triggered by two sources of nerve impulses: a major one from the lesion; and a minor one from normal skin which add together. If one source is removed, it becomes more difficult for the other to trigger the feeling of pain.[83]

Factors determining reference of pain

Referred pain is a faulty perception of the origin of a pain. In orthopaedic medicine it is common to see marked differences in the extent of reference between segments, between distinct affected tissues and between different degrees of the same condition.

The degree of reference – that is the distance between the localization of the perception and the site of the lesion – depends on four different factors (Box 1.3). Some can be explained on the basis of the known pathways, others remain unexplained and result purely from clinical observations.

Box 1.3

Factors favouring reference of pain

Strength of the stimulus:

- The stronger the stimulus, the more reference of pain

Position of the affected tissue:

- The more central the lesion, the more reference of pain
- The more distal the lesion, the less reference of pain

Depth of the affected structure:

- More reference from deep-seated structures
- Less reference from superficial structures

Nature of the affected tissue:

- Little reference: bone and periosteum
- More reference: muscle
- Much reference: capsule, ligament, bursa, tendon, dura, dural sleeve and perineurium

The strength of the stimulus

The greater the stimulus, the more extensive the reference of pain. In other words, intense stimulation radiates the pain widely and slight irritation localizes the pain closer to its origin.

This phenomenon is used in orthopaedic medicine to estimate the degree of irritation or to evaluate treatment. A

classic example is the C5 pain that results from shoulder arthritis. In this disorder there is a typical development of pain which gradually increases. At first, pain is felt only in the deltoid area, close to the shoulder. During the following months it gradually spreads to the arm, first above the elbow but later also to the forearm. At its worst, the pain can even be felt at the distal end of the radius and the base of the thumb. If treatment is successful or the condition regresses, the pain gradually leaves the forearm and moves upwards until it is only at the shoulder area. That the area of reference of pain becomes smaller indicates that the strength of the stimulus is decreasing and inflammation improves. Serious sacroiliac arthritis can provoke pain in the whole of the S1 and S2 dermatomes, with pain at the back of the thigh and the leg, down to the heel and the sole. If the condition improves, pain first leaves the heel and the calf. Further regression of the arthritis will probably result in localized pain in only the neighbourhood of the sacroiliac joint, with some reference to the buttock.

The mechanism of this phenomenon is probably based on the fact that the more the peripheral sensory nerve fibres are stimulated, the more there is cerebral cortical activity.[84]

The position of the affected structure

Pain seems to refer distally only; this being so, the closer to the midline the affected structure lies, the greater the possibility of extensive reference of pain. The further the lesion lies from the midline, the more accurate will be the localization of the lesion by the pain it provokes. As a rule, a lesion in the wrist or in the ankle does not give rise to diffuse pain and the patient usually knows quite well where the source is. Lesions in the hand or foot can therefore be precisely indicated. Also lesions in the elbow and knee cause quite well-defined pain that does not radiate enough to confuse either the patient or the examiner. Lesions that involve the shoulder, the hip, the sacroiliac joints and the spine usually provoke extensive pain reference. The segments to which the shoulder, hip and sacroiliac joints belong (C5, L3 and S1–S2) have the longest dermatomes of the body; as a consequence, pain can be referred a long way distally – calf pain in sacroiliac arthritis or knee pain in arthritis of the hip.

The depth of the affected structure

As early as 1939, Kellgren[35], and Lewis and Kellgren[85] stated that the localizing ability of a structure depended largely on its depth from the surface. This was confirmed later by other studies.[38,44]

Pain originating from a superficial lesion is usually pinpointed correctly by the patient but deep lesions can cause wide reference. This follows immediately from the way referred pain originates. We have seen that referred pain is an error of perception and that pain memory is based upon the experience gathered by recurrent stimuli through the skin, which is adapted correctly to localize pain. It follows that the deeper structures lie from the skin, the less the chance that they will be stimulated by external factors. When internal (pathological) factors activate the nociceptors in these deeply situated structures, the memory mechanism is inadequate and places the pain within the affected segment.

The nature of the structure

There are many discrepancies in our knowledge of pain referral and further research is required to clarify why some structures give more pain reference than others. For example, pain originating in bone or periosteum, although usually located deeply, hardly radiates at all. This does not mean that bone pain cannot be very severe, but it seldom gives extensive reference. This phenomenon is of great value in clinical diagnosis. Serious but localized pain always points to the possibility of a lesion of the bone. For example, an intense but localized pain in the lumbar spine is typical of a bony lesion, such as fracture, infection or new growth at a vertebra. Also intense, deep, but very localized pain in a limb draws attention to bone disease. In addition, severe but localized pain at the shoulder, precisely felt at the true site, is always an indication of a bony lesion.

Pain stemming from a lesion in a joint capsule, bursa, ligament or tendon is referred in an uncharacteristic way – the degree of pain reference is not determined by the type of tissue involved. Pain originating in a muscle seems to cause less reference than pain stemming from the tendon or the tenoperiosteal insertion.

Intense pain reference can also result from pressure on the different parts of the peripheral nervous system. Depending on the localization of the compression, the reference will be segmental or extrasegmental (see earlier).

Anatomy

Peripheral nerves contain both neural and supportive elements. A large multifascicular nerve is composed of a number of different bundles of nerve fibres or fasciculi (Fig. 2.1). These are bound together by the epineurium, a condensation of areolar connective tissue derived from the mesoderm. In humans, the epineurium normally constitutes 30–50% of the total cross-sectional area of the nerve bundle: it contains fibroblasts; collagen (types I and III); variable amounts of fat (possibly to cushion the nerve fibres it surrounds); lymphatic; blood vessels (vasa vasorum); and free nerve endings. In a monofascicular nerve, the epineurium only surrounds the fasciculus and is fused with the perineurium.

The perineurium surrounds and protects one fascicle. It has two different layers; an outer collagen-rich connective one and an inner epithelial layer of contiguous cells. The perineurium has an important role in maintaining the osmotic milieu and fluid pressure within the endoneurium and also acts as a barrier against chemical and bacterial invasion.[1]

The connective tissue of peri- and epineurium possesses blood and lymph vessels – the so-called vasa vasorum.[2,3] Also free nociceptive nerve endings which come from the related multifascicular nerve trunks are embedded in the perineurium and epineurium.[4,5]

Enclosed in the perineurium is the fasciculus – a bundle of nerve fibres bound together and protected by the endoneurium. The latter consists of long collagen fibres running with the nerve fibres. The fibrous and cellular components of the endoneurium are bathed in endoneural fluid.[6]

The nerve fibres are axons – the distal offshoots of nerve cells (Fig. 2.2). Most axons are surrounded by a myelin sheath formed from the compressed and concentric Schwann cell membranes. Axons range in diameter from 0.2 μm (small non-myelinated nociceptive axons) to 20 μm (large and myelinated efferent motor axons) and in length from 1 to 100 cm. They contain most of the cell volume.

From central to peripheral, the nervous system can be clinically divided into four zones (Fig. 2.3):

- The spinal cord
- The spinal nerve, which contains fibres belonging to one segment
- In the brachial and sacral area, and distal from the spinal ganglion, the different spinal nerves form a nerve plexus, from which originate the large multifascicular nerve trunks
- Further distally the trunks split into peripheral nerves, with motor, sensory or combined function.

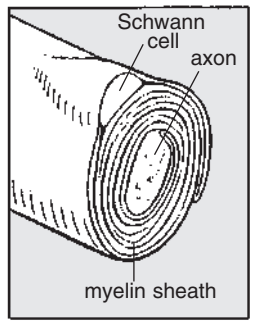

Fig 2.1 • A peripheral nerve is composed of a number of different fasciculi.

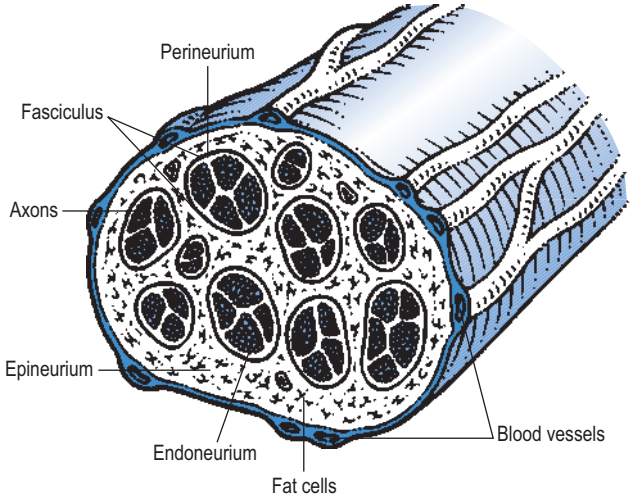

Fig 2.2 • Axon, surrounded by myelin sheath.

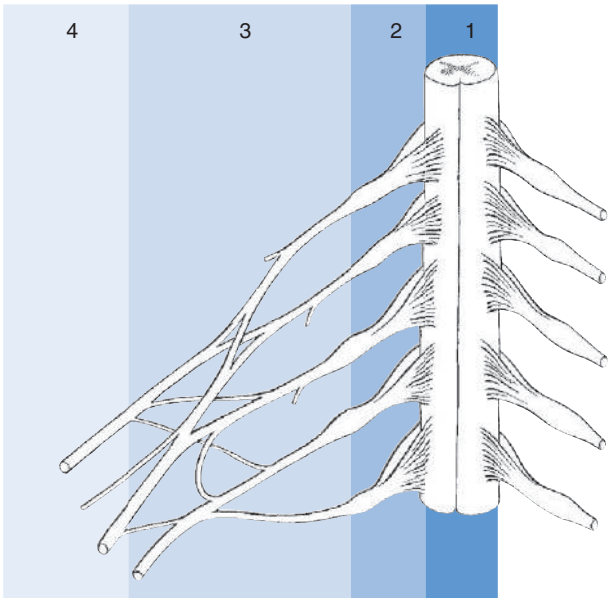

Fig 2.3 • Anatomy of the peripheral nervous system: 1, spinal cord; 2, nerve root; 3, nerve plexus and nerve trunk; 4, peripheral nerve branches.

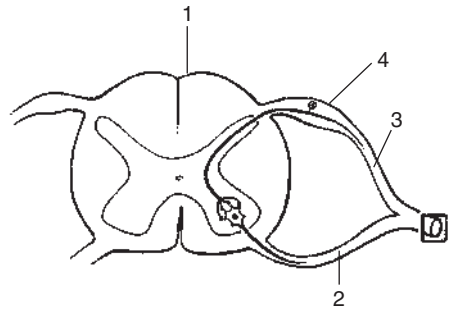

Fig 2.4 • Structure of an intraspinal root: 1, spinal cord; 2, ventral root; 3, dorsal root; 4, dorsal ganglion.

Although the fasciculi, from their exit from the central nervous system to the distal extremity of the nerve, exhibit the general morphology summarized above, the structure and behaviour of the connective supportive elements differ considerably. This may explain the different clinical behaviour of a compressed cord, a compressed nerve root (within or without its dural sleeve), a compressed nerve trunk and a compressed small peripheral nerve.

Roots

The course of the spinal nerve within the spinal canal, from the emergence of the rootlets at the anterior and posterior aspect of the spinal cord to the outer border of the foramen, is called the intraspinal root (Fig. 2.4).[7] Being inside the meningeal membranes of the spinal cord, the posterior and anterior roots are devoid of the elaborate epineural and perineural membranes that are characteristic of peripheral nerves.

Proximally, the rootlets float freely within the cerebrospinal fluid which is the main source of their metabolic needs. In this intrathecal part of the intraspinal root, the rootlets are held together by the endoneurium which is more loosely arranged than is typically seen in peripheral nerves.[8] Further distally, the nerve root becomes enclosed in the dural sheath – a tubular prolongation of the dura. In this dural investment the nerves do not lie freely but are bound by the arachnoid membrane (Fig. 2.5).[9,10] This area is known as the extrathecal part of the intraspinal nerve root – that length of the root *and* the dural sleeve between the main dural sac and the exit from the foramen. The extrathecal portion is short in the cervical region but becomes longer with the increasing obliquity of the intraspinal roots in the thoracolumbar and lumbar regions.

Distal to the posterior root ganglion, at the level of the foramen, the posterior and anterior roots are fused into one single bundle. Here the nerve root becomes extraspinal. The tissue of the epidural pouch becomes more condensed and blends with the epineurium of the extraspinal nerve root.

The segment of the spinal root which is liable to compression, whether by a disc protrusion, an osteophytic outgrowth or a narrow lateral recess, is the extrathecal part of the intraspinal root. To understand the symptom of a compression or inflammation of this part of the peripheral nerve system, it is necessary to recognize the importance of the dural investment

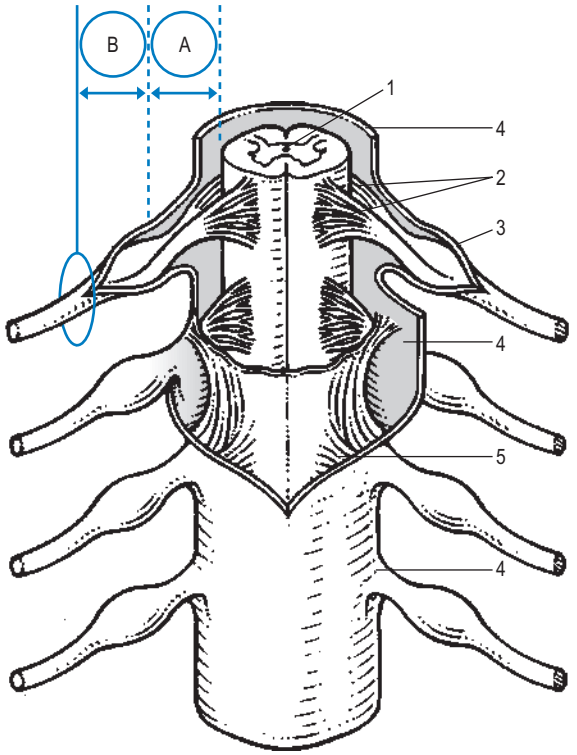

Fig 2.5 • Course of spinal nerve: A, intrathecal part of the nerve root; B, extrathecal part of the nerve root; 1, spinal cord; 2, ventral and dorsal rootlets; 3, spinal ganglion; 4, dura mater; 5, arachnoidea.

– the nerve root sheath. The dural sheath has considerable sensitivity:[11] it has many nociceptive nerve endings, especially at the anterior aspect where it receives its innervation from the sinuvertebral nerve belonging to the same segment.[12–14] Pain arising from the dural sheath is segmental and obeys the rules of segmental reference of pain (see Ch. 1). There is no evidence that root pain arises from involvement of the axons. For example, pressure at the extraspinal nerve root, which misses the nerve root sleeve, as happens in some types of spondylolytic compression, causes not pain but only paraesthesia and neurological deficit.

From a clinical point of view, it is important to consider this structural duality: the outer investment is responsible for segmental pain, whereas the parenchymatous content is responsible for the paraesthesia and the conduction deficits.

Nerve plexus and nerve trunk

Immediately distal to the foramen, the single fasciculus of the extraspinal root is enclosed in a thin, but strong, perineurial sheath, external to which is the epineurial areolar connective tissue. Within a few millimetres of its formation, the single fasciculus of the spinal nerve divides into several bundles which form the plexuses. Motor and sensory fibres of one nerve root mix, and more distally there is a redistribution of the fasciculi of various consecutive nerve roots.[15] The brachial plexus is thus formed of the anterior rami of roots C5–T2, and the sacral plexus of the roots L2–S5. Distally, the fasciculi continue in the large nerve trunks of the limbs.

The fasciculi of plexus and trunks do not differ significantly from those of the roots or the peripheral nerves. The connective support tissue, however, has some anatomical particularities. Because the monofascicular spinal nerve changes into a multifascicular structure, there is an increased amount of epineurial tissue, forming a protective packing for the nerve tissue. The perineurium is also reinforced by elastin fibres. The fasciculi have an undulating course, whereas the collagen fibres run more longitudinally. This structure ensures that the nerve fibres are protected from mechanical deformation (compression and elongation) during normal movements of the limbs.[16] Although the epi- and perineurium contain nociceptive nerve endings, these seem to be relatively insensitive.[17]

Small peripheral nerve

A small peripheral nerve is the distal termination of a branching nerve trunk. The nerve ending is often monofascicular. The epineurium is then fused with the perineurium. Peripheral nerves can either have only a motor or a sensory function, or both can be combined. They all have nociceptive nerve endings in their supporting connective tissue.

Terminology

Lesions of the peripheral nervous system are characterized by a pathognomonic sensation: paraesthesia ('pins and needles'). Although all tissues in the human body which contain nociceptive structures can be a source of pain, pins and needles will only arise when some part of the peripheral nervous system is at fault. Hence, the medical world tends to use the term 'neuritis' when pain is accompanied by pins and needles. Strictly, however, the suffix '-itis' implies inflammation. Therefore the word neuritis should only be used when the peripheral nerve is affected by infectious or toxic irritation – i.e. there is an intrinsic disorder of the nervous parenchyma. Classically, these lesions are classified into mono- and polyneuritis. They are not discussed in this book, except in the shoulder region, where the clinical appearance of three mononeurites and neuralgic amyotrophy of the shoulder girdle is reviewed (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

When external pressure is applied to a normal nerve, pins and needles arise, although the nerve tissue is initially not inflamed. If the compression is not severe, the nerve continues to conduct normally. This situation of extrinsic pressure on a normal nerve is not a 'neuritis' and requires a totally different therapeutic approach. In this situation, the terms 'pressure on nerve' or 'entrapment neuropathy' are preferred.

Pain originating from the peripheral nerve system

Nociceptive pain

Peripheral nociceptors in the connective tissue of the peripheral nerves are stimulated, and via Ad and C fibres of the nervi

nervorum conducted to the spinal cord and thence to the pain projection areas in the cortex.[18] There are indications that most of the pain that stems from direct irritation of the peripheral nervous system is of nociceptive origin.[19,20] 'Nerve pain' thus behaves identically to other peripheral pain,[21] obeys exactly the rules of referred pain and is not to be distinguished from pain of ligamentous, tendinous or arthrogenic origin (see Ch. 1).

Neuropathic pain

This type of pain, also called 'de-afferentation or neuralgic pain' is less common than nociceptive pain and results from prolonged damage to peripheral nerve tissue, such as avulsion, dissection or amputation.[22] The pain is felt in the anaesthetic area, is continuous and burning and is independent of posture or movement, although local pressure can increase the pain considerably.[23]

Chronic damage or formation of scar tissue seems to provoke pain mechanisms without involvement of peripheral nociception. Also, the formation of a neuroma leads to increased sensitivity and spontaneous pain.[24] Research on experimental neuromata has shown that regenerating axons have a spontaneous excitability and an increased sensitivity to mechanical stimuli. An action potential in one axon probably leads to an impulse in a nearby axon. This mechanism of 'cross-talking fibres' accounts for the repetitive train of action potentials in a bundle of regenerating axons.[25] A small stimulus thus leads to a self-perpetuating series of action potentials, and excessive and long-standing pain.[26]

Another mechanism that may account for neuropathic pain is the loss of inhibitory effects of the large diameter mechanoreceptor afferents in a traumatized nerve. This leads to a relative increase of the activity from the small nociceptive afferents, and thus an opening of the gate at the dorsal horn.[27] (see Ch. 1).

Superficial dysaesthetic pain

This type of pain is also rare, and is typical of diffuse polyneuritis, for example in diabetes,[28] vitamin B_1 deficiency or chemical irritation. Damage to small C fibres leads to sprouting of small offshoots in the regenerating axons. This leads to increased excitability, which results in unpleasant painful sensations during normal stroking of the skin (allodynia).[29] The patient also complains of a burning feeling and 'electrical sensations' when the skin is gently touched (dysaesthesia), and there is also some analgesia (see Box 2.1 for an overview of neurogenic pain).

Box 2.1

Neurogenic pain

Nociceptive pain

- Common
- Irritation of nociceptive structures in the connective support tissues of the nerve
- 'Normal' pain sensation, obeys the rules of segmental reference

Neuropathic pain

- Rare
- Results from damage to the nerve tissue
- Intense pain, sharp, burning

Superficial dysaesthetic pain

- Rare
- Polyneuritis: irritation of C fibres
- Dysaesthesia, allodynia and anaesthesia in the innervation area of the peripheral nerve

Behaviour of nervous tissue during pressure

Entrapment of peripheral nerve tissue is defined as mechanical compression of the nerve, which includes the reduction of radial dimensions in the neural cells, the neural support elements or any combination of these. Depending on the degree and the duration of compression, the effects can be subtle or can lead to displacement, deformity and morphological changes in the compressed tissue (neural tissue or neural support tissue).[30]

The clinical effects of nerve compression are pain, paraesthesia and loss of function (see Box 2.2 for an overview of pressure on nerves).

Pain

The pain mechanism in entrapment phenomena is usually nociceptive: free nerve endings in the connective tissue of the nerve or in the dural investment of the nerve root are depolarized by application of mechanical forces or after exposure to irritating chemical substances, released from inflamed tissues.[31] The pain stems from irritation of the support tissue enclosing the nerve fibres and only exceptionally does it result from pathological processes in the nerve tissue itself (neuropathic and dysaesthetic pain). This has the following clinical consequences.

The pain will depend largely on the density of the nociceptive receptors in the support elements. It follows that the intensity of the pain depends not only on the intensity of compression but also on the localization along the course of the peripheral nerve. Pressure on a nerve root, for instance, will be more painful than an equal degree of force applied on a nerve plexus.

Because an external force acts first on the outer supporting structures of the nerve, pain will usually be the first symptom and it sometimes appears before involvement of the parenchyma is present. A chronic but moderate pressure that is insufficient to impair conduction solely influences the outer structures and results in pain only. It is thus possible to have a completely normal examination of the peripheral nervous system, even though the patient does have nerve compression.[32]

Paraesthesia

Pins and needles are pathognomonic of involvement of the peripheral nervous system in that the sensation cannot be produced in any way other than compression or inflammation of nerve tissue.[33] Paraesthesiae are always felt in the cutaneous area supplied by the nerve tissue involved and distal to the site of the lesion. It is therefore extremely important to ascertain the precise site of the symptom, in that this helps to determine the site of compression.

Provocation of pins and needles by movements (distant movements or local pressure) or by stroking over the affected skin demonstrates an external origin for the symptoms. In primary afflictions of the peripheral nerve (neuritis), the pins and needles come and go spontaneously and movements do not influence them.

Loss of function

The epineurium and perineurium initially buffer the fasciculi from constrictive effects, but with a greater amount of compression, structural changes of the elements within the endoneurium follow.[34] Recent research has demonstrated that the intraradicular oedema caused by alteration of the blood–nerve barrier is the most important factor in the nerve root dysfunction of chronic compression.[35,36]

Sometimes only the Schwann cells are affected, without damage to the axons. Destruction of the myelin sheath then results in loss of conduction. This type of lesion (lesion of Schwann cells without lesion of the axon fibre) is termed 'neuropraxis'. If the compression has been only temporary, recovery of the Schwann cells will not take more than 2 weeks. This is the type of lesion responsible for the 'Saturday night palsy' seen after prolonged pressure on the radial nerve, or the 'gardener's palsy' seen after prolonged traction on the peroneal nerve.

If considerable compression is maintained for a longer period, atrophy of the nerve tissue occurs and is followed by Wallerian degeneration of the distal part of the axon. Oedema, cellular proliferation and ingrowth of connective tissue also follows.[37] If the compression is maintained for long periods, fibrotic degeneration appears at the site of the lesion, which makes recovery most unlikely.[38]

Clinical syndromes

Cyriax[39] (see his pp. 37–39) distinguished four different syndromes in entrapment phenomena, corresponding to the site of compression along the peripheral nerve: at the small peripheral sensory nerve, at the nerve trunk/plexus, at the nerve root and at the spinal cord (see Fig. 2.3).

Depending on the localization of compression, the peripheral nervous system behaves differently. These differences are a major help to the clinician trying to ascertain the precise site of the lesion.

Small peripheral nerves

Pressure on a small peripheral sensory nerve results in pain, paraesthesia and numbness. Pain is usually moderate and the main symptom is numbness. Together with some paraesthesia, these symptoms occupy the appropriate area of supply, which is usually well defined with clear-cut borders. The patient can tell precisely where the cutaneous analgesia is felt and where sensation is still normal. The centre of the region is often completely anaesthetic. A typical example is 'meralgia paraesthetica', which results from compression of the lateral cutaneous femoral nerve of the thigh.

Nerve trunk/plexus

Minor and intermittent pressure on a nerve trunk or a plexus causes paraesthesia and numbness. Sudden and serious tissue damage may provoke neuropathic pain. Constant pressure on a nerve trunk leading to parenchymatous damage does not usually provoke pain nor paraesthesia but only loss of motor and sensory function.

If the pressure is intermittent, a neurological deficit does not appear, even after many years. Paraesthesiae do not appear during the time of compression but only when the pressure on the nerve trunk has been released. It is common knowledge that pressure on the sciatic nerve while sitting causes only vague analgesia in the affected area or no symptoms at all. The shower of pins and needles then only appears when the subject relieves the pressure by standing up. The interval between the cessation of the pressure and the onset of the tingling depends on the duration of the compression: the longer the pressure is applied, the longer is the interval between the relief of pressure and onset of symptoms.

There is also a relation between the duration of compression and the duration of paraesthesia. Thus, after 15 minutes of pressure, the pins and needles appear 20–60 seconds after the release and last only 1 or 2 minutes. After release from 15 hours' compression, paraesthesiae will probably appear only after an interval of some hours, then persist for 1 to 2 hours before recovering spontaneously. Cyriax[39] calls this strange and hitherto unexplained phenomenon the 'release phenomenon' (see his p. 37). Lundburg and Rydevik have demonstrated that fluctuations in membrane permeability of the structures within the endoneurium are more noticeable when compression on the nerve trunk is released and oedema appears, than during the compression of the nerve and its supplying blood vessels.[40] This might explain the release phenomenon.

Another characteristic of paraesthesia induced by compression at the level of the plexus is that active movements of the limb or the digits, or stroking over the analgesic area of skin usually brings on or increases the pins and needles. It is a common experience that the paraesthesia in the feet that comes on after relieving pressure on the sciatic nerve increases when the subject walks around or stamps the feet on the ground.

Paraesthesia and numbness are usually felt in the distal part of the cutaneous area supplied by the compressed plexus or nerve, no matter at what point in its course the compression

occurs. The lesion lies proximal to the upper edge of the paraesthetic area but not always close to it. Therefore it must not be thought that, if movement of the foot provokes the pins and needles, the lesion lies in the ankle or foot. Clinical examination must include the entire length of the nerve involved.

The release phenomenon is typical of compression of the sacral plexus and the nerve trunks of the lower limb. The phenomenon is also provoked by compression at the brachial plexus (thoracic outlet syndrome) but ceases to operate when a nerve trunk distally to the thoracic outlet is compressed. It is a curious clinical fact that pressure on a nerve in the upper limb only provokes paraesthesia during the moment of compression. Pins and needles in the two ulnar fingers, caused by compression of the ulnar nerve at the elbow, immediately stop when the compression is released. Similarly, in carpal tunnel syndrome, the paraesthesiae are felt during the moment of compression.

Compression of the nerve root

Pressure on the extrathecal intraspinal nerve root results in a typical set of symptoms (pain and paraesthesia) and signs (motor and sensory deficit) strictly related to the segment involved. Contrary to the pins and needles brought on by the release of pressure on a nerve trunk, the paraesthesiae only appear during the period of compression, and cease immediately thereafter.

The sequence of appearance of pain, paraesthesia and deficit and their mutual interrelation have important clinical significance and are often of considerable help in the diagnosis of nerve root compression.

Pain

The nerve root has a dural sheath, which is innervated by the sinuvertebral nerve.[12] The latter is derived from the corresponding nerve root. Therefore pain originating from the dural sheath is strictly segmental and follows the rules of segmental reference of pain. Compression applied to the dural sleeve of the nerve root thus results in pain occupying all or any part of the dermatome. Pain felt in a particular dermatome in combination with other symptoms of nerve compression, immediately draws attention to an impingement on the nerve root.

Paraesthesia

Pins and needles stem from pressure on the parenchyma itself. In root pressure, they accompany the segmental pain, or appear at a later date. Pins and needles indicate that the parenchyma itself is irritated, whereas radicular pain is a symptom of compression of the dural sheath.

In nerve root compressions, paraesthesiae are felt in the distal extremities of the dermatomes, which are areas often not supplied by a particular nerve trunk or nerve. As in compression of a nerve trunk, stroking the skin may provoke or increase the pins and needles, but moving the digits does not influence them.

Deficit

The absence of the protective packing by epineurial tissue renders the nerve roots more susceptible to direct compression than nerve trunks. Compression disturbs nerve conduction by interfering with the blood supply of the nerve fibres.[41] Loss of function of the nerve fibres results in sensory and motor deficit. Paraesthesiae usually disappear with the onset of cutaneous analgesia.

Progressive compression of a nerve root within its dural sleeve causes a typical sequence of symptoms: pain, paraesthesia and numbness will follow each other, rather than coincide. This is typically the case in a progressively increasing pressure exerted by an evolving disc lesion: slight compression on the epidural sheath of the nerve root causes pain only (Fig. 2.6a). As the pressure increases, paraesthesia and muscle fasciculations – symptoms of parenchymatous hyperexcitability – appear[42] (Fig. 2.6b). In the final stage, pressure has induced such ischaemic damage to the nerve root that function is completely lost, including the conduction of pain (Fig. 2.6c). The patient then complains of weakness and numbness, but pain and paraesthesia have disappeared.

Spinal cord

Pressure on the anterior aspect of the spinal cord results, *inter alia*, in bilateral paraesthesia. Pain is absent if the compression is slowly progressive, but dural pain may accompany the paraesthesia if the compression is sudden. The main cause

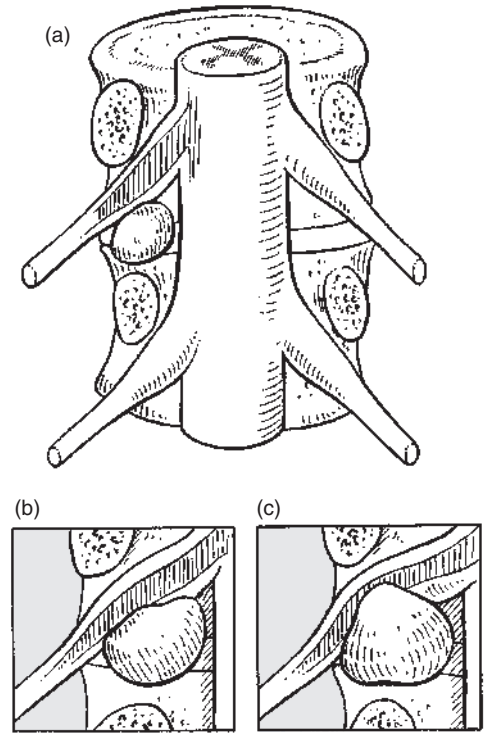

Fig 2.6 • Progressive compression of a nerve root.

Box 2.2

Pressure on nerves: Summary

Peripheral nerve	Numbness > paraesthesia > pain
	Clearly delineated area
Nerve trunk	Paraesthesia > numbness > pain
	Vaguely delineated area
	Release phenomenon:
	—The pins and needles appear after the compression has ceased
	—There is a direct relation between the interval of onset and duration of compression
Nerve root	Pain > paraesthesia > numbness
	Segmental distribution of symptoms
	Chronological sequence of symptoms
	Compression phenomenon:
	—The pins and needles appear during the compression
Spinal cord	Completely painless (sometimes dural pain)
	Extrasegmentally and bilaterally distributed paraesthesia
	Positive neck flexion

of spinal cord compression is spinal stenosis at the cervical or thoracic level. When the cord is compressed over the thoracic region, the paraesthesiae are felt only in the limbs. In compression at the cervical level, pins and needles will be present in all limbs or in the lower limbs only. The paraesthesiae are usually bilateral and extend beyond the borders of the areas of the cutaneous innervation of any spinal nerve, nerve trunk or peripheral nerve. For instance, the patient may complain of pins and needles in both hands and forearms at both aspects or in both legs from the knees to all the toes.

The symptoms are provoked neither by movements of the limbs nor by stroking the skin. Neck flexion is the only way to bring on the pins and needles (L'Hermitte's sign). Together with the extrasegmental and bilateral distribution of the painless paraesthesiae, positive neck flexion provides the clue to the diagnosis of incipient spinal cord compression.

Structural composition

Together with muscle, nerve and epithelium, connective tissue is one of the basic components in the human body. It binds structures together, helps in mechanical and chemical protection and also plays a principal role in reparative processes.

Connective tissues are defined as those composed predominantly of the extracellular matrix and connective tissue cells. The matrix is made up of fibrous proteins and a relatively amorphous ground substance. Many of the special properties of connective tissues are determined by the composition of the matrix, and their classification is also largely based on its characteristics.

Connective tissue cells

Cells of general connective tissues can be separated into the resident cell population (mainly fibroblasts) and a population of migrant cells with various defensive functions (macrophages, lymphocytes, mast cells, neutrophils and eosinophils), which may change in number and moderate their activities according to demand.

Fibroblasts, the majority of cells in ordinary connective tissue, arise from the relevant undifferentiated mesenchymal stem cells[1] and are involved in the production of fibrous elements and non-fibrous ground substance (Fig. 3.1). During wound repair they are particularly active and migrate along strands of fibrin by amoeboid movements to distribute themselves through the healing area to start repair. Fibroblast activity is influenced by various factors such as the partial pressure of oxygen, levels of steroid hormones, nutrition and the mechanical stress present in the tissue.[2]

The other cell types are migrant cells and only occasionally present, such as: *macrophages*, *lymphocytes*, *mast cells*, and *granulocutes* (Table 3.1).[3,4]

Extracellular matrix (ECM)

The extracellular matrix is composed of insoluble protein fibres, the fibrillar matrix and a mixture of macromolecules, the interfibrillar matrix. The latter consists of adhesive glycoproteins and soluble complexes composed of carbohydrate polymers linked to protein molecules (proteoglycans and glycosaminoglycans), which bind water. The extracellular matrix distributes the mechanical stresses on tissues and also provides the structural environment of the cells embedded

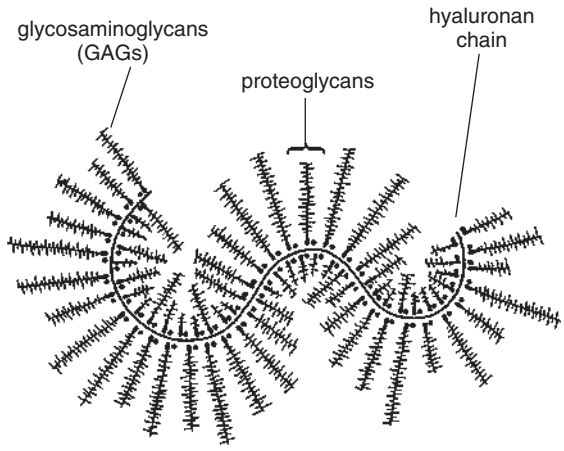

Fig 3.2 • The complex shape of proteoglycans. Polysaccharide molecules (GAGs) bound to a central protein core: proteoglycans are in turn bound to a long central chain of hyaluronan to form a proteoglycan aggregate. This arrangement is typical of cartilage. In other types of connective tissue hyaluronan chains may be absent. Redrawn from Walker PS[6] with permission.

in it, forming a framework to which they adhere and on which they can move.[5]

Non-fibrous ground substance

The interfibrillar ground substance is composed of proteoglycans (a family of macromolecules) which bind a high proportion of water (60–70%) and glycoproteins. The latter have a complex shape and are soluble polysaccharide molecules (glycosaminoglycans) bound to a central protein core. In cartilage, the proteoglycans are in turn bound to hyaluronan (a long chain of non-sulphated disaccharides) to form a proteoglycan aggregate – a bottlebrush three-dimensional structure (Fig. 3.2).[6] Glycoprotein secures the link between proteoglycan and hyaluronan and also binds the components of ground substance and cells.

The three-dimensional structure of the proteoglycan aggregates and the amount of water bound gives ground substance its high viscosity. A semi-fluid viscous gel is formed within which fibres and fibroblasts are embedded, so facilitating normal sliding movements between connective tissue fibres. In structures subject to high compression forces (e.g. articular cartilage), there is a large amount of proteoglycans but the content is relatively small in tissues such as tendons and ligaments exposed to tension forces.

Fibrous elements

The fibrous elements are collagen and elastin – both insoluble macromolecular proteins. Collagen is the main structural protein of the body with an organization and type that varies from tissue to tissue. Collagen fibres are commonest in ordinary connective tissue such as fascia, ligament and tendon. The fibrillar forms have great tensile strength but are relatively inelastic and inextensible. By contrast elastin can be extended to 150% of its original length before it ruptures. Elastin fibres return a tissue to its relaxed state after stretch or other considerable deformation. They lose elasticity with age when they

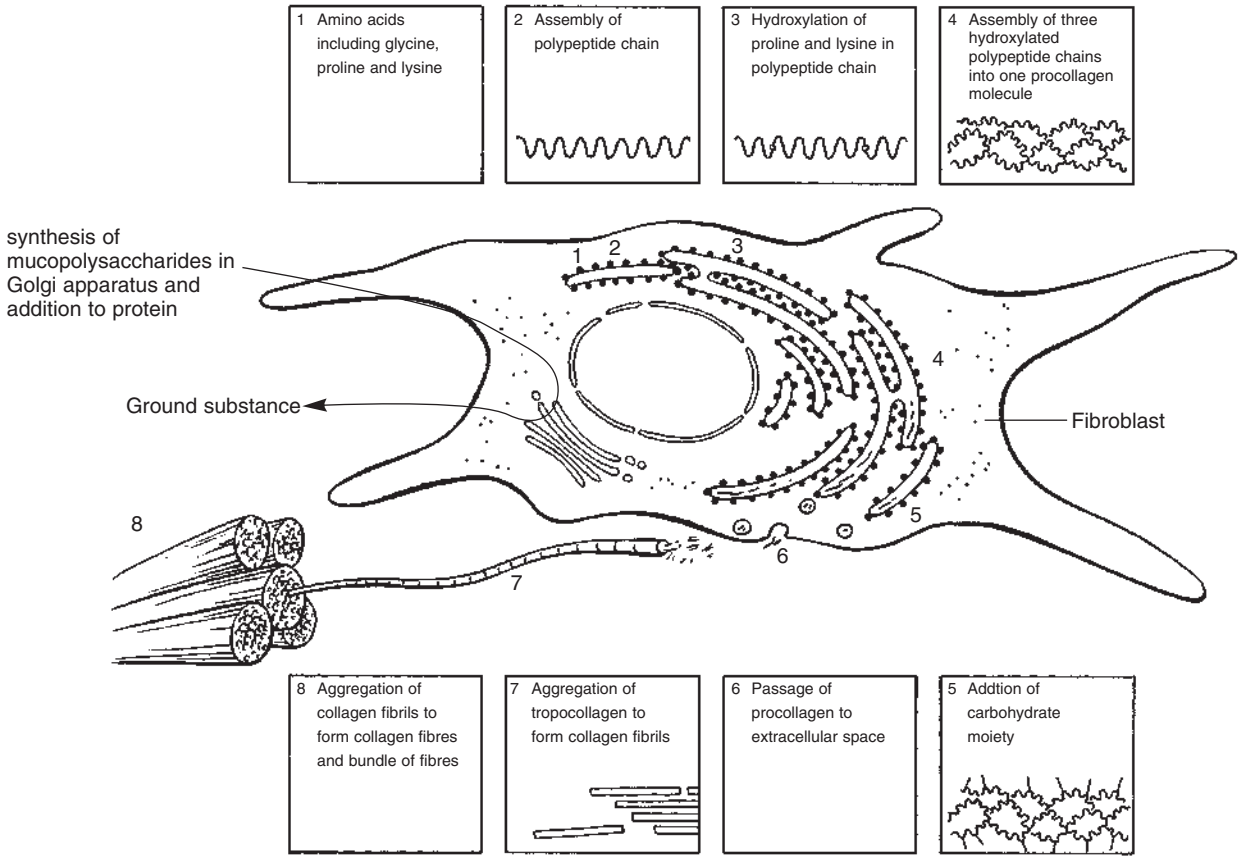

Fig 3.3 • The successive steps in collagen synthesis by fibroblasts.

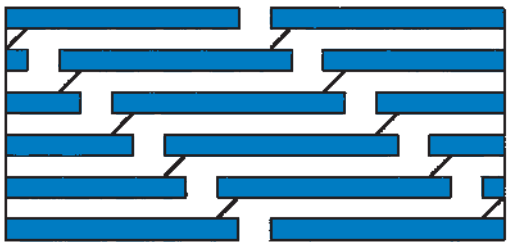

Fig 3.4 • Crosslinking and interspaces between head and tail of neighbouring tropocollagen molecules. They overlap each other by a quarter of their length. Molecules in the same parallel row are separated from each other by small interspaces.

tend to calcify. Box 3.1 outlines the components of connective tissue.

The basic molecule of collagen is *procollagen*, synthesized in the fibroblast, illustrated in Figure 3.3, steps 1–4. It is formed of three polypeptide chains (α-chains). Each chain is characterized by repeating sequences of three amino acids – glycine, proline and lysine joined together in a triple helix. The helical molecules are secreted into the extracellular space where they slowly polymerize and crosslink (Fig. 3.4). They overlap each other by a quarter of their length, lie parallel in rows and are collected into large insoluble fibrils. The fibrils unite to form fibres, finally making up a bundle. An aggregate of bundles makes up a whole structure such as a ligament or a tendon. The individual bundles are in coils, which increases their structural stability and resilience, and permits a small physiological deformation before placing the tissue under stress, and in consequence permits a more supple transfer of tractive power in the structure itself and at points of insertion (Fig. 3.5). The process of collagen synthesis is stimulated by some hormones (thyroxine, growth hormone and testosterone), although corticosteroids reduce activity.

Box 3.1

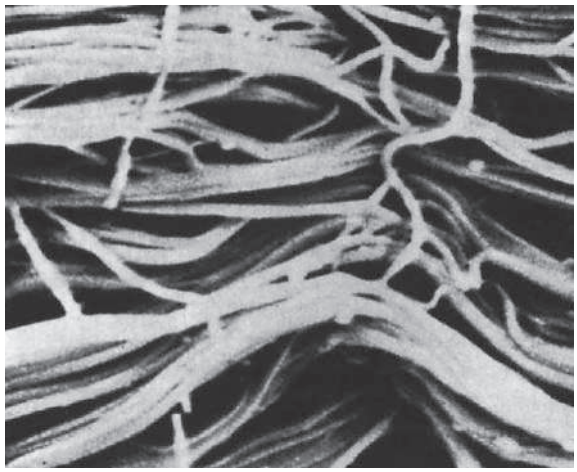
Components of connective tissue

Cells

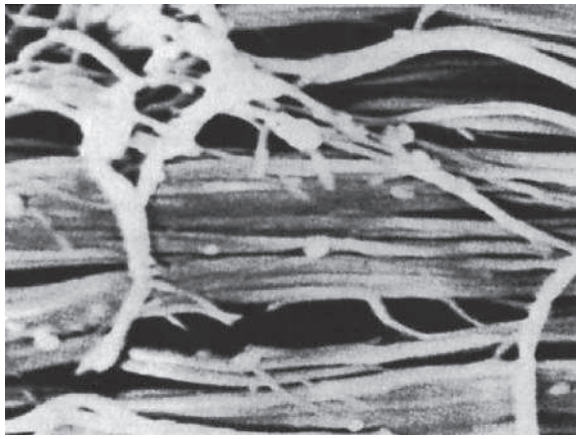
- fibroblasts → fibrous connective tissue
- chondrocytes → cartilage
- osteoblasts and osteocytes → bone

Extracellular matrix (ECM)

- fibres: collagen → framework of the ECM
- elastin → extensible element of ECM
- proteoglycans: hydrators, stabilizers and space fillers of ECM
- glycoproteins: stabilizers and linkers of ECM
- fluid



(a)



(b)

Fig 3.5 • (a) Unloaded collagen fibres in a human knee ligament. (b) Physiological deformation after stress. From Kennedy *et al*[7] with permission (http://jbjs.org/).

Connective tissue collagen can be classified into different types of which at least 14 are now genetically characterized and the others are being investigated. In the context of this book the most important are:

- *Type I*: the most abundant of all collagen. Strong thick fibres packed together in high density. It predominates in bone, tendon, ligament, joint capsule and the annulus fibrosus of the intervertebral disc.
- *Type II*: thin fibres found in articular cartilage and the nucleus pulposus of the intervertebral disc. They particularly function in association with a high level of hyaluronan and sulphated proteoglycans to provide a hydrated and pressure-resistant core.
- *Type III*: essentially present in the initial stages of wound healing and scar tissue formation. It secures early mechanical strength of the newly synthesized matrix. These relatively thin, weak fibres are replaced by the strong type I fibres as healing proceeds.

In relation to the degree of orientation of fibrous tissue elements, ordinary connective tissues can also be classified into *regular* and *irregular* types.

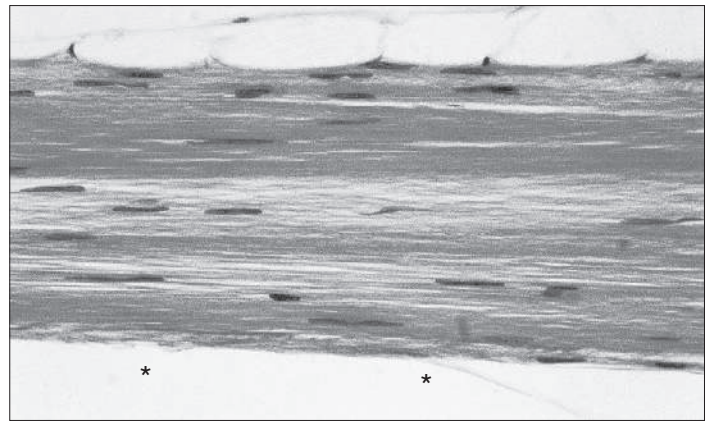


Fig 3.6 • Dense regular connective tissue in a tendon. Thick parallel bundles of type 1 collagen (asterisks) give tendon its white colour in life. The elongated nuclei of inactive fibroblasts (tendon cells) are visible between collagen bundles. From Standring, Gray's Anatomy, 40th edn. Churchill Livingstone, Edinburgh, 2008 with permission.

Regular types

Highly fibrous tissues such as ligaments, tendons, fascia and aponeuroses are predominantly collagenous and show a dense and regular orientation of the fibres with respect to each other. The direction of the fibres is related to the stress they experience. Collagen bundles in ligaments and tendons are very strong and rupture usually takes place at the bony attachments rather than by tearing within their substance (Fig. 3.6).

Irregular types

The irregular types consist of collagen and elastin interlacing in all directions. It is loose, extensible and elastic and found between muscles, blood vessels and nerves. It binds partly together, although allowing a considerable amount of movement to take place. In the sheaths of muscles and nerves and the adventitia of large blood vessels, the tissue is more dense with a high proportion of collagen fibres to protect these structures against considerable mechanical stress. The dura mater is also an example of an irregular connective tissue sleeve.

Vascularization

Connective tissue is poorly supplied with blood vessels. In dense fibrous tissues these usually run parallel to and between the longitudinal bundles with communicating branches across these.

Lymphatic vessels are more numerous, especially in loose connective tissues such as the dermis. They are also abundant in tendons and tendon sheaths.

Innervation

Dense connective tissues, for example, ligaments, tendons and fascia, have a rich supply of afferent nerve endings. The various sensory receptors transmit information to the central nervous system about changes in length and tension which allows constant monitoring of the position and movement of a joint as well as of injurious conditions that threaten these structures.

Structural and physiological studies[8,9] have shown the presence of at least four types of receptor. Three of these have encapsulated endings but the fourth consists of free unencapsulated endings:

- *Type 1* (Ruffini endings) are present in the superficial layers of a fibrous joint capsule. They respond to stretch and pressure within the capsule and are slow adapting with a low threshold. They signal joint position and movement.
- *Type 2* are particularly located in the deep layers of the fibrous capsule. They respond to rapid movement, pressure change and vibration but adapt quickly. They have a low threshold and are inactive when the joint is at rest.
- *Type 3* are found in ligaments. They transmit information on ligamentous tension so as to prevent excessive stress. Their threshold is relatively high and they adapt slowly. They are not active at rest.
- *Type 4* are free unencapsulated nociceptor terminals which ramify within the fibrous capsule, around adjacent fat pads and blood vessels. They are thought to sense excessive joint movements and also to signal pain. They have a high threshold and are slow adapting. Synovial membrane is relatively insensitive to pain because of the absence of these nerve endings.

All these receptors influence muscle tone via spinal reflex arcs which are formed by the same nerves that supply the muscles which act on the joint. Parts of the joint capsule supplied by a given nerve correspond with the antagonist muscles. Tension on this part of the capsule produces reflex contraction of these muscles to prevent further overstretching of the capsule. In consequence all receptors have an important function in stabilization and protection of the joint. After rupture of a capsule, ligament perception is considerably disturbed because of the disruption of the transmission of afferent information. For example in a sprained ankle there is loss of control of locomotion. Even months after repair of ligamentous and capsular tissues has taken place, perception may still be distorted.

Structures containing connective tissue

Synovial joints (Fig. 3.7)

In synovial articulations, the bones involved are linked by a fibrous capsule, usually containing intrinsic ligamentous thickenings, and often also internal or external accessory ligaments. The articulating bony surfaces are generally not in direct continuity but are covered by hyaline articular cartilage of varying thickness and precise topology. Smooth movement of the opposing articular surfaces is aided by a viscous synovial fluid, which acts as a lubricant, and whose production requires the presence of a synovial membrane which is one of the defining characteristics of the joint type.

Fibrous capsule and ligaments

In synovial articulations the bones are linked by a fibrous capsule of parallel and interlacing connective tissue fibres – a cuff that encloses the joint cavity. With some exceptions, each end is attached in a continuous line around the articular ends of the bones concerned. Within this the capsule is lined by synovial membrane. A fibrous capsule usually exhibits local thickenings of parallel bundles of collagen fibres, called capsular (intrinsic) ligaments, that are named by their attachments. Some capsules are reinforced by tendons of nearby muscles or expansions from them. Accessory ligaments are separate from capsules and may be extracapsular or intracapsular in position.

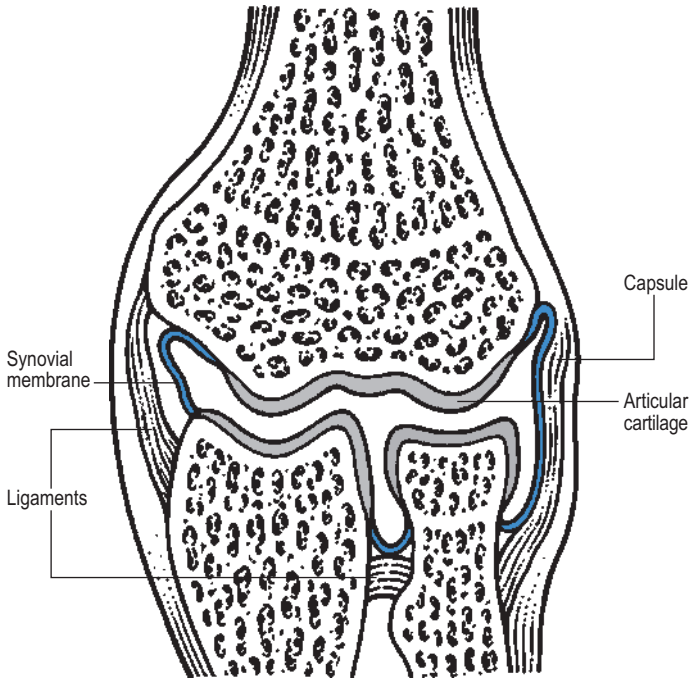

Fig 3.7 • Example of a synovial joint.

All ligaments are slightly elastic: collagen comprises about 70–80% of the dry weight, elastin 3–5%. They are taut at the normal limit of a particular movement but do not resist normal actions, since they are designed to check excessive or abnormal movements. Further they are also protected from excessive tension by reflex contraction of appropriate muscles.

The mechanical response of a ligament to a load can be represented on a load–deformation curve (Fig. 3.8). In the first part of such a curve (its foot) the ground substance is almost completely responsible for absorbing the stress and displaces the fibres in the direction of the stress. When the load is increased, ligamentous tissue responds slowly and maximum resistance to distraction is only possible if there is enough time for realignment of the collagen bundle. The linear part of the curve shows the slow elastic stretching of the collagen. During this stage, recovery of the original shape of the tissue occurs when the deforming load is removed. This slow rate of deformation is known as 'creep deformation'. Even in this linear part of the curve, breaking of intermolecular crosslinks begins. For this reason it is assumed that, in physiological circumstances, the load on ligaments is kept within that shown in the foot of the curve, where collagen is not yet under undue strain and the role of ground substance is maximal.[10] The composition and the amount of gel ground substance are therefore

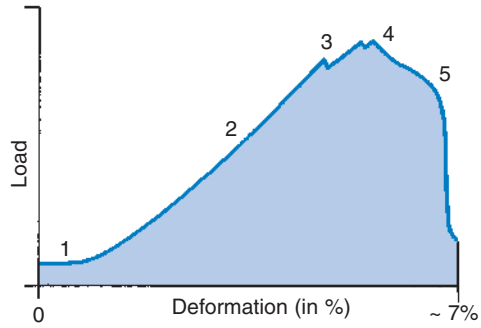

Fig 3.8 • Mechanical response of the anterior cruciate ligament of the knee to a load. 1. Foot of the curve, the ground substance alone almost completely absorbs the stress. 2. Linear part of the curve, slow elastic stretching of the collagen which is known as 'creep deformation'. 3. Yield point, a non-elastic or plastic deformation occurs. 4 and 5, the ligament progressively ruptures. Redrawn from Frankel[33] with permission.

important in load bearing. On reaching the yield point, a non-elastic or plastic deformation occurs and the ligament progressively ruptures. Some investigators have found that in bone–ligament–bone preparations, separation occurs at the point of insertion.[11]

In normal circumstances, mechanical stress induces early firing of mechanoreceptors in capsuloligamentous tissues. This causes a well-balanced reflex action of all musculotendinous units acting across the joint to avoid inert tissue becoming overloaded and damaged. If this muscular defence fails, strain falls on the ligament which is unable to stabilize the joint and so ruptures.

Synovial membrane and fluid

The synovial membrane lines the non-articular parts of synovial joints such as the fibrous capsule and the intra-articular ligaments and tendons within the margins of articular cartilage. The internal surface of the membrane has a few small synovial villi which increase in size and number with age. It also has flexible folds, fringes and fat pads. These accommodate to movement so as to occupy potential spaces and may promote the distribution of synovial fluid over the joint surfaces (Fig. 3.9).

Structurally the membrane consists of a cellular intima which is one to four cells deep that rests upon a loose connective tissue subintima and contains the vascular and lymphatic network which has an important function in the supply and removal of fluid. On ultrastructural examination, two cell types (A and B) are apparent. These are closely involved not only with the production of synovial fluid[12] but also in the absorption and removal of debris from the joint cavity. The A cells especially have marked phagocytic potential.[13] Some synovial cells can also stimulate the immune response by presenting antigens to lymphocytes if foreign material threatens the joint cavity.[14]

Synovial fluid is a clear, viscid (glairy) substance formed as a dialysate containing some protein. It occurs not only in synovial joints but also in bursae and tendon sheaths. Secretion and

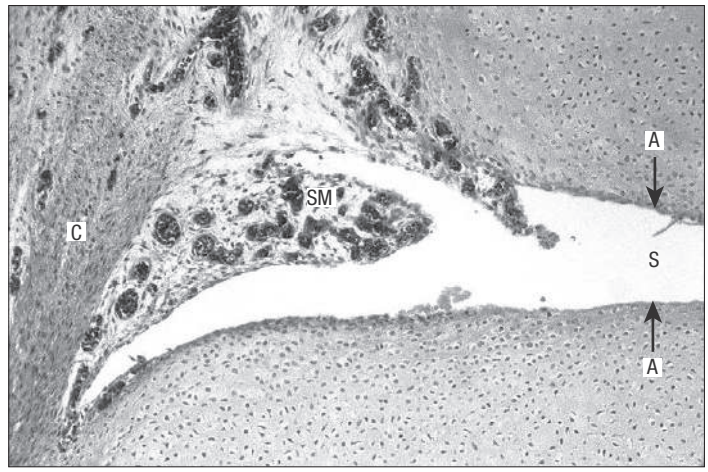

Fig 3.9 • A section of a synovial joint and its associated highly vascular synovial membrane in a human fetal hand. The two articular cartilage surfaces (A, arrowed) are separated on the right by a layer of synovial fluid (S) secreted by the synovial membrane (SM) which extends a short distance into the joint space from the capsule (C). From Standring, Gray's Anatomy, 40th edn. Churchill Livingstone, Edinburgh, 2008 with permission.

absorption are functions of the cells of the intima and of the vascular and lymphatic plexus in the subintima. The synovial initima cells also secrete hyaluronan molecules into the fluid and much evidence has accumulated to show that the viscoelastic and plastic properties of the fluid are largely determined by its hyaluronan content. Chains of hyaluronan bind proteins; these complexes are negatively charged and in turn bind water. The biophysical process is similar to that of the proteoglycans in the matrix of connective tissue and a thick viscous liquid which resembles egg white is formed. Its viscosity varies widely according to circumstances. With a low rate of shear, water is driven out of the hyaluronan–protein complexes and the fluid becomes highly viscous; increase in shear lowers viscosity and the fluid tends to behave more like water. In contrast to viscosity, elasticity increases with higher rates of shear. Both viscosity and elasticity decrease with increasing pH and temperature.[15]

Cartilage

Articular cartilage is essentially a specialized type of connective tissue.

Composition

Although the same three tissue elements – cells, ground substance and fibres – are present, their properties differ from ordinary connective tissue and determine its biochemical and biomechanical behaviour.

The composition of proteoglycans in the ground substance changes with increasing depth

In the superficial layer, chrondroitin sulphate is a prominent constituent in the GAGs but the deeper layers contain more and more keratan sulphate. A high concentration of chrondroitin sulphate stimulates the condensation of thin collagen fibres to form a dense network at the surface but keratan sulphate

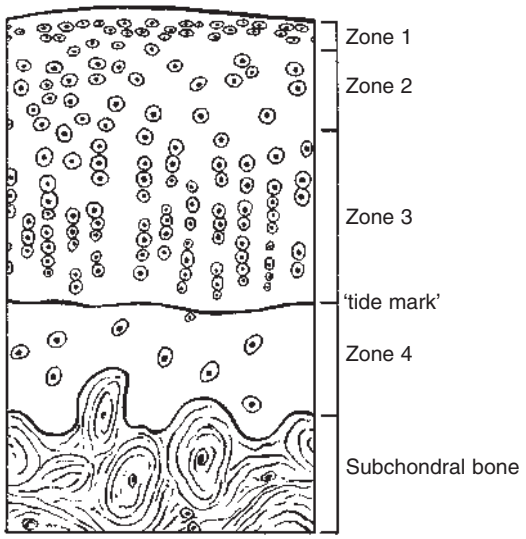

Fig 3.10 • Zones in articular cartilage. Zone 1, cells, small and flattened, disposed parallel to the surface; zone 2, cells become larger and more rounded; zone 3, cells are largest and arranged in columns, perpendicular to the surface; zone 4, mineralized cartilage. The border between mineralized and non-mineralized cartilage is called the 'tide mark'.

enhances synthesis of thick, easily movable fibres in the deeper layers. This adapted synthesis influences the local architecture and strength and resistance to compressing and shearing forces.

Cartilage cells or chondrocytes occupy small spaces in the matrix

They are involved in the production and turnover both of type II collagen and ground substance, processes stimulated by variation in load.

Chondrocytes change with increasing depth from the surface[1,16] (Fig. 3.10). In the superficial stratum (zone 1), cells are small, flattened and disposed parallel to the surface. They are surrounded by fine tangentially arranged collagen fibres. A thin superficial layer of this zone has been shown to be cell-free. Cell metabolism in this part is low, which is consistent with the absence of wear and tear in normal healthy tissue. The cells of the intermediate stratum (zone 2) are larger and more rounded and those in the radiate stratum (zone 3) are large, rounded and arranged in columns perpendicular to the surface. In these deeper zones, cells are screened from the coarse fibres by a coat of pericellular matrix bordered by a network of fine collagen fibres. In this way, cells are protected against the stresses generated by load conditions.

The collagen fibres vary in structure and position with increasing depth from the surface (Fig. 3.11a)

In the superficial or tangential stratum, a dense network of fine fibrils is arranged tangential to the articular surface to resist tensile forces that result from compression on certain points of the articulating surface during normal activities. Analysis has also shown the existence of certain 'tension trajectories' in accordance with the more or less fixed patterns of tensile forces that take place during movements. These preferential directions have been elaborated during growth as a result of forces acting on the joint. Near the border of the joint, the fibrils blend with the periosteum and joint capsule.

In the intermediate stratum, collagen fibres are coarser and more spread out to pursue an oblique course that forms a three-dimensional network. In non-load conditions the fibres are orientated at random but when load is applied they are immediately stretched in a direction perpendicular to that of the applied force (Fig. 3.11c). When the load is removed the fibres return to their original oblique position. This behaviour partly explains the resilience and elasticity of cartilagenous tissue.

In the radiate stratum, collagen fibres are arranged radially and correspond with the fibrous architecture of the subchondral and osseous lamina. The result is a series of arcades which extend from the deepest zone towards the surface.

Characteristics of cartilage

These include low metabolic and turnover rates, rigidity, high tensile strength, and resistance to compressing and shearing forces while some resilience and elasticity is retained. The proportion of collagen in matrix increases with age.

On the basis of variations in the matrix and the number of fibres present, cartilage in the locomotor system is divided into two types: hyaline and fibroelastic.

Most cartilage is hyaline: exceptions are the surfaces of the sternoclavicular and acromioclavicular joints and of the temporomandibular joints, all of which are of dense fibrous tissue. Although the light microscope appearance of hyaline cartilage is translucent, electron microscopy shows a system of fine fibrils and fibres. The water content is up to 80%. Strength, resistance and elasticity are the results of the proteoglycans in the ground substance together with the specific properties of the collagen fibres. Negatively charged proteoglycans bind a

large number of water molecules and causes the cartilage to swell. Swelling is limited, however, by the increasing tension of the collagen fibre networks in the superficial and deep layers which are closely interconnected. The result is an elastic buffer that, together with the elasticity of the periarticular structures, dissipates the effect of acute compressive forces. It also provides the articular mechanism with some degree of flexibility, particularly at the extremes of range. If the load is applied over a very short time, cartilage deforms in an 'elastic' way almost without disturbance of its water content. However, if compression is maintained for hours, water is displaced to surrounding regions that are under less or no compression and the compressed cartilage undergoes 'plastic' deformation. In engineering terms, this slow predictable rate of deformation is known as 'creep' and is greatest within the first hour of compression. When the deforming load is removed, recovery of the original shape of the tissue occurs at a rate that is specific for each form of cartilage.

Water transport during dynamic load conditions probably also has significance in the transport of nutrients and metabolites to and from the chondrocytes.

Articular cartilage lacks a nerve supply and is also completely avascular. Nutrition is derived from three sources: synovial fluid, vessels of the synovial membrane and vessels in the underlying marrow cavity which penetrate the deepest part of the cartilage over a short distance. This last source is available only during growth because, after growth is completed, the matrix at the deepest part of the cartilage becomes impregnated with hydroxyapatite crystals which form a zone of calcified cartilage impenetrable by blood or lymph vessels (Fig. 3.10, zone 4).

Articular discs and menisci consist of fibroelastic cartilage and are predominantly fibrous. They separate certain articular surfaces that have a low degree of congruity (e.g. the knee and the radiocarpal joint). Their functional roles are to improve the fit between joint surfaces, distribute weight over a larger surface, absorb impacts and spread lubricant.

With age, articular cartilage becomes firmer but also thinner and more brittle. The number of cells decreases. In normal healthy joints these changes are extremely slow. Erosion particularly occurs when joints become dehydrated or when synovial fluid viscosity permanently alters. Replacement of an eroded surface by proliferation of deeper layers has not been demonstrated. Deposits of calcification and surface ruptures are signs of degeneration. Except in young children, regeneration cannot be expected. However, there is evidence that a defect can be filled with newly synthesized collagen.

Synovial bursae

In situations where skin, tendons, muscles or ligaments move in relation to other structures under conditions that involve fluctuating pressure, synovial bursae are formed to reduce friction. They can be compared with flattened sacs of synovial membrane which create discontinuity between tissues and provide complete freedom of movement over a short distance. A capillary film of synovial fluid on their internal surfaces acts as a lubricant. Depending on their position they are classified as subcutaneous, subtendinous, submuscular or subfascial bursae. Sometimes they communicate with the joint cavity with which their synovial membranes are continuous.

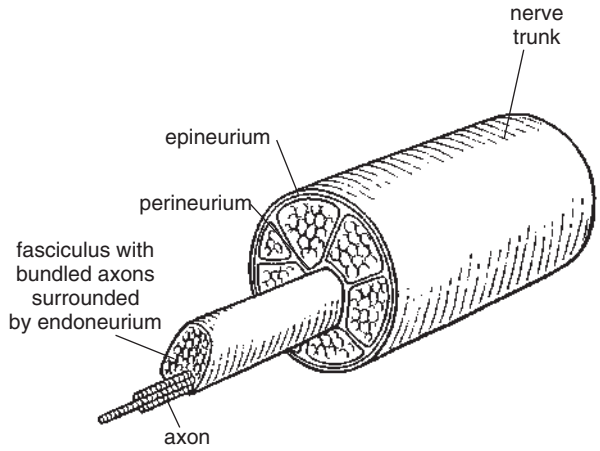

Fig 3.12 • Connective tissue in peripheral nerves: epineurium, a collagen coat that encases the nerve trunk; perineurium, fine collagen and laminae of fibroblasts that surround each fasciculus; endoneurium, loose delicate collagen that surround axons in the fasciculi.

Nerves

Peripheral nerves also possess supporting connective tissue. Within the nerve trunk the efferent and afferent axons are grouped together in a number of fasciculi (Fig. 3.12). The bundled axons in the fasciculi lie roughly parallel, surrounded by loose delicate collagen fibres running longitudinally along them. Both structures show a wavy appearance which disappears when gentle traction is applied.

Each fasciculus is surrounded by a fibrous *perineurium*, a regular structure of flattened laminae of fibroblasts alternating with fine collagen, running in various directions. These fibroblasts are connected together and form a diffusion barrier against noxious chemical products, bacteria and viruses. In this way, the enclosed axons are to some extent isolated from the external environment. Inside this perineural tube a protein-poor liquid flows centrifugally. This axoplasma is cerebrospinal fluid, which is re-assimilated into the blood circulation at the end of the peripheral nerve. In this respect, the spinal canal and the endoneural spaces are continuous (Fig. 3.13).

The *epineurium* encases the nerve trunk as a collagen coat with little regular organization. Connective tissue surrounding nerves serves as an important mechanical protection to maintain the conductile properties of the nerve.[17] During movement, nerves are potentially exposed to tensile forces that can be avoided by mobility in relation to surrounding structures. Here, the wavy form of both axons and surrounding collagen fibres is an important consideration: this 'waviness' of the axons is paramount, allowing them to remain relaxed even when the collagen fibres are stretched. Thus, within the normal range of movement, the axons will be protected by the tensile force of the collagen component. When there is a severe sprain or fracture perhaps with dislocation, the range of plastic

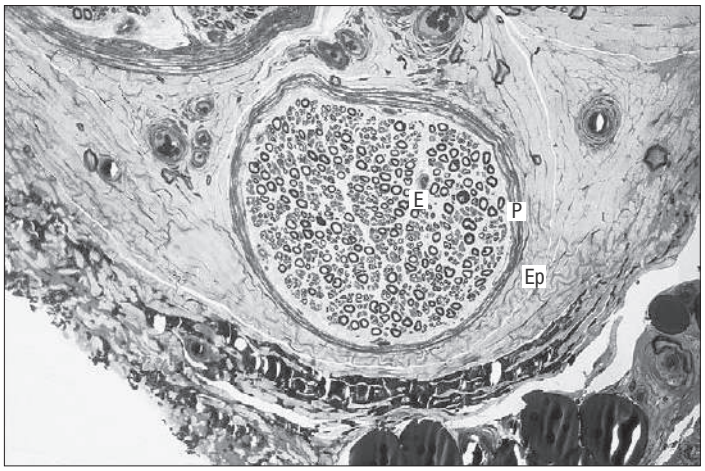

Fig 3.13 • Transverse section through a human peripheral nerve, showing the arrangement of its connective tissue sheaths. Individual axons, myelinated and unmyelinated, are arranged in a small fascicle bounded by a perineurium. P, perineurium; Ep, epineurium; E, endoneurium. deformation of collagen can be exceeded and ultimately rupture of collagen fibres and neurotmesis results.

The tolerance of nerves to tension is much greater than it is to compression. However, the mobility of nerves allows them to move laterally, so avoiding a compressive force. When space is inadequate for such movement or the nerve is firmly anchored – which is the case in cervical nerve roots – the epineurium may absorb a certain amount of pressure but sooner or later the blood supply within the nerve is affected by increasing compression. Further compression may result in interference with the conductile properties of the nerve. In such circumstances, the Schwann cells and subsequently the myelinated sheath are damaged. Although the axons remain intact, action potentials become blocked, leading to loss of sensory and motor function (see Ch. 2).

Muscles

Muscular tissue consists of specialized cells or myofibrils embedded in a network of fine connective tissue that transmits the pull of the muscle cells during contraction to the adjacent parts of the skeleton. For this purpose, connections exist between the muscle cells and the finest collagen fibres of the connective tissue network.

The muscle cell or myofibril consists of sarcomeres or myofilaments – the basic contractile units of a muscle – arranged in parallel (Fig. 3.14). In each sarcomere two types of filament are distinguishable, chemically characterized as actin and myosin. The actin filaments are each attached at one end to the inner side of the cell membrane forming the so-called Z-line. At the other end they are free and interdigitate with the central myosin filaments. During muscle contraction, the actin filaments slide in relation to the myosin towards the centre of the sarcomere which brings the attachments at

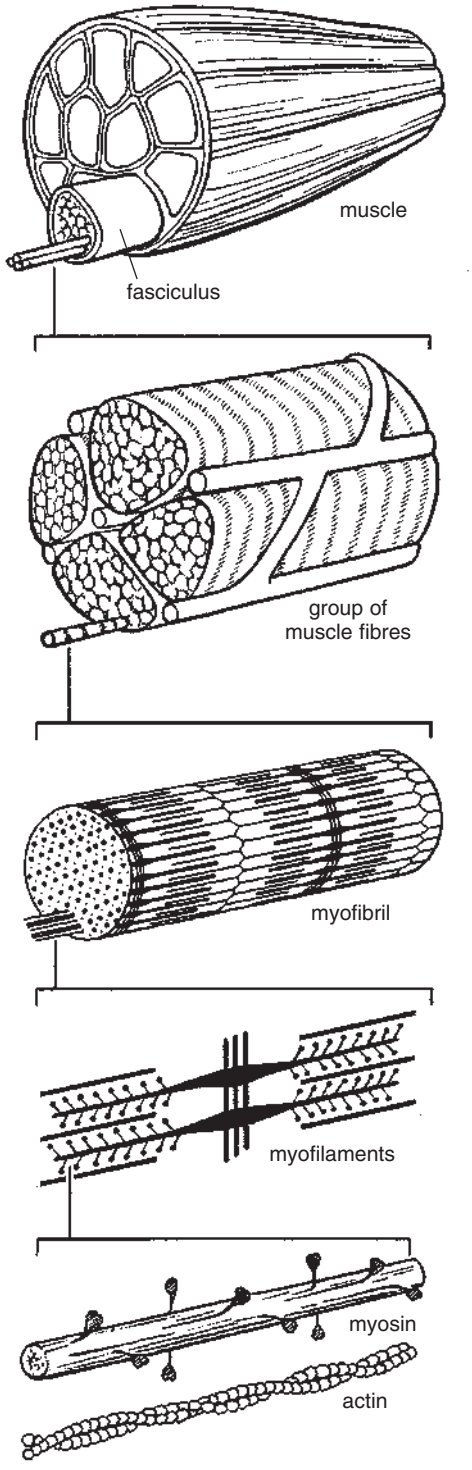

Fig 3.14 • The various levels of organization within a skeletal muscle, from whole muscle through fasciculi, fibres, myofibrils, myofilaments, down to molecular dimensions. The myofilaments are the basic contractile units of a muscle. Groups of myofilaments are arranged in parallel to form muscle fibres. These, in turn, are arranged in bundles or fasciculi. A network of connective tissue transmits the pull of the muscle cells during contraction via a tendon to the adjacent parts of the skeleton.

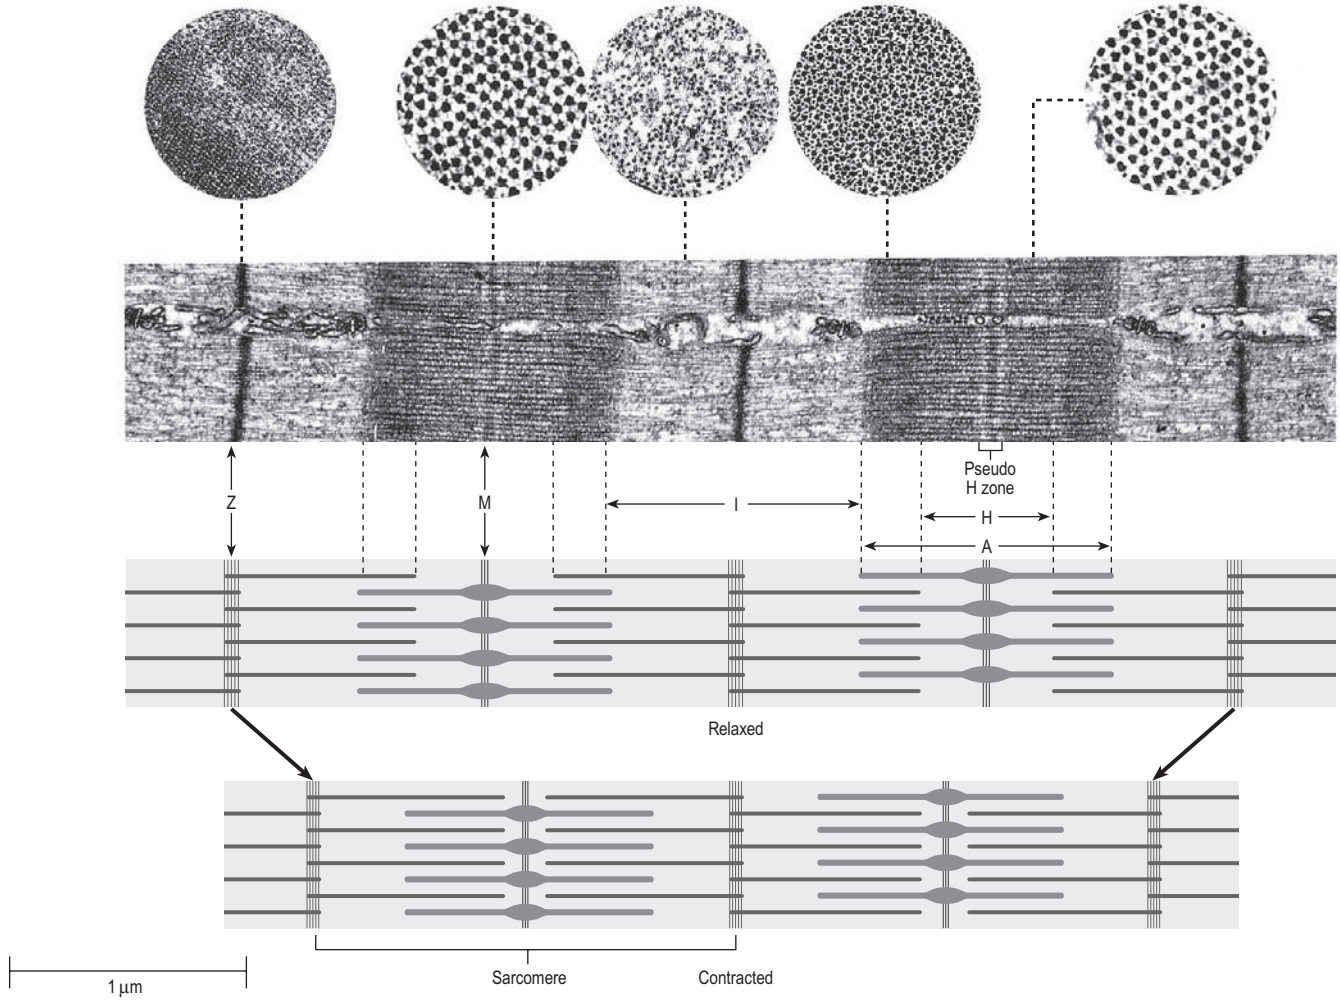

Fig 3.15 • Sarcomeric structures. The drawings below the electron micrograph (of two myofibrils sectioned longitudinally and with their long axes, orientated transversely) indicate the corresponding arrangements of thick and thin filaments. Relaxed and contracted states are shown to illustrate the changes which occur during shortening. Insets at the top show the electron micrographic appearance of transverse sections through the myofibril at the levels shown. Note that the packing geometry of the thin filaments changes from a square array at the Z-disc to a hexagonal array where they interdigitate with thick filaments in the A-band. the Z-lines closer together with shortening of the whole contractile unit (Fig. 3.15).

Exercises increase the number of myofibrils (hypertrophy). During periods of immobilization cell volume decreases (atrophy).

Groups of sarcomeres are arranged in parallel to form muscle fibres. These in turn are arranged in bundles or fasciculi of various sizes within the muscle.

The network of the fine collagen fibrils within a fasciculus is known as the *endomysium* and fills the spaces between muscle fibres. In this way, each muscle fibre is surrounded by a thin sheet of connective tissue that provides the pathway for the capillaries, which lie mainly parallel with the muscle fibres and facilitate the exchange of metabolites between muscle fibres and the capillary bed.

The *perimysium* is the stronger connective tissue that surrounds each fasciculus. It consists of parallel bundles of collagen that are partly arranged in a circular manner around the muscle fibres as well. These bundles are in close connection with the collagen of the endomysium.

Finally, the whole muscle is surrounded by the stout *epimysium*, which is continuous with the septa of the outer perimysium and blends with the connective tissue that forms the tendon, fascia or aponeurosis (Fig. 3.16).

At the myotendinal junctions the connective tissue of the endo-, peri- and epimysium becomes very fibrous and thickens, whereas the muscle fibres taper or flatten and show terminal expansions. The connection is so strong that rupture seldom occurs at the myotendinal junction.

Nerve supply to muscles

Nerves supplying muscle are frequently referred to as 'motor nerves', but they contain both motor and sensory components. The motor fibres comprise α-efferents, which

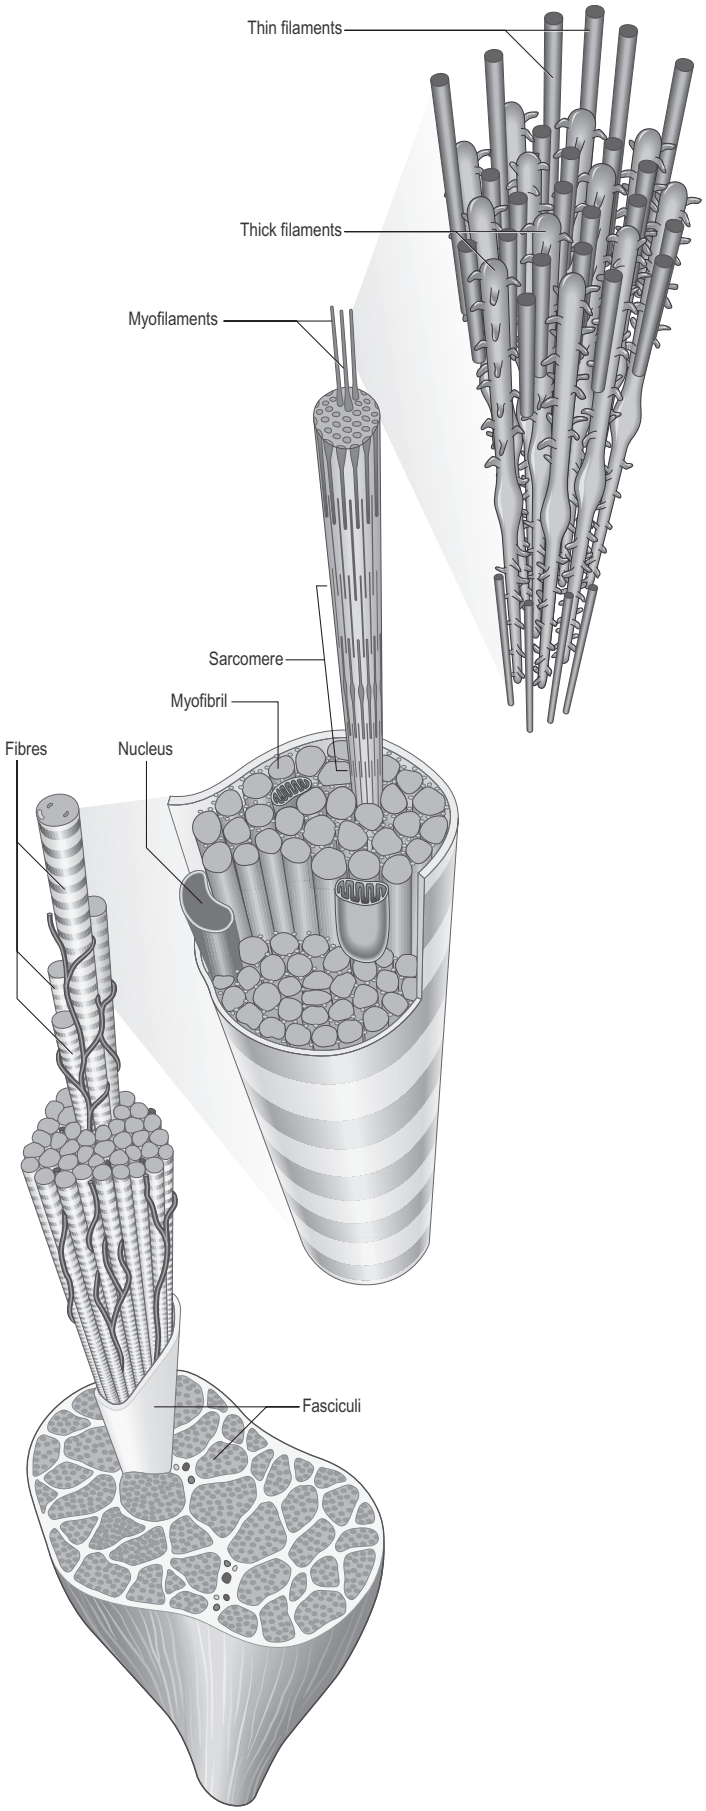

Fig 3.16 • Levels of organization within a skeletal muscle, from whole muscle to fasciculi, single fibres, myofibrils and myofilaments. From Standring, Gray's Anatomy, 40th edn. Churchill Livingstone, Edinburgh, 2008 with permission.

supply extrafusal muscle fibres, γ-efferents, which run to the muscle spindles, and autonomic efferents, which supply the smooth muscles of the vascular wall. The sensory component consists of large, myelinated IA and smaller group II afferents from the neuromuscular spindles and fine myelinated and non-myelinated axons which convey from free terminals in the connective tissue sheaths of the muscle.

Tendons

These structures are largely composed of collagen fibres with a low amount of proteoglycans. On a dry weight basis, collagen represents 60–80% of the total weight of tendon.[18]

Tendons, which consist of fascicles of collagen fibres running parallel and partly interweaving, are highly resistant to extension. Although elastin is absent and their collagen is difficult to stretch, tendons are nevertheless slightly stretchable. The wavy form of the fibres, together with the interweaving pattern of the fascicles, results in a slight elongation at the moment of muscle contraction which damps any abrupt pull on the insertion.

At the surface, the epitendineum or tendon sheath consists of irregularly arranged condensed collagen as well as elastin fibres. It is continuous with the loosely arranged connective tissue that permeates the tendon between its fascicles and provides a route of ingress and egress for vessels and nerves. At the insertion, the collagen bundles of the tendon permeate into bone. It has been shown[19,20,21] that the insertion of the connective tissue of ligaments into bone involves a transition from non-mineralized through mineralized fibrocartilage to bone.

In young growing tendons, fibril diameter and tensile strength can be increased by exercise. In adults, however, the effect is minimal although regularly applied tension is necessary to maintain structural integrity. Immobilization has demonstrated loss of tensile strength (see p. 46).

The nerve supply to tendons appears to be entirely afferent. Vascularization of tendons is low – the reason they appear white. Small arterioles ramify in the interfascicular intervals and are accompanied by veins and lymphatic vessels. Passage of vessels through the teno-osseous junction seems not to occur.

Where tendons pass under ligaments or through osteofibrous tunnels, synovial sheaths are formed which separate the tendon completely from its surroundings. These synovial sheaths have two concentric layers, separated by a thin film of synovial fluid and form a closed double-walled cylinder (Fig. 3.17). The fluid acts as a lubricant and ensures easy mobility of the tendon. The internal (visceral) layer is attached to the tendon and the external (parietal) layer to neighbouring structures such as periosteum and retinaculum.

Table 3.2 Stages of repair after mechanical damage to soft connective tissue

Stage	Reaction
I	Inflammation: clearance of debris and preparation for repair Vasoconstriction (5–10 min) followed by vasodilatation and increased capillary permeability leading to: Exudation Liquid component Fibrinogen Cellular component
II	Granulation: formation of scar tissue (48 h to 6 weeks) Vascular infiltration Fibroblast proliferation
III	Remodelling (starts at the third week and may continue for 1–3 years): Devascularization Maturation Remodelling

Trauma to soft connective tissue

Introduction

Soft tissue injury involves damage to the structural elements of connective tissue with rupture of arterioles and venules. A general inflammatory reaction follows (Table 3.2), one role of which is defensive in that it prompts the subject to restrict activities while recovery takes place.

Regardless of the site of injury and the degree of damage, healing comprises three main phases: inflammation, proliferation (granulation) and remodelling. These events do not occur separately but form a continuum of cell, matrix and vascular changes that begin with the release of inflammatory mediators and end with the remodelling of the repaired tissue. Connective tissue regenerates largely as a consequence of the action of inflammatory cells, vascular and lymphatic endothelial cells and of fibroblasts.[22,23]

Inflammation

The first reaction is vasoconstriction of small local arterioles that lasts about 5–10 minutes and is followed by active vasodilatation and increased blood flow for 1–3 days. In major injuries with damage to blood vessels, blood escapes to form a haematoma that temporarily fills the injured site. Within the haematoma, fibrin accumulates and platelets bind to collagen fibrils to form a clot that provides the framework for invasion of vascular cells and fibroblasts.[24] The vascular changes and further inflammatory reactions are initiated by chemical mediators released from destroyed tissue cells.[25,26] Mast cells release heparin (anticoagulant) and histamine (vascular dilator). Plasma cells produce bradykinins and substance P (pain and vasodilatation). Platelets produce serotonin, prostaglandins and growth factors that stimulate migration, proliferation and differentiation of cells.[27,28] In addition, mediators cause migration of leukocytes into the injured area and swelling of the endothelial cells that line vascular channels. The endothelial cells pull away from their attachment to each other to leave sizeable gaps between cells that increase the permeability of vessels and so allow plasma, cells and proteins to escape. As a result, the presence of these proteins enhances the flow by osmosis of more plasma into the injured extracellular space. The whole process is the *exudative phase*. The liquid part of the plasma exudate dilutes potentially noxious substances and products of cell destruction and helps in their elimination by the supply of globulins and enzymes.

Another important substance is fibrinogen which forms an extensive network of fibrin into which fibroblasts can migrate along with other reparative cells.

The cellular parts of the exudate are:

- neutrophil granulocytes responsible for phagocytosis and proteolysis of the products of cell destruction
- lymphocytes which increase permeability and help to activate the phagocytosis of damaged cells
- macrophages whose role is probably to engulf and digest protein and to supply amino acids to the fibroblast; macrophages remain present throughout the entire inflammatory phase to assist in the phagocytosis of tissue debris and are also key cells in repair.

The well-known clinical signs of inflammation are: *swelling*, *warmth*, *pain*, *tenderness* and *functional loss* – a defensive

reaction of the body that prompts the subject to restrict activities while recovery takes place.

Repair

It is worthwhile to mention that only the synovial capsules of the joints, skeletal muscle and bone are, to some degree, capable of *regeneration*. All other connective tissues heal by *repair* with the formation of collagen and thus scar tissue.

Once the exudative phase has cleared debris by dilution and phagocytosis, fibroblasts and capillaries migrate along the fibrin network. The process of vascular infiltration, fibroblast proliferation and the deposition of collagen usually begins within 48 hours of injury overlapping with the end of the exudative phase and the later remodelling phase. Repair is begun and directed by the release from macrophages of chemotactic agents which attract fibroblasts and endothelial cells, secrete growth factors which stimulate these cells to proliferate and produce lactic acid which enhances the synthesis of collagen by fibroblasts. High levels of corticosteroids prevent the migration of macrophages.

During their proliferation, fibroblasts develop into cells termed myofibroblasts that generate a traction-like activity on the matrix required for the reduction of any gap in the healing area.[29]

Capillaries, at the edge of the injured area, send forward buds which then turn and meet each other to form new capillary loops capable of maintaining a circulation that ensures oxygen and nutritional supply in the relatively hypoxic region where the healing tissues meet and, at the same time, enables the removal of metabolic waste products. These new capillaries are fragile and stay within the support of newly synthesized collagen which has already been deposited ahead of the formation of the capillary loops. The highly vascular mass produced gives the surface of the tissue its granular appearance and hence its name – *granulation tissue*.

By the fourth or fifth day after injury the amount of collagen is significant and there is a progressive but gradually slower increase up to 6 weeks after injury. Corticosteroids decrease the number of fibroblasts and result in a diminished formation of collagen fibres and possibly a weaker fibrous scar. Normally the initial arrangement of collagen fibres is at random but after 6 weeks, tensile strength continues to increase because of orientation of fibres along the lines of stress in the injured tissue (remodelling).

Remodelling

Around the end of the third week maturation begins – the process of reshaping and strengthening the scar tissue by removing, reorganizing and replacing cells and matrix. A better structural orientation and increase in tensile strength result.[30] The remodelling phase can be divided into a consolidation and maturation stage:[31]

- First, vascularization decreases and many of the new vessels atrophy and disappear as the blood supply becomes appropriately adjusted to the needs of the scar tissue.
- Second, the amount, form and strength of scar collagen changes: the immature and weak tissue with a random orientation of fibres in three planes is remodelled into linearly arranged bundles of connective tissue. The process is the result of a number of factors, including turnover of collagen, fibre linkage and increased intermolecular bonding.

It is now generally recognized that internal and external mechanical stress applied to the repair tissue is the main stimulus for remodelling. Tension by gentle movements in functional directions reorientates the collagen and breaks any weak or unnecessary crosslinks that may have formed. Mechanical stress thus has its greatest influence on remodelling at this time. Non-functional collagen is cleared away by phagocytosis.[32–36]

Remodelling may continue for years although more slowly as time passes. The tensile strength of replaced or repaired collagen in ligaments reaches 50% of normal by 6–25 months after injury and 100% only after 1–3 years.[37] The strength of a scar formed in an injured muscle increases faster because of its superior vascular supply.[25]

Self-perpetuating inflammation

The linear sequence of events described above – an inflammatory reaction followed by repair and remodelling – is typical for acute wounds, either accidental or surgical. Orthopaedic medicine, however, also deals with chronic repetitive strains and tissue disruptions, overuse phenomena and excessive tension on devitalized tissues. Here the reaction of the tissues involved is often not linear; the inflammation may be prolonged and the formation of scar tissue excessive and inappropriate.

Rest usually initiates adhesion formation in and around the healing breach. Oedema raises tissue tension and causes pain, so impeding functional movements that are extremely important in the early stage of regeneration. Without proper movement there is no balance between formation and lysis of the regenerating elements of the involved tissue. Proper alignment of collagen does not result and the final form of the scar tissue tends to remain ill-organized. Any small stress applied to an inappropriate tissue is sufficient to disrupt newly formed fibres in the healing breach. This in turn starts another inflammatory response and a vicious circle of chronic repetitive disruptions of inferior quality connective tissue will result. If such a state of chronic inflammation is maintained, the function of the affected area continues to deteriorate and leads to further tissue damage.

Cyriax drew attention to such chronic types of inflammation of soft tissues that began as a result of trauma but continued long after the cause had ceased to operate – *self-perpetuating inflammation* (see Fig. 3.18) – particularly prone to happen after a minor injury to a ligament. Occasionally it also occurs as an overuse phenomenon in a tendon. With knowledge of the inflammatory reaction in traumatized soft tissues, it is clear that lack of movement during the period of repair and remodelling which leads to adhesive scar tissue formation can be responsible for some chronic lesions.

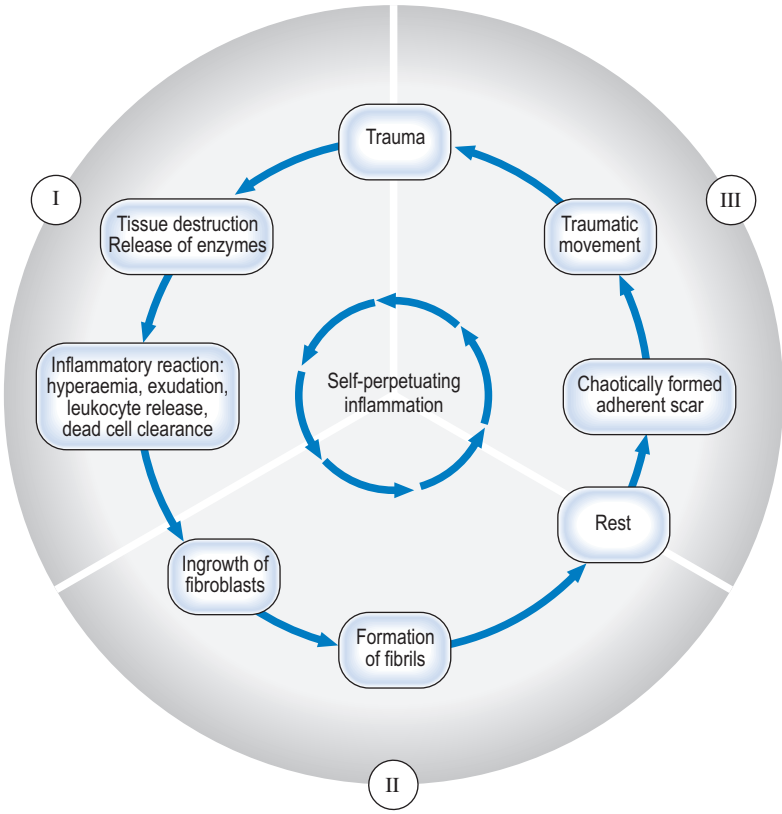

Fig 3.18 • Self-perpetuating inflammation: rest initiates adhesion formation; stress applied at the inappropriate time disrupts the newly formed fibres, which starts another inflammatory response. I, inflammation; II, repair; III, remodelling.

The decision whether a lesion requires rest or movement cannot be taken by the patient, who feels pain and loss of function and interprets these symptoms as a potential threat that can be reduced by immobilization. The main goal in the treatment of musculoskeletal lesions is therefore to guide the healing soft tissues through the stages of inflammation and repair by the provision of sufficient and appropriate motion that can restore painless function. If a chronic self-perpetuating inflammation has become established, a local infiltration of corticosteroid may interrupt the process. The scar becomes painless and the tissue, no longer deprived of its functional motion and appropriate stress, starts to remodel. Another approach which helps to reduce the amount of disorganized scar tissue is to perform deep transverse friction followed by manipulation (see p. 54).

Effects of immobilization on healing

Joint capsule and ligaments

Disturbance of the blood and lymph stream in the synovial membrane influences the supply of nutrients and the scavenging of metabolic products and destroyed cells. Joint immobilization reduces synovial fluid hyaluronan concentration and is accompanied by changes in the synovial intimal cell populations.[38]

In a study on the effects of immobilization of knee joints of dogs, deposition of excessive connective tissue was noted.[39] In the course of time, mature scar and intra-articular adhesions were found which restricted joint motion. Within the matrix a 4.4% loss of extracellular water and a significant reduction in GAG content (30–40%) was established. Ingrowth of new capillaries at the edge of injured tissue was diminished. Other workers studied the effects of immobilization on the knee joint of the rabbit.[40,41] They confirmed the findings in the dog but also postulated that loss of water and GAG content would decrease the space between collagen fibres and thus restrict normal interfibre movement. Random orientation of newly generated fibrils and the formation of crosslinks between newly regenerated fibrils and pre-existing collagen fibres were other findings responsible for decreased collagen mobility and restricted movements. These matrix changes are relatively uniform in ligament, capsule, tendon or fascia. Some specific studies on collateral and cruciate ligaments have demonstrated laxity, destruction of ligament insertion site and failure at a lower load after immobilization for 3 months.[42–44]

Cartilage

Several authors have also demonstrated the deleterious effects of immobilization on cartilage:[44–51]

- Shortening and thickening of fibrous articular capsule gives rise to a three-fold increase of the compression of articular cartilage, which may eventually initiate degenerative changes in the joint.
- Loss of water content and GAGs in cartilage decreases its elastic properties.
- Decreased capsular blood supply leads to a deposit of some end-products of metabolism at the joint surface.

Table 3.3 Effects of immobilization and mobilization on soft tissue injuries

Tissue	Immobilization	Mobilization
Joint capsule	1. Distribution of blood and lymph flow 2. Intense synovitis 3. Loss of extracellular water and GAG content 4. Deposition of excessive connective tissue 5. Decreased collagen mobility 6. Intra-articular adhesions 7. Laxity and destruction of ligament insertion site	1. Increased circulation 2. Prevention of abnormal adhesions 3. Beneficial influence on the remodelling process 4. Increase of strength of connective tissue in ligaments
Synovial fluid	1. Alteration of viscoelastic properties	
Cartilage	1. Increase of compression 2. Deposit of end-products of metabolism 3. Decrease of elastic properties 4. Autolysis of cartilage	1. Beneficial effect on assimilation of nutrients
Muscles	1. Atrophy 2. Decrease of strength 3. Increase of amount of connective tissue 4. Disturbance of neuromuscular coordination of muscle groups	1. Increased circulation 2. Increase of muscle strength and endurance 3. Maintenance of proprioceptive reflexes which ensure active joint stability

- Lysosomal enzymes released from dead chondrocytes lead to an autolysis of cartilage which is proportional to the time of immobilization.

Muscle

Muscular reactions to immobilization have also been investigated.[52,53] There is:

- decreased capillary density and muscle atrophy
- decrease in muscle strength most dramatically during the first week of immobilization. After 2 weeks in a plaster cast, there is 20% loss of maximum strength. Slow muscle fibres, with predominantly oxidative metabolism, are more susceptible to immobilization atrophy than are fast fibres
- an increased amount of connective tissue. Proliferation first takes place in the perimysial spaces, followed sometimes by the endomysial spaces. It is suggested[53] that this may impair the vascular supply of muscle fibres and could facilitate degeneration and also could make regeneration more difficult. Although muscle structure, metabolism and function are severely impaired after immobilization, almost complete recovery is possible provided that the training programme starts with very moderate exercises and avoids maximum voluntary efforts of regenerating muscle fibres
- disturbance of neuromuscular coordination of muscle groups.

The same studies drew attention to the reactions of organ systems, such as the cardiovascular, respiratory, locomotor and autonomic, which may also become disturbed.

Effects of mobilization on healing

The benefit of early mobilization in most soft tissue lesions was advocated by Hippocrates more than 2400 years ago. Capsular circulation is increased (Table 3.3) which aids the supply of nutrients and elimination of cartilagenous debris. Physical joint movements have a beneficial effect on the assimilation of nutrients by the cartilage.[54]

Experimental findings[11,55,56] on the influence of physical activity on ligaments and tendons support the view that the strength of connective tissue is increased with exercise training and decreased with immobilization, provided that the exercise programme is of an endurance nature. Trained animals have significantly heavier ligaments, stronger ligament–bone junctions and junction strength to body weight ratios. Similar effects pertain in repaired ligaments,[42,57] which show significantly higher strength values after repair is complete if they have not been immobilized. Early mobilization also considerably influences the remodelling process and prevents formation of abnormal adhesions that may restrict joint movements.[58]

Another advantage of early mobilization is the positive effect on skeletal muscles,[57,59,60] with increased circulation, muscle strength and endurance and maintenance of proprioceptive reflexes, which ensure the active stability of the joint.

Treatment of traumatic soft connective tissue lesions

The overall aim of treatment in orthopaedic medicine is to restore painless function of the connective tissue. During the last decades it has become clear that application of functional movement to healing connective tissue is extremely important and should be the first and principal objective for the therapist. Of course, the selection of the techniques will depend on several factors such as the stage of the lesion, the tissue involved, the severity of the lesion, the irritability of the tissue and the pain perception of the patient.

Muscular lesions

Delayed muscle soreness, contusion, (minor) rupture, myosynovitis and myositis ossificans are different types of lesion which can occur in skeletal muscle.

Delayed muscle soreness

A delayed, specific soreness sometimes appearing 12–24 hours after intense exercise is well known in athletics and may be caused by the disturbance of metabolism, with a high concentration of lactic acid and the resulting inflammatory reactions: vasodilation, increased capillary permeability and intercellular oedema. Swelling and oxygen deficiency may irritate free nerve endings and lead to muscle spasm.[61] Another, more recent, theory is that there is injury to sarcomeres and intramuscular collagen fibres and, in consequence, an inflammatory reaction.[62]

Passive stretching and active contraction cause discomfort. Pain lasts 3–4 days, gradually diminishing during the subsequent days. Improper warm-up, unusual exertion, early season training and running before muscles are properly conditioned are some conditions that are thought to bring on the pain.

The best way to avoid this condition is to stay 'in shape' between seasons. Other precautions to be advised are:

- warm up before beginning an exercise programme
- include stretching exercises in the warm-up
- gradually increase the load and duration of the exercises
- avoid excessive tension on muscles
- allow the muscles to dissipate waste products (warm-down).

Muscular contusion

This results from a direct blow on the muscle belly. There is a variable degree of severity, characterized by pain and intra- or intermuscular bleeding with extensive swelling. Intramuscular bleeding is more serious and lasts longer because of difficulty in dispersing the haematoma. Such a blow does not cause much discomfort or pain while the athlete is warm and actively taking part in sport; it is some hours afterwards that stiffness and disability set in. Active contractions against resistance cause discomfort and passive stretching of the muscle is painful and limited.

Treatment involves aspiration of the haematoma (within 3 days), after which compression is applied immediately, using an elastic wrap. A short period of rest may be prescribed but rest should never be total and prolonged.

After a few days, treatment with gentle deep transverse frictions and active contractions with the muscle in a fully shortened position can be started (see Minor muscular tears).

Minor muscular tears (or 'muscle strain injuries')

Acute lesions

These are the common 'muscle pull' or 'strain' injuries that result from sudden and over-violent effort or movement in the muscle and usually cause immediate disability. Tears occur most often during unusual contractions,[63] which produce significantly higher muscle force than when the muscle is held at the same length or is allowed to shorten. It has also been shown that muscles crossing two joints, such as hamstrings and gastrocnemii, are particularly at risk. The vulnerable site appears to be near the muscle–tendon junction. The immediate response to the trauma is inflammation, associated oedema and localized haemorrhage. Excessive oedema and haemorrhage should be reduced as much as possible. Blood collections are not confined to the muscle proper but escape through the perimysium and fascia into the subcutaneous space. As a rule, the degree of pain is consistent with the extent of the rupture.

Treatment

The immediate induction of *local anaesthesia* at the site of the lesion effectively blocks the nociceptive impulses which are responsible for muscle spasm at the site of damage. Cold therapy as an alternative has been criticized.[64] Although it has a positive effect on pain threshold,[65,66] physiological effects and procedures of application are still chiefly based on empirical and clinical findings. Van Wingerden suggests that cold therapy, especially when applied in the acute phase of injury, could lead to increased oedema, inhibition of the healing process and even to increased inflammatory reactions.[64]

From the next day on, *active or electrical contractions* follow, with the muscle in a fully shortened position to maintain mobility by broadening the muscle belly. Meshwork of regenerating fibrils in the healing breach may hinder the broadening capacity of the muscle fibres during contraction. In the later stages of healing (granulation and remodelling), intramuscular formation of abnormal crosslinks takes place and the inappropriate scar tissue will form a mechanical barrier to broadening during contraction, a chief muscle function (Fig. 3.19).

Deep transverse friction also imitates broadening and prevents newly formed bonds from matting muscle fibres together. It should be started the day after injury, as it can be expected that repair has begun by this time. A gentle type of massage is performed daily for a short period of time (see Ch. 5). At this stage, it should not be done to an extent that interferes with the capillaries and fibrils consolidating themselves in the healing breach. Both intensive passive stretching and resisted movements may cause damage at the site of injury and must be avoided until recovery is well established. It has been demonstrated[67,68] that contractile ability recovers rapidly.

Once the patient is free from pain and has a full range of mobility, repetitive stretching exercises seem to make an important contribution to the future prevention of these injuries.[69–72] Return to sport can be allowed when the strength of the injured limb has been restored to within 10% of that of the unaffected limb (usually after 3–6 weeks).[73]

Chronic lesions

Scarring takes place in chronic lesions, matting fibres together transversely. The range of broadening is impaired and contractions against resistance are painful. A painful area can be palpated, although it may be difficult when the lesion is deeply situated, for example, the belly of biceps brachii or the extensor carpi radialis brevis. Pain probably results from overstretching at the junction between normal and scar tissue, from local variations in tension. This explanation seems logical because

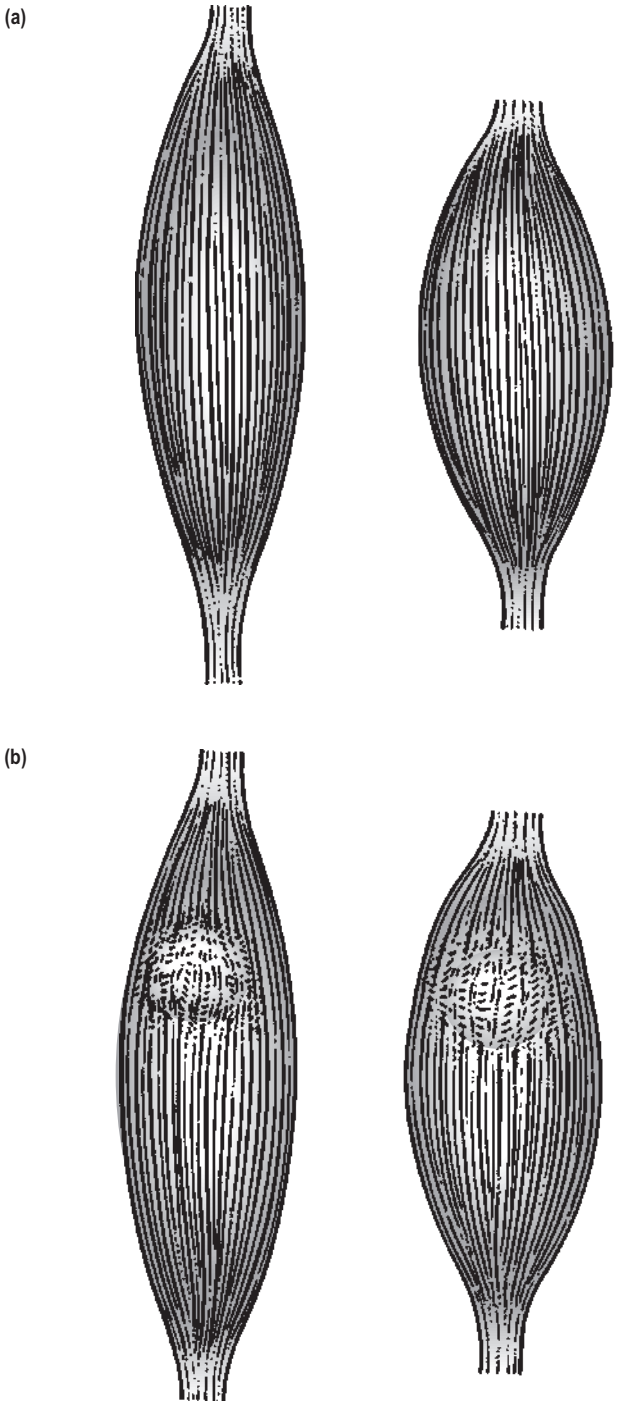

Fig 3.19 • (a) The muscle belly broadens during contraction; (b) scar tissue and intramuscular formation of connective bridges form a mechanical barrier to broadening during contraction.

pain is absent in diffuse fibrosis after sclerosing injections and in ischaemic contracture.

Treatment

Deep transverse friction for about 20 minutes twice a week to the site of the established scar is indicated. The muscle fibres are teased apart, abnormal crosslinks ruptured and mobility restored. To maintain the effect of the friction, *active* and *electrical contractions* with the muscle belly in a fully relaxed position should follow. The muscle contracts to its fullest extent and this is repeated for 5 minutes at regular times. When the lesion is at the musculotendinous junction, active or electrical contractions are ineffective and treatment is by deep friction only.

Steroids do not have a place in the treatment of muscular lesions. Recent research in an animal model indicates that corticosteroids may be beneficial in the short term but they cause irreversible damage to healing muscle in the long term, including disordered fibre structure and a marked diminution in force-generating capacity.[74]

Myosynovitis

Myosynovitis is a painful condition described by Cyriax,[75] arising from a muscle as the result of overuse. In severe cases it is accompanied by crepitus on movement. This uncommon condition seems to occur only in the bellies of the long abductor and the extensor muscles of the thumb and in the musculotendinous junction of the tibialis anterior. The last disorder is a well-known complaint in new military recruits who march unaccustomed distances.

Myositis ossificans

This condition is characterized by progressive benign heterotopic bone formation, which may occur after severe contusion to muscle fibres, connective tissue, blood vessels and underlying periosteum. The pathogenesis is poorly understood. It is seen most often in males, aged between 15 and 30 years. Highly common sites are the brachialis and quadriceps muscles. The condition is sometimes found in the hip adductors and pectoralis major and the bony deposit is often connected to the underlying bone.

There is the following triad of symptoms:

- Increasing pain
- Palpable and increasing firm mass in the affected muscle
- Gradual decrease in the range of movement of the neighbouring joint(s).[76,77]

The history of severe contusion to the affected muscle is helpful in the early evaluation of these patients because radiographic changes become evident only 2–4 weeks following the trauma. The condition can mimic benign or malignant bone tumour and osteomyelitis.[78,79]

Specific treatment is not recommended. Bone formation may resorb with time but recovery may take from 1 to 2 years. Early surgery is to be avoided because it may exacerbate the bone formation. Removal can be considered if symptoms persist, but only after the heterotopic bone is mature and no further radiological changes occur.[80,81]

Tendinous lesions

Tendons transmit power from the muscle belly to bone. In that the tendon is always less in diameter than the muscle, the load transmitted to the tendon will be much greater per unit diameter than in the muscle belly. Dysfunction may result from changes either within the tendon or in the surrounding tissues of the tendon (paratenon).

Terminology

Within the literature, there is much confusion about the terminology and over the last decades, numerous terms have been used to describe the pathology of tendons. The most common term is 'tendinitis' which focuses on clinical inflammatory signs. Puddu et al.[82] proposed the term tendinosis as a histological description of a degenerative pathology with a lack of inflammatory change. As these terms are often used interchangeably and without precision[83] it may be more appropriate to refer to a symptomatic primary tendon disorder as a tendinopathy as this makes no assumption as to the underlying pathological process.[84]

'Tendinitis'

When strain on a tendon tears some fibres, it always seems to occur in those parts of the tendon where vascularization is relatively poor. The insertion into bone and sometimes a specific part of a tendon are such 'critical' vascularized zones. Good examples are a zone in the Achilles tendon about 2.5 cm above its insertion into the calcaneus[85,86] and the supraspinatus tendon close to its insertion on the major tubercle.[87]

Above the age of 25, vascularization of tendinous tissues also decreases (ultimately by about 30%) which enhances their vulnerability.

Lesions result principally from overuse. However, the mechanical response of a tendon to a load not only depends on the amount of the externally applied force but also is closely bound up with the state of the tendon involved. Overuse may disturb the microcirculation which, especially in zones of hypovascularity, will negatively influence metabolic processes. If this continues, a process of degeneration starts, called 'tendinosis'. In the beginning of the process this is a degenerative condition without accompanying inflammatory reactions and therefore clinical signs and symptoms may be totally absent.

From the moment that a normal load strains the tendon and tears some fibres, an inflammatory reaction begins. Long-standing treatment with corticosteroids or periods of immobilization will further negatively influence the condition of collagen and lead to further deterioration and decrease in the number of fibrocytes and fibres. In sports, a cold climate, bad equipment and wrong training procedures (e.g. lack of warm-up including absence of stretching, too progressive an increase of load and duration of the exercise programme, bouncing exercises and jerky muscle contractions) may all negatively influence the condition.

The inflammatory reactions in tendinitis are located not only at but also around the ruptured fibres, in the areolar tissue between the fasciculi. Here oedema, growth of capillaries, migration of leukocytes and invasion with mesenchymal cells take place, which induces new generations of fibroblasts and leads to a large proliferation of connective tissue around the site of the lesion.

Acute traumatic lesions

In acute traumatic lesions 48 hours after the injury, newly generated collagen fibrils start to close the tissue defect by the formation of scar tissue. Scars may remain lastingly painful and often have an inferior tensile strength, especially if the initial inflammatory reaction was excessive and the granulation and remodelling phases inadequate.

Treatment

To prevent excessive inflammation and to stimulate better remodelling, gentle mobilization and transverse friction are used to orient the randomly distributed collagen in a functional direction. This also prevents the formation of abnormal adhesions. Treatment starts the day after the injury and massage should be superficial and light in order not to rupture newly generated fibrils. Treatment along these lines is continued daily for the first week and on alternate days for the second and third weeks. After 3 weeks, active unloaded contractions can be added. A tape or bandage to support the structure and prevent undue movement is advisable. Careful evaluation is necessary, gauging the degree of activity against the degree of local reaction.

The patient should be very cautious about returning to full activity until the lesion is completely pain free.

Chronic (overuse) lesions

Treatment

In chronic tendinous lesions, transverse friction massage applied precisely to the exact area may be an extremely useful technique and can often bring lasting relief.

Modalities and effects of this treatment form are discussed in the online chapter *Applied anatomy of the cervical spine* but transverse friction aims to achieve transverse movement of the collagen structure of the connective tissue. In this way adhesion formation is prevented and existing adhesions are mobilized. The cyclic loading and motion of the healing connective tissues may also stimulate formation and remodelling of the collagen.

Another approach is to infiltrate locally a low dose of corticosteroid. This will quickly reduce the chronic inflammatory reaction but it also affects the proliferative and even the remodelling phase – the biosynthesis of collagen is altered by corticosteroids. For this reason, local steroid infiltrations should only be at the tenoperiosteal insertion and never in relation to the body of a tendon for fear of possible tendon rupture. A further disadvantage of steroid infiltration is the higher recurrence rate (about 25%) after initial therapeutic success.

Persistent pain is thought to be caused by irreversible degenerative changes within the tendon. Removal by surgical treatment may then be indicated. Again treatment may include sessions of transverse friction applied in a progressive way until the patient is free of symptoms. Thereafter, a programme of rehabilitation is undertaken.

Tenosynovitis

Tenosynovitis is a well-known lesion at the ankle or the wrist where tendons possess a sheath. Roughening of the gliding surfaces of a tendon and the internal or visceral layer of the sheath results from an inflammatory reaction; commonly occupational overuse or strain. During movement, pain is evoked as the roughened surfaces move against each other. In severe cases fine crepitus is palpable and swelling obvious. Coarse crepitus is a warning sign that points to rheumatoid disease or tuberculosis.

Treatment

This consists of deep transverse friction whether the condition is recent or chronic but it is indicated only in posttraumatic lesions. Friction restores the smooth and painless movement of the tendon in relation to the internal layer of the sheath.

An injection of a small amount of steroid suspension between tendon and sheath is an alternative. Some lesions respond better to the massage and for others injection is the treatment of choice (see Ch. 5).

All activities that cause pain should be avoided until symptoms have ceased.

Tenovaginitis

Tenovaginitis is primarily a lesion of the tendon sheath itself and is often associated with considerable swelling and tenderness but there is never crepitus. It may have a detectable cause in overuse but also occurs spontaneously. Non-specific types of tenovaginitis should be differentiated from those with a specific cause, such as bacterial infection, rheumatoid arthritis, gout and gonorrhoea.

Treatment

For the non-specific types of tenovaginitis, treatment is the introduction of a small amount of steroid between tendon and sheath, which brings quick relief. In persistent cases, deep transverse friction can be tried but incision of the tendon sheath is often necessary.

In specific tenovaginitis, treatment is that of the underlying disease.

Tendinosis

This is a degenerative condition of the tendon without accompanying inflammatory reactions and therefore often without clinical symptoms. The lesion is characterized by visible discolouring of the tissue and loss of the mirror-like gloss of the tendon surface and is typically described as 'mucoid degeneration'.[88]

Microscopically, tendinosis is characterized by a marked loss of collagen. The fibres show an irregular entangled course and an irregular waving pattern. Between the fibres, cavities filled with fluid loosen the tissue. The number of fibroblasts is decreased and their nuclei transformed.

Besides this local destruction, there are also signs of regeneration as shown by slight fibroblast proliferation, formation of capillary sprouts and new mesenchymal cells, which synthesize young collagen fibrils to fill up the tissue defect. If this process of granulation is insufficient, necrosis and calcification result.

Tendinosis and mucoid degeneration often lead to spontaneous ruptures (long head of the biceps, Achilles tendon). It is suggested that the 'typical' histopathological changes characterized by tendon degeneration may not necessarily be directly linked to increased nociception giving the patients warning signals; while in painful 'tendinitis' the mechanically weaker tendons may be protected from ruptures due to decreased impact levels since painful activities will be avoided.[89]

Complete rupture

Complete rupture of a tendon usually results from indirect trauma. It always seems to occur at the midsubstance of the tendon. Acute tears are those occurring suddenly, usually as a result of a single injury. Chronic tears are those that are insidious in onset and result from repetitive loading of a degenerated and weakened tendon (see above). Tendinous ruptures occur predominantly at the shoulder, wrist and heel. At the shoulder, the incidence of full thickness rotator cuff tears in cadaveric populations ranges from 30%[90] to 60%.[91]

Ruptures of Achilles and tibialis posterior tendons are also quite common. The special anatomical situations of the flexor and extensor tendons of thumb and fingers subject them to high loads which may alter their histological structure and finally rupture them.

Healing of a ruptured tendon depends on the capabilities of both the tendon itself as well as on reactions from the surrounding tissues. Some tendons such as the Achilles tendon have a remarkable ability to heal after rupture, whereas others do not. Rotator cuff tears for instance usually do not heal and, if they do, a permanent weakening results. Healing of a ruptured Achilles tendon does not differ from the general tissue reactions after mechanical damage: the initial stage of exudation is followed by vascular granulation and fibroblast proliferation. Collagen synthesis begins within the first week and reaches its maximum after about 4 weeks. It then continues for about 3 months. Maturation and remodelling begin at the end of the third week and continue for up to 1 year after the injury.

Mechanical strength of a healing tendon is related to the histological process of repair. During the second phase, strength increases but is still insufficient to prevent further stretching of the healing wound. For this reason, the region always has to be immobilized until the process of maturation has begun (about 3 weeks after injury). At that time the arrangement of collagen fibrils is not organized and remodelling depends entirely upon the presence of repetitive tensile forces applied to the scar tissue. Several studies support the concept that controlled cyclic passive loading of the healing tendon, performed after the initial healing phase (3 weeks) is effective in decreasing the formation of abnormal adhesions and increasing the tensile strength of the healing tissue.[92–94]

Local swelling of a tendon

This is not infrequently seen in the digital flexor tendons in the palm of the hand. When these swellings are localized at the level of the heads of the metacarpals, they engage and may become fixed in the distal part of the tendon sheath at the moment of flexion. Extension is often only possible with help. This symptom is known as 'trigger' finger or thumb.

Treatment

Infiltration of steroid, to influence the inflammatory component of the swelling, is sometimes effective. If this fails, surgical removal of the swollen tissue (scar and/or calcium deposits) or slitting of the narrowed part of the sheath is the alternative.

An overview of the localization and treatment of musculotendinous lesions is given in Figure 3.20.

Musculotendinous lesions	Localization	Treatment
	1 Tenoperiosteal	Infiltration with triamcinolone or deep friction
	2 Tendinous	Deep friction
	3 Musculotendinous	Deep friction
	4 Muscular	Infiltration with local anaesthetic Deep friction Active and electrical contraction
	5 Tenosynovitis	Infiltration with triamcinolone or deep friction
	6 Tenovaginitis	Infiltration (or deep friction)

Fig 3.20 • Localization and treatment of musculotendinous lesions.

Ligamentous lesions

Rationale for treatment of acute and chronic lesions

Treatment regimes remain the subject of controversy and range from a policy of no treatment through early mobilization and strapping to plaster immobilization. However, experimental studies of the past decades confirm the existing clinical feeling that sprained ligaments heal better and stronger under functional loading than they do during rest. The effects of loading on healing ligaments have been studied extensively and the available evidence indicates that the remodelling of the repair tissues responds extremely well to cyclic loading and motion.[95] Long-term studies in ankle sprains have shown better results when early mobilization is used.[96,97] Other prospective and randomized studies also show the best results with early functional treatment (see Cyriax[98] p. 8, Larsen[99] and Freeman[100]). Because late reconstruction of ruptured ligaments at the ankle still gives very good results,[101–103] there is no need for early surgical treatment and conservative treatment with early mobilization must always be tried first. At the knee joint, several studies have also demonstrated that the non-operative management of an isolated medial collateral ligament rupture gives results equally as good as surgical repair but with significantly quicker rehabilitation.[104–109]

In spite of these findings, most physicians and surgeons dealing with the management of ligamentous ruptures reason 'anatomically': if a rupture is suspected or proven radiologically, the medical approach must be to repair the defect as soon as possible. This is achieved by partial or total immobilization or by early suture – the same approach as is taken in fractures, where the separated pieces of bone are fixed in apposition. This anatomical way of thinking does not correspond to the functional reality of connective soft tissue lesions – the function of a ligament is in no way comparable with the function of a bone. Where bone must be strong and solid, a ligament must allow and control movements within certain limits. To serve that purpose, ligamentous tissue must be mobile enough to change its position continuously. The same properties apply to scar tissue, which must not only be strong to prevent excessive movement but must also be mobile enough to allow sufficient movement. If this principle is neglected and a scar becomes unduly adherent (e.g. to bone), continuous functional problems will result. Early mobilization prevents such adhesions within or around the healing structure. Tension during the state of collagen deposition aligns newly generated collagen fibrils in the direction of stress and also prevents the formation of crosslinks in a random pattern. Consequently, the scar is strong in the direction along which force is applied. Tension also prevents scar tissue becoming adherent to bone. Movement stimulates proteoglycan synthesis important in lubrication of connective tissue and maintaining the critical distance between pre-existing fibres.

It is most effective to start mobilization from the onset, before the newly generated fibrils develop crosslinks in an abnormal and irregular pattern. This may be effectively achieved by deep transverse friction and passive movements. However, the serious traumatic inflammation and the intense pain during the slightest movement are very strong impediments to early mobilization of connective tissues. In these circumstances, Cyriax advocated the infiltration of localized lesions with small amounts of triamcinolone as soon as the patient is seen. This shortens the acute phase of the inflammatory process and therefore encourages the patient to move the injured part at an early stage with all the associated beneficial effects. In diffuse lesions this approach is impractical, and deep transverse massage and passive movements are substituted, although exercise and movement have to be modified until pain has abated.

'Sprain' of a ligament is the result of excessive joint movement with lack of muscular control. The transitional zone between mineralized fibrocartilage and bone is the site of most separations between ligaments and bones.[11] However, sprain may also occur in the substance of a ligament. A good example of this is the medial collateral ligament at the knee, where tears are often situated in the midportion or just below the joint line adjacent to the tibia. Experiments with strength and failure characteristics of rat medial collateral ligaments[110] have shown that this especially results from a large load that is rapidly applied. The failure point is reached before significant elongation can take place. The same load applied more slowly results in failure at the transitional zone between mineralized fibrocartilage and bone, where the connective structure is weakest.

In accordance with the degree of the injury, ligamentous lesions can be divided into three grades:

- *Grade 1*: a slight overstretching with some micro-tears within the ligamentous structure
- *Grade 2*: a more severe sprain with partial rupture of the ligament
- *Grade 3*: the ligament is completely torn across or is avulsed from the bony attachment.

This classification is rather arbitrary and, although it might be possible to distinguish a small lesion from a total separation, the difference between grades 1 and 2 is always subjective.

Ligamentous lesions can also be classified according to the time that has elapsed since the causative accident:

- *Acute*: within 48 hours
- *Subacute*: 48 hours to 6 weeks
- *Chronic*: more than 6 weeks.

This classification is of importance in relation to treatment.

Sprains with incomplete ligament rupture are often quite painful and accompanied by muscle spasm and pseudolocking. This makes clinical examination difficult, and diazepam or general anaesthesia may be needed to complete a thorough examination.

In complete tears there is rarely pain of a significant degree and in knee and ankle sprain the patient can often walk without aid. It is a fear of 'giving way' that characterizes the lesion and prevents the patient from doing more strenuous activities such as going up or down stairs, jumping or doing full squats.

Clinical evaluation of an acutely injured joint should be carried out as soon as possible – within a few hours of the accident – otherwise pain, swelling and muscle spasm will often make it impossible to perform proper ligamentous tests. This is particularly necessary in first and second degree lesions, in which these symptoms are so evident. History and knowledge of the mechanism of the injury are important aids in diagnosis and point to the injured ligament(s). Tenderness and localized oedema indicate the anatomical site of the tear in most instances.

Treatment

Minor ligament sprain should be treated conservatively. Ligaments will heal but it is essential not to strain them again during the first part of the granulation stage. For example, after damage to the medial collateral ligament of the knee joint, full extension should be prevented during the first 10 days.

In the acute stage, traumatic reactions such as pain and swelling should be kept to a minimum. Therefore, early application of compression and an elevated position of the extremity are most important.

In a sprained ligament of the knee or ankle, crutches should be used if movement is necessary. The next day, physiotherapy is started. Effleurage diminishes swelling and pain, which are impediments to movement. Thereafter transverse friction is performed to move the damaged tissue to and fro over the subjacent bone in imitation of its normal behaviour. This prevents the random orientation of newly generated fibrils and formation of abnormal crosslinks between newly regenerated fibrils and pre-existing collagen fibres. In this acute stage, really deep transverse friction will take no more than 1 minute since there is no question of breaking down strong scars. However, it should still be as gentle as is compatible with securing adequate movement of the damaged tissue. Then the joint is moved passively through its greatest possible range without causing pain. The same movement(s) is repeated actively. There should be no attempt to increase this range in the acute or subacute stage. In a sprained joint of the lower limb, instruction on gait follows. Strapping the joint to protect it from unwanted movements is a useful additional measure, especially if the patient seems anxious. Patients treated along these lines recover most rapidly.

An infiltration with a small amount of steroid at the site of the lesion is an alternative. The injection should be given during the first 48 hours – the initial and exudation stage. It reduces traumatic inflammation and prevents most structural and reflex changes. Pain also disappears, which enables the patient to move the joint in a normal way. Deep transverse friction then loses its efficacy.

Steroid injections during granulation and repair may lead to fewer fibroblasts, a diminished collagen fibre formation and a weaker scar.[111] However, these effects are not seen after a single injection during the acute, inflammation stage.[112]

Overstretching a ligament often leads to permanent laxity with consequent instability of the joint. Cyriax emphasized the propensity of ligaments not controlled by muscles to develop such permanent laxity and cited the sternoclavicular, acromioclavicular, sacroiliac and sacrococcygeal ligaments, the symphysis pubis, the cruciate ligaments at the knee and the inferior tibiofibular ligaments as examples.[75] After trauma, reflex muscle spasm is not capable of stabilizing these joints. In intracapsular ligaments (e.g. the cruciate ligaments), unsuccessful repair may also result from the synovial environment, limited fibroblast migration and reduced vascular ingrowth.

The subsequent traumatic inflammation can be reduced by the means already described. To prevent laxity, it is a principle of treatment to completely avoid movements which can be achieved by immobilization of the joint or by surgical repair. Such measures are best executed within 7 days.

After recovery, minor laxity is compatible with excellent function, whereas painful chronic laxity becomes painless in due course or can be converted into painless laxity by use of a local steroid infiltration.

In joints controlled by muscles, permanent laxity is much less likely to occur. Reflex muscle spasm efficiently stabilizes the joint. Grade I and II lesions treated on the lines set out will heal adequately. The results of conservative treatment in grade III lesions are also successful in almost all cases but it is essential that the lesion is isolated.[106,113] It is then advisable to immobilize the joint partially so as to prevent any unwanted movement taking place during recovery. Lasting instability in these joints can be more or less compensated for by tautness of the muscles and tendons passing over the joint. Strength-building exercises are of great importance and must be on an exact and planned basis. If necessary, strapping or braces may provide added support.

In surgical repair, dense fibrous tissue is used to reconstruct the ligament – the fascia lata, part of the patellar tendon on other tendons. Following transplantation a graft heals to the recipient tissues but never approaches the strength it had before transplantation. Nevertheless grafts can significantly improve the stability of joints.

Capsular lesions

Traumatic arthritis, capsulitis or synovitis all have an identical meaning: inflammation of the entire capsule as a result of a more or less recent trauma. This is invisible on X-ray and therefore this investigation cannot exclude the diagnosis. If trauma has damaged the lymph and vascular network in the

subintima, the integrity of the synovial membrane and therefore its cellular function will be severely disturbed. Increased permeability of small venules allows plasma to leak through and effusion results. Intra-articular swelling increases tension within the capsule and further irritates various sensory receptors. Pain and reflex inhibition of muscles result which can further affect the joint.

If the patient states that the joint suddenly became very painful and swollen over a few minutes, haemarthrosis is suspected. The speed of appearance of the effusion and the severe pain by far exceed that caused by clear fluid. Palpation of the joint also shows it to be hot and more tense than if the effusion is clear. Blood in the joint is a strong irritant and has an erosive action on the cartilage. It must be aspirated at once, after which the remaining blood-tinged synovial effusion is removed a few days later.

After injury, joints supported by muscles soon develop limitation of movement with a capsular pattern (see Ch. 4). In recent arthritis such limitation results from defensive muscle action which is reflexive and controls movements that could further irritate the capsule. Muscles spring into action, which can be felt (*hard end-feel*) and seen on gently forcing a particular movement.

In the chronic stage, inflammation is maintained by the effects of cartilagenous debris, blood elements and enzymes from destroyed cells which activate cells of the synovial membrane to produce excessive fluid of inferior quality containing hyaluronic acid molecules that are decreased in size and concentration. Friction resistance between joint surfaces is consequently increased and inhibition of excessive collagen proliferation reduced. Contraction of the capsule occurs and restricts movements, in the capsular pattern. In the absence of muscle spasm, end-feel then becomes rather hard, resembling leather being stretched.

In joints without muscles surrounding them to control movements, no limitation of movement can result, however severe the arthritis. Muscle spasm cannot occur and there is pain at the extremes of range only.

Table 3.4 Symptoms, signs and indications for therapy in traumatic capsulitis

Inflammation stage	Symptoms and signs	Therapy
Active	Constant pain Wide reference of pain Inability to bear weight on the joint Local warmth Spastic end-feel	Intra-articular steroid suspension Alternative technique: Slight distraction techniques
Chronic	No pain except on forced movement Little reference of pain Ability to bear weight on the joint Elastic capsular end-feel Resistance to passive movements is perceived before appreciable pain is evoked	Capsular stretching

Box 3.2

Contraindications of forced movements in traumatic arthritis of peripheral joints

- Elbow joint
- Hip joint
- Interphalangeal and metacarpophalangeal joints
- Lower radioulnar joint
- Acromioclavicular joint
- Sternoclavicular joint
- Sacroiliac joint

Treatment (Table 3.4)

Movements retain mobility at a joint. They have the effect of keeping a joint structure normal.[98]

In recent trauma, pain limits active movement and it is essential, particularly in middle-aged and elderly people, in whom posttraumatic adhesions are apt to form, to restore a full range of movement as soon as possible. Gentle assisted active and passive movement increases vascular supply, removes cartilagenous debris, resorbs oedema or joint effusion more quickly, aids in the transport of nutrients and metabolites to and from cartilage cells, and prevents the formation of adhesions and capsular contraction. Movements should be performed to the point of discomfort but not of pain. All possible directions of movement should be attempted, one by one, and a small but definite increase in range of movement should be achieved each day. If this fails, intra-articular corticosteroid injections are indicated.

In the chronic stage, stretching out the capsule requires many repetitions of a long steady push, maintained as long as the patient can bear it – e.g. 1 minute. Dense capsular adhesions finally yield but no increase in range of movement can be expected after the first few sessions. During the period when progress is slow, therapist and patient must show forbearance and persistence, respectively. Short-wave diathermy given for 15 minutes before mobilization diminishes the pain of capsular stretching.

Symptoms and signs of activity may contraindicate forced movements. Spontaneous pain, especially at night, wide reference of pain and inability to bear weight upon the affected joint all indicate that the lesion is in an active stage and that forced movements will increase the problem. Local warmth, effusion and muscle spasm are signs accompanying such an event and are indications for an injection of a steroid suspension. If the patient refuses, slight distraction techniques in the neutral position of the joint are an alternative. The therapist coaxes painless distraction of minimal amplitude, intermittently and with slight irregularity in depth and timing. Performed daily for the first week and on alternate days for the next week(s), pain abates and range increases slowly, although not in all cases of traumatic inflammation.

Forced movements should not be done in traumatic arthritis of the following peripheral joints (see also Box 3.2):

Table 3.5 Treatment of ligamentous lesions

Phase	Treatment (1)	Treatment (2)
Acute phase		
Joints controlled by muscles		
First day	Compression Elevation	Alternative (within 48 hours) Steroid infiltration
Following days	Effleurage + Deep transverse massage Controlled movements (active and passive) Gait instruction	Controlled movements (active and passive) Gait instruction
Joints not controlled by muscles	Deep transverse massage Immobilization	Infiltration (steroid or sclerosant) Immobilization
Chronic phase		
Adhesive scar formation	Deep transverse friction + Manipulation	(Steroid infiltration)
Lasting instability	Strength-building exercises Proprioceptive training	Surgical reconstruction (Infiltration with sclerosant)

- *Elbow*: passive mobilization for recent posttraumatic stiffness is apt to diminish rather than increase the range of movement; moreover, it is contraindicated because of the ever-present danger of setting up myositis ossificans. An intra-articular injection with corticosteroid suspension is indicated and will give quick recovery
- *Hip*: traumatic arthritis is best treated by rest in bed
- *Interphalangeal and metacarpophalangeal joints of the hand and foot*: these joints respond badly to forced movements. Joints of the toes can be injected with corticosteroid suspension
- *Lower radioulnar joint*: aggravation of symptoms can be expected even with active exercises.
- *Joints not under voluntary control*: after an injury the formation of adhesions is not to be expected. Forced movements are useless and harmful. Rest, support and corticosteroid injections are then good alternatives.

Treatment of acute and chronic ligamentous lesions is summarized in Table 3.5.

Diagnostic difficulties 80

Introduction

The major part of this book is about making a clinical diagnosis: a system of clinical reasoning leading to a proper diagnosis. The final stage of the diagnostic procedure is the precise anatomical description of the lesion, for example: supraspinatus tendinitis at the superficial aspect of the tenoperiosteal junction, chronic subdeltoid bursitis, lesion at the origin of the extensor carpi radialis brevis muscle, periostitis at the anteroinferior surface of the fibula, annular disc protrusion at the L4–L5 level irritating the fifth lumbar nerve root.

During the last decades, new technology has revolutionized diagnosis and decision making in orthopaedic medicine. Previously, soft tissue lesions were characterised by a lack of objective findings. This has changed dramatically since the arrival of sonography, computed tomography and magnetic resonance imaging (MRI). These new techniques can demonstrate anatomical changes in soft tissues and therefore contribute significantly to the understanding of non-osseous orthopaedic lesions. However, they do not make clinical assessment redundant. Contrary to popular belief, diagnosis is not made by only looking at the result of a technical investigation. In the best case, an anatomical picture may be the ultimate confirmation of the clinical diagnosis. If imaging is undertaken too early during the diagnostic process it will create more problems and questions than it resolves, and often puts the examiner on the wrong track and leads to wrong therapeutic decisions.

First of all, not every detected anatomical lesion causes pain or dysfunction. Asymptomatic lesions do exist and are present in numbers that are much larger than previously assumed: asymptomatic herniations in cervical, thoracic and lumbar spine are present in up to 50% of the population.[1,2,3] Also the high prevalence of rotator cuff tears in elderly asymptomatic individuals is very well known.[4,5] It is estimated that in the general population, approximately two-thirds of all rotator cuff tears are asymptomatic.[6,7] Large numbers of asymptomatic lesions have also been demonstrated in the knee. A recent MRI study on asymptomatic soccer players demonstrated one or more MRI abnormalities in no less than 64%. Another study with MRI scans performed on the knees of asymptomatic male professional basketball players demonstrated an overall prevalence of articular cartilage lesions of 47.5%[8] and meniscal lesions of 20%.[9]

Another shortcoming of technical investigations is that they only detect an anatomical lesion (defect, swelling or other structural changes) and not the functional deficiency (weakness, limitation, laxity). In other words, the behaviour of the tissue during activity is not assessed.

© Copyright 2013 Elsevier, Ltd. All rights reserved.

For all these reasons, there is no place for high-tech visualization techniques in the beginning of the diagnostic process and they should never be used as screening tests. A biased examiner who is looking for a particular lesion will often find that lesion, whether it is responsible for the complaints or not. Too many and too early technical investigations substantially increase the cost of medical care but do not give a better outcome. On the contrary, in the hands of an unprofessional doctor, high-tech investigations are potentially dangerous as they may lead to major, unwanted and unnecessary surgery.

Principles of diagnostic procedure in orthopaedic medicine

Clinical examination is all about behaviour of the tissues involved. The examiner must have a very good knowledge of the behaviour of the lesions that he is dealing with and of the behaviour of the normal tissue. Tissue behaviour is described by the patient during the inquiry and checked by the examiner during the functional examination. Looking for tissue behaviour, the following general principles are important.

1. Look for 'inherent likelihoods'

Some things are likely to happen

Soft tissue lesions behave in a very typical way and the examiner will therefore regularly be faced with the same history and the same response to functional testing. The symptoms and signs are closely related to the lesion present. The examiner should therefore try to recognize 'inherent likelihoods', a term defined as *the sequence of symptoms and/or signs that belong to the clinical picture of a certain pathological disorder and that are likely to be found, more or less in a sequence which is typical for that disorder*.

For example: in the history, a patient with lumbar pain may mention that on some days the pain spreads down the lower limb; tennis elbow is characterized by sudden twinges when objects are picked up; and in lumbar disc lesions pain may shift from one side to the other.

Functional examination can also show some inherent likelihoods. When resisted extension of the wrist hurts at the elbow, a tennis elbow is suspect and can be confirmed by positive responses to resisted extension of the wrist with the fingers held actively flexed and to resisted radial deviation of the wrist. In tendinitis at the radial insertion of the brachial biceps, apart from pain on resisted flexion and supination of the elbow, full passive pronation is also painful. In L5 sciatica, pins and needles in the medial three toes may be accompanied by numbness in the same area and by weakness of the extensor hallucis longus and peroneal muscles.

The examiner who has a knowledge of what is likely to happen should recognize this and compare the pattern to the 'unlikelihoods' presented by some patients, which indicate either a non-organic lesion, a somatic but non-orthopaedic problem or an unusual lesion. These inherent probabilities can of course only be recognized if the clinical examination is performed thoroughly.

2. Look for objective physical signs

Examination of the moving parts is an exercise in applied anatomy

The examination should include questioning (history taking) and testing which provokes or elicits symptoms and/or signs that can be assessed, judged and interpreted as objectively as possible.

The soft tissues of the locomotor system have the advantage that their functional anatomy is well known. It is clear how joints behave, how capsules and ligaments guide and limit movements, how muscles function and what movements they provoke.

Therefore, examination of the moving parts is an exercise in applied anatomy. Each tissue or group of tissues in turn must be tested and the answer interpreted in the light of the anatomical possibilities.

3. Avoid palpation as much as possible

The function of the different tissues is known

Although *palpation* is very often used as a diagnostic procedure, it is unreliable for several reasons:

- Some regions in the body are always tender to touch (e.g. lesser tuberosity at the shoulder, lateral epicondyle at the elbow, border of the trapezius muscle).
- Some structures lie too deeply and cannot be reached by the palpating finger (e.g. capsule of the hip joint, cruciate ligaments at the knee).
- The painful area does not always correspond to the site of the lesion (referred pain) and referred dural tenderness is sometimes present.
- Some patients with altered perception or desire to deceive the examiner may produce misleading responses.

It is easy to understand that, in these circumstances, palpation offers no help at all or, even worse, may misdirect the examiner.

Diagnosis, therefore, rests largely on the correlation of a series of semi-subjective data, obtained from a proper *functional examination* – an indirect approach. By assessing the function of each tissue in turn and interpreting the signs in the light of the anatomical knowledge, the examiner should be able to come to a correct description of the lesion.

The patient is asked to answer some very precise questions. A patient with an organic lesion exactly describes what is felt and gives the examiner a fairly precise clinical picture. The neurotic or malingering patient will feel the need to embellish so as to give a colourful description of suffering rather than of the symptoms.

4. Functional testing: the principle of 'selective tension'

The soft tissues can be put under tension

The different tissues of the moving parts can be subjected to strain which may increase the pain and tests are used to elicit or influence the patient's symptoms.

The possibility of making a diagnosis by selective tension depends largely on the characteristics of each tissue and on its capacity either to contract or to become stretched.

Muscles and tendons may be stressed by isometric contraction of the muscle or by passive stretching in the opposite direction. By contrast, ligaments and joint capsules can be put under tension by passive stretch.

If a certain test is positive, in that it provokes the symptom for which the patient consults, it establishes the relationship between the structure that becomes stretched, squeezed or contracted and the lesion.

It is important to try to use movements that put tension on one structure only, so that interpretation is as simple as possible. If a movement tests more than one tissue, accessory tests or palpation may be required to obtain further information that can differentiate between potential causes. For example, when testing the lateral ligaments at the ankle, a combined movement of passive plantar flexion and inversion is performed. If this is positive and, later in the examination, passive internal rotation at the mid-tarsal joints is negative, involvement of the calcaneocuboid ligament is excluded. In examination of the shoulder, painful resisted flexion of the elbow incriminates either the biceps or brachialis muscle; if resisted supination of the elbow is also positive, the lesion lies in the biceps muscle.

5. Use physiological movements as much as possible

Normal movements may become disturbed

This approach has some advantages:

- The structures that participate in the movement are well known (applied anatomy).
- The movements are easily controllable and reproducible. Pain may be provoked, but also limitation can be seen and weakness is not difficult to detect. The inter- and intra-tester reliability is quite high.[10–15]
- Patterns can be found: pain patterns, patterns of limitation and patterns of weakness. The recognition of a known pattern confirms the symptoms and signs presented.[16]

6. Distinguish between inert and contractile tissues

Soft tissues are either inert or contractile

This distinction is one of the pillars on which the whole system of orthopaedic medicine rests. The soft tissues of the locomotor system can be divided on the one hand into tissues that can contract (the contractile structures) and on the other hand, tissues that do not possess this capacity (the non-contractile or inert structures) (Box 4.1).

Contractile structure

The complex of muscle origin, muscle belly, musculotendinous junction, body of tendon, tenoperiosteal junction and also the bone adjacent to the attachment of the tendon are considered clinically as contractile (Fig. 4.1).

Box 4.1

Inert and contractile tissues

Inert tissues	Contractile tissues
• Joint capsules • Ligaments • Bursae • Aponeuroses • Dura mater • Dural sleeve of the nerve root • Peripheral nerves	The complex of: • Muscle–bone attachment (origin) • Muscle belly • Musculotendinous junction • Body of tendon • Tenoperiosteal junction (insertion) • The bone adjacent to the attachment of the tendon

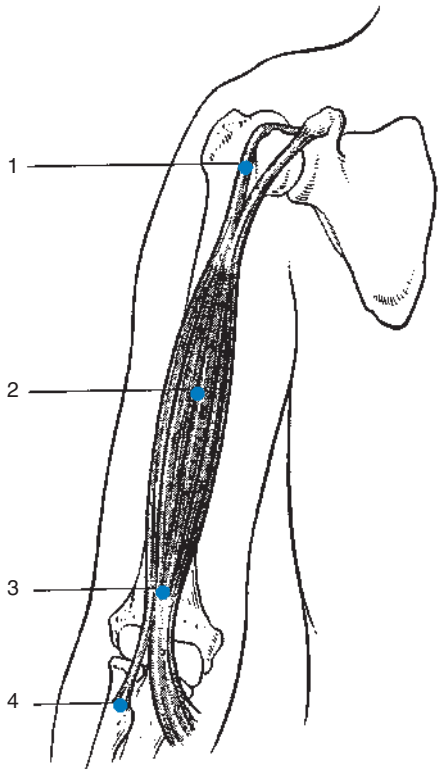

Fig 4.1 • Contractile structures – the musculotendinous unit: 1, tendon; 2, muscle belly; 3, musculotendinous junction; 4, insertion.

The only worthwhile method of testing these structures is by maximal contraction against resistance. The movement should be performed isometrically so that the applied tension, which causes pain, falls only on the muscle and the structures attached to it.

Passive movement in the opposite direction, which stretches the contractile tissue, can also elicit the pain but cannot be used as a specific test for it because non-contractile tissues are also stretched. For example, a lesion in the subscapularis tendon at the shoulder gives rise to pain on resisted internal rotation. Full passive external rotation may also hurt. This sign fits the clinical picture of subscapularis tendinitis but has neither diagnostic nor localizing value because the passive

movement also stretches the anterior joint capsule and the pectoralis major muscle and tendon.

However, a pain elicited by resisted movement does not invariably mean that a contractile tissue is at fault. If the bone close to the tendinous insertion is affected (fracture or other bony disorder), pain is evoked by the pull of the muscle. A contraction may also squeeze an underlying structure such as a lymphatic gland or bursa. When such tissues are inflamed, squeezing may evoke pain. The same applies when there is a disorder adjacent to muscles, for example an abscess. This explains why, for example, contraction of the sternocleidomastoid muscle may be painful in glandular fever and why contraction of the gluteal muscles can hurt in a trochanteric bursitis.

Inert structure

An inert structure does not possess an inherent capacity to contract and relax and can thus be tested only by passive stretching or squeezing. The inert tissues are shown in Box 4.1.

Active movements may also stretch or squeeze an inert structure but, because they also activate the contractile tissues, interpretation is subject to ambiguity and they cannot be used to test inert structures. For example, during active elevation of the arm, many muscles are in action (deltoid, supraspinatus, serratus anterior, trapezius). At the same time, certain parts of the joint capsule and some ligaments are stretched (acromioclavicular, sternoclavicular, conoid and trapezoid ligaments) and other structures are compressed (subacromial bursa, inferior acromioclavicular ligament, tendinous insertions of supraspinatus, infraspinatus, subscapularis and biceps).

7. Concentrate on 'the' pain

'The' pain is that pain for which the patient consults

When tests evoke pain, the examiner must make sure that this is the pain that is the patient's complaint. It is possible that some movements elicit pain in a certain area and that other tests provoke another pain in another region: one of these will be recognized by the patient as the presenting symptom. The examiner should then concentrate on this pain alone.

The situation often occurs because combined lesions are quite common. A patient may come to see the doctor with pain down the arm. If, after the history has been taken, it is not clear whether the pain originates either from the cervical spine or shoulder girdle or from the shoulder itself, the preliminary examination aims to clarify the situation. It may show some discomfort at the base of the neck when cervical movements are tested (especially in middle-aged and elderly people) but if only shoulder movements elicit the pain complained of, then this pain ('the' pain) is the primary problem; the other pain ('a' pain) is secondary. The arm pain will, of course, be dealt with first and only when this problem is solved is the other problem (if still present) approached.

Difficulties may arise in hypersensitive patients who report every tension they experience and for which they use different words: 'it hurts, it aches, it pulls, it stretches, …'.

8. The patient's cooperation is vital

The patient knows the symptoms

The patient's cooperation is essential, and it is vital that the questions put are understood. Details are sought on what activities have an influence on the symptoms and how symptoms behave over time. Except in psychologically disturbed patients, the more precise the questioning, the easier it is to obtain accurate answers. The patient must realize that, during functional examination, the examiner is looking for tests or movements that *elicit* symptoms. Most difficulties arise with those who are in constant pain, in that they tend to answer every question positively. It is the task of the examiner to explain carefully that movements that *alter* the pain are being sought. Not only tests that make the pain worse (a frequent occurrence) but also those that decrease the pain are considered important.

9. Take into account the patient's personality

The patient is a person

The history in particular will give an idea about the patient's personality. The reaction to pain can be assessed and a picture built up of the extent of disability. The findings can then be related to what is actually found when the examination takes place.

The view obtained from the history and physical examination may have therapeutic significance: for example, most patients can cope with active treatment such as manipulation or deep transverse massage but the clinician may obtain a 'perception' for those who cannot.

10. Keep the balance between credulity and excessive scepticism

Objectivity is a fair attitude

Orthopaedic medical disorders produce symptoms and signs that may be difficult to analyse objectively. Patients who have a reason to assume disorders for some type of personal gain, therefore, commonly use clinical features in the locomotor system to try to establish their credibility (see online chapter *Psychogenic pain*).

Although the examiner must be on guard against feigned illness, great care must also be taken to maintain a dispassionate attitude during the clinical encounter. The diagnosis of 'psychogenic pain' must not be made too quickly. Only when many inherent unlikelihoods are encountered during the history and functional examination should the examiner be suspicious about the veracity of the patient's story. Also, the discovery of a series of lesions is self-contradictory, because the development of several problems at the same time is most unlikely.

11. Request technical investigations only when necessary

Looking is not a substitute for thinking

Clinical testing is the first approach in orthopaedic medicine. Technical investigations, although sometimes very valuable, are only asked for in some situations:

- To exclude major lesions for which the functional testing has not been sufficient.
- To exclude contra-indications for some therapeutical actions (manipulations or infiltrations).
- To confirm the tentative diagnosis made after the clinical examination.

Warning

Incorporated into this system of clinical evaluation are *warning signs*: certain symptoms or combination of symptoms and signs indicate that something unprecedented is taking place and so alert the examiner to the possible presence of a potentially serious condition. Possible warning signs are, for example, pain in the upper lumbar area, deficit of more than one nerve root in the cervical spine, or a capsular pattern of the hip in children.

The presence of such warning signs will put the examiner on guard and indicate accessory clinical tests, further technical investigations or reference to a neurologist, an internist, a cardiologist or an oncologist.

These warning signs will be discussed further in later chapters.

Clinical evaluation

History

History is of prime importance in reaching a diagnosis. It is so well known as a method of determining symptoms that most examiners fail to realize how much information can be gained from it.

Patients are the best source of information in that they are suffering from the lesion and can best report precisely what is felt. It is then the examiner's task to translate the subjective *symptoms* into anatomical and functional conclusions.

Cyriax said: 'Every patient contains a truth. He will proffer the data on which diagnosis rests. The doctor must adopt a conscious humility, not towards the patient, but towards the truth concealed within the patient, if his interpretations are regularly to prove correct'.[17]

History taking is a slow business that requires time, patience and concentration; the examiner must do everything possible to gain the maximal detailed information. Vague, general description of the complaints should not be accepted but precise and detailed answers sought.

Most patients, and certainly when they are frank, are able to provide precise answers to the examiner's questions or can spontaneously give a well-structured, detailed and chronological account. They try to be as helpful as possible and are visibly pleased to talk to an interested physician. However, taking the history becomes more difficult in those who cannot express themselves or give a disjointed story. It is the examiner's task then to make sure that the right questions are asked in order to get useful answers. The same applies to talkative patients who try to be too helpful by adding all manner of irrelevant details. In these circumstances the examiner should concentrate on the important items only and bring the patient back to the point whenever there is a digression.

Patients with a clinical presentation that may rest in non-organic causes try to escape from precise questioning. They offer a garbled story full of internal contradictions.

Remarks

Questions should be asked in such a way that the account of the symptoms is given in *chronological order* which enables the examiner to get an idea of the duration and behaviour of the condition present. Knowledge of different dermatomes and of the possible likelihoods will help in interpretation of the evolution of the patient's symptoms.

Leading questions should be avoided, because they suggest to the patient what answer is expected. *The questions should be neutral*, so that the patient has to think about what is felt. An honest patient will have no problems in giving exact answers; one who dissembles has the opportunity to make mistakes and display inconsistencies.

Examples of questions that should be recast are as follows:

- Not: does the pain spread down your leg?
  - But: does the pain spread at all?
    If so, where to?
- Not: is it painful to cough?
  - But: what happens when you cough?
- Not: is it painful to bend forwards?
  - But: does anything bring the pain on?
- Not: do you feel pins and needles in your hand?
  - But: have you got any pins and needles?
    And if so, where?

When there is a *relationship between the patient's symptoms and rest, exertion, certain activities or certain postures*, then it is probable that the patient suffers from a lesion of the locomotor system. The main exceptions are angina and intermittent claudication. Questions should therefore be asked about the movements and positions that evoke, increase or influence symptoms, for example:

- What brings the symptoms on?
- What makes the symptoms disappear?

Some information can be obtained only from the history, and not from any other diagnostic procedure. For example, to ascertain the stage of shoulder arthritis, to find out whether a displaced fragment of cartilage is stable or unstable, to determine whether sciatica is caused by a primary or secondary posterolateral disc protrusion, depends on the answers to some very specific questions. These are not only diagnostically important but also have a prognostic value and can determine correct treatment.

For lesions of the knee or spine, the history is of extreme importance; the examiner must go into great detail and if this is done the diagnosis becomes apparent. For example, a patient may mention that pain started in the centre of the back, soon spreading unilaterally towards the buttock, and later radiating down the lower limb into the lateral border of the foot and the two little toes while at the same time pain in the back and buttock disappeared. After a while pins and needles began to

occur in the same toes and additionally they would go numb. The patient has revealed everything: the normal evolution of a protruded fragment of disc at the L5–S1 level, compressing the first sacral nerve root, is immediately apparent.

In some other joints, such as the shoulder, the history matters less but examination will disclose the lesion.

Taking the history

Age, sex, profession, hobbies and sports

Some disorders are confined to certain age groups so that the age of the patient may indicate diagnostic possibilities. For example, a patient of 14 who mentions internal derangement at the knee probably suffers from osteochondritis dissecans. The same story in a patient of 20 suggests a meniscal problem and at 60 years points to a loose body in an arthrotic joint. The same applies to the hip: trouble at the age of 5 is probably due to Perthes' disease; at 15 it could be the result of a slipped epiphysis; at 30 ankylosing spondylitis is a possibility; and at 50 arthrosis is more likely. A similar age distinction applies in root pain of cervical origin: under the age of 35 it is extremely rare that this is caused by a disc protrusion.

Certain disorders are more typical for men (e.g. primary sciatica and ankylosing spondylitis) and others occur more often in women (e.g. de Quervain's disease and the first rib, thoracic outlet syndrome).

The profession of the patient may sometimes give an idea about the causative strains that have acted on the affected joint. Also it may – in conjunction with hobbies or sports – have an influence on the decisions to be taken on treatment. Treatment for acute lumbago will be different in an employee who sits most of the day than in a docker who has to do heavy work; a patient with regular attacks of sudden backache will be advised against tennis, a sport full of quick movements.

Initial symptoms

The examiner should get an accurate picture of *the moment the symptoms first appeared*. The patient should be encouraged to recall that period and questions should proceed from that first instant.

The *onset* of the symptoms has to be clear. If they came on after an *injury*, a very detailed description of the accident should be elicited. The events immediately following the accident must be ascertained, in that compensation may be claimed because of inadequate or inappropriate management. The subsequent condition of the joint may not allow complete examination and therefore an idea of the direction of the forces acting on that joint and the position in which the joint was held at the moment of the accident are essential and will give a notion of the possible structures affected. The knee is an important example. In a 'sprained' knee the inflammatory reaction that follows the accident is so spectacular (swelling, limitation of movement) that proper functional testing becomes difficult, which means that in the acute phase the examiner has to rely mainly on the history to get an idea of what has happened. If the pain is felt at the medial aspect of the joint and the patient mentions a valgus injury, the medial collateral ligament or the medial meniscus are most likely to have been damaged.

Swelling of a joint after an injury may have come on immediately, in which case blood is the cause, or after a few hours, which is typically the result of a reactive effusion.

When the patient mentions a *spontaneous onset*, this may be either sudden or gradual. Apart from diagnosis this distinction may have therapeutic consequences. Backache, as the result of disc protrusion, that comes on suddenly is annular and requires manipulation, whereas a gradual onset suggests nuclear displacement, which is treated with traction.

The patient must exactly define the *first localization* of the symptoms. The area where the pain was first felt very often lies quite close to the site of lesion, referred pain usually coming on later. This does not apply to 'pins and needles'. They are mostly felt distally in the limb, from wherever along its length the nerve is affected.

Questions are also asked about *what influenced* the symptoms. The examiner looks for a relationship between activities, movements or posture and the symptoms.

Progression/evolution

The symptoms may be present without interruption from their onset. However, it is also possible that the patient describes a recurrence (see Box 4.2).

The progression of symptoms since their first onset is ascertained. The condition may have continued *uninterrupted*, in which case details are asked about the development of the severity of the symptoms and of the localization of pain. If the latter has remained *unchanged* from the beginning, this indicates that the lesion is quite stable and not evolving. When pain has *diminished* it usually indicates an improvement, although there are conditions (e.g. nerve root atrophy and certain cases of mononeuritis), in which the pain disappears long before the condition has resolved. Pain becomes *worse* as the condition progresses: in such circumstances it is important to know the length of time for which it has been present. This has diagnostic significance: it is clear that conditions such as metastases have quite a short time course. In contrast, slowly worsening pain is characteristic of some other conditions such as a neurofibroma. When the patient describes *intermittent* pain, details are sought about the occasions on which pain is

Box 4.2

Evolution of symptoms

- Uninterrupted
  - Unchanged
  - Diminished
  - Worsening
  - Intermittent
- Recurrent

felt. Nocturnal pain, for example, suggests an inflammatory condition.

A very important distinction should be made between the following definitions.

Reference of pain

Referred pain is a very typical feature in non-osseus lesions of the locomotor system. It is mostly segmental and thus experienced in a single dermatome, which indicates the segment in which the lesion should be sought. Reference of pain is influenced by the severity of the lesion: the more severe it becomes, so giving rise to a stronger stimulus, the further distally does the pain (usually) spread. The reverse also holds: reduction in the distal distribution is synonymous with improvement.[18,19]

It is therefore always important not to forget the question: 'Where was the pain originally and where has it spread since?'

Shifting pain

Pain coming on in one place as it leaves another indicates a *shifting lesion*.

This extremely significant phenomenon is well known in internal medicine: for example, when a renal calculus moves from the kidney down the ureter to the bladder and urethra, the pain experienced will follow the displacement. Pain is felt in the loin first, then in the iliac fossa, later in the groin and finally in the genitals. When the pain leaves one point, it is felt in another *instead*.

The same happens in soft tissue lesions. A good example is central backache, which becomes unilateral, then later on shifts to the buttock and finally to the lower limb – *the backache has become sciatica*. This shift can only be explained as follows: a structure lying in the midline and originally compressing the dura mater (backache) has shifted to one side and now compresses the dural sleeve of the nerve root (root pain). To be able to shift, that structure has to lie in a cavity and, because the pain was originally central, this has to be a central cavity. The only structure lying in a central cavity and able to change its position is the intervertebral disc: there is no other possibility (Fig. 4.2).

The same situation is encountered when a loose fragment of cartilage moves within a peripheral joint as, for example, often happens in the knee. Dependent on the position of the loose body in the joint space, the pain can be felt at the inner aspect, anteriorly or posteriorly and on other occasions even at the lateral side. Such moving pain indicates a moving lesion.

Expanding pain

This is synonymous with an *expanding lesion* – one that grows, for example a tumour. When it appears in another region the pain does not leave the area where it originated. It spreads, even beyond the boundaries of dermatomes. A patient may describe a pain that begins in the centre of the back and then becomes bilateral. It spreads to one buttock, and later to both, also increasing in the back. Later it spreads to one leg and even subsequently to both, while still becoming worse in the back as well as in the lower limbs. Such a course is one of expanding pain, as the lesion becomes more extensive.

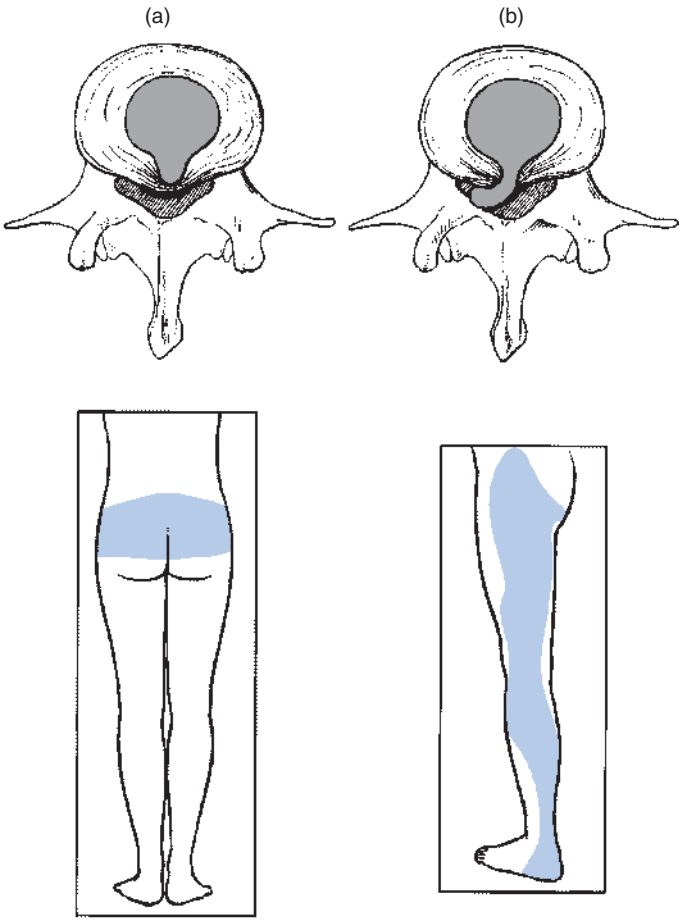

Fig 4.2 • Shifting pain: posterocentral disc protrusion causing central backache (a); shifts to posterolateral position causing unilateral sciatica (b).

Warning

An expanding pain, in which pain spreads but does *not* regress at the original site (in the way that a shifting pain does), is indicative of an expanding lesion and is usually the manifestation of a serious condition.

Another course is *recurrence*. Certain disorders, such as those causing internal derangement or of rheumatoid type, have a recurrent character. Some occur suddenly, others more gradually. If the symptoms occur intermittently, it is important to know whether the patient is or is not free of pain between attacks, because this has both prognostic and therapeutic consequences. Freedom from symptoms for a certain period of time suggests that the same may happen again. In internal derangement, regular recurrence implies that the loose fragment of cartilage or bone is unstable, in which case the maintenance of reduction will be the main concern of the therapist. A patient who is doing heavy work and who gets lumbago every 2 years must be regarded as having a stable lumbar disc which is completely different from a man with a light job who gets

Box 4.3

Pain

- Description
- Character: mechanical
  inflammatory

• During loading	• Morning stiffness
• Worse at evening	
• Moving in bed	

lumbago three times a year. In the first case reduction suffices, whereas the second will need other prophylactic measures to maintain the disc in place.

The onset of pain may vary from one attack to another. Backache that starts suddenly on some occasions, but gradually on others, very strongly suggests discal trouble. The localization of the pain may also change from one attack to another: it may be felt on one side of the body or of a joint and on the next occasion on the other side. This shifting pain is very typical of internal derangement, although there are some other conditions that may present the same picture (e.g. alternating buttock pain in sacroiliac arthritis caused by ankylosing spondylitis and alternating headache in migraine).

Actual symptoms

After having built up a complete picture of the patient's symptoms, information is sought about what is experienced at the time of interview.

Most patients consult the doctor because they have pain but other symptoms may also be described: pins and needles, numbness, limitation of movement, twinges, weakness and vertigo. These are sometimes forgotten by the patient and therefore the examiner must inquire about them. Every symptom must be given due weight and examined in detail.

Pain (Box 4.3)

There are many different ways of describing pain: it is amazing how much variation patients can achieve in their vocabulary and how many different descriptive terms can be used for the different sensations perceived. The reason lies in the fact that pain is mainly an unpleasant emotional state that is aroused by unusual patterns of activity in specific nociceptive afferent systems. The evocation of this emotional disturbance is contingent upon projection to the frontal cortex.[20,21] The nature of the pain may have some diagnostic value: everybody knows the throbbing pain of migraine, the stabbing pain of lumbago or the burning sensation of neuralgic conditions. Although the way the patient describes the pain may sometimes point to a certain disorder, it can also indicate the emotional involvement of the patient with the lesion.

Pain may have either a mechanical or an inflammatory character (Box 4.4). Mechanical pain (e.g. in arthrosis) is characterized by pain and stiffness at the beginning of a movement; augmentation when load is put on the joint; pain at the end of the day and absence of pain at rest, although moving in bed may also be uncomfortable. Inflammatory pain (e.g. rheumatoid arthritis, gout or infectious arthritis) wakes the patient at night and gives rise to frank stiffness early in the day.[22]

The severity of pain may be a determinant of the type of treatment that is chosen. For example, although sciatica without neurological deficit is not immediately an indication for surgery, discectomy may become the treatment of choice when the pain has become unbearable.

Finally, localization has some diagnostic significance. Pain may be felt centrally (on the midline), bilaterally or unilaterally. Central and bilateral pain usually point towards a lesion lying in the midline. A bilateral lesion is another possibility, but this is much less frequent. It should be realized, however, that central symptoms do not arise from a unilateral structure. And, although some structures lie very close to the midline (facet joints, costovertebral joints, erector spinae muscles), they are still unilateral and can only give rise to symptoms felt unilaterally. Unilateral pain originates in a unilateral structure or, when dealing with the spine, in a central structure that moved to one side and compresses nerve tissue unilaterally (e.g. a disc).

When the lesion is in the locomotor system, there should still be a relationship between symptoms and rest, exertion, activities, movements or posture. When coughing, sneezing or breathing hurts in an area other than in the chest, the dura mater could very well be responsible. Dural pain can be felt in the trunk far beyond the relevant dermatome.

Of special interest to the examiner are 'twinges': sudden short bouts of pain, which last only one second and are often associated with momentary functional incapacity. The occurrence of painful twinges may be the result of one of the following:

- Internal derangement
- Tendinous
- Neurological.

A momentary subluxation of a loose fragment of cartilage in a joint

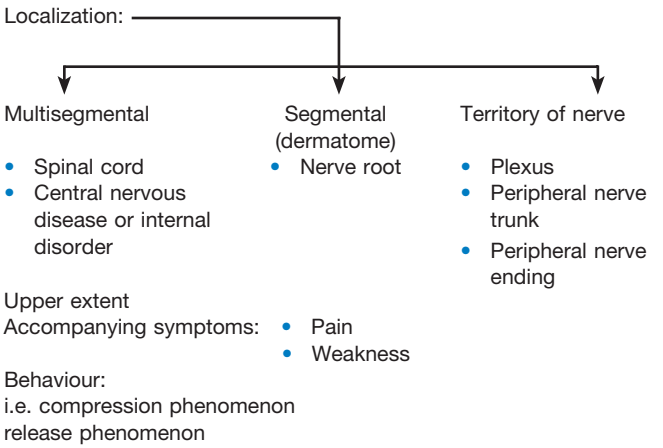
This happens quite often in the lumbar spine, the knee and the hip and less frequently in the elbow, ankle and subtalar joints. If there are any signs found during clinical examination, they will be articular – a non-capsular pattern (see p. 74). The combination of twinges and articular signs is pathognomonic of the existence of internal derangement.

A tendinous lesion

The patient recounts that, especially when the tendon is involved in movement, there are bouts of painful momentary

Box 4.5

Paraesthesia



weakness which arrest movement. This is common in tennis elbow, where the lesion lies at the origin of the extensor carpi radialis brevis muscle from the lateral epicondyle. It also occurs, although less frequently, in tendinitis at the shoulder, especially of the supraspinatus.

A neurological condition

These include tabes, post-herpetic or trigeminal neuralgia and Morton's metatarsalgia.

Paraesthesia

Non-painful sensory disturbances, paraesthesia, are strongly indicative of a condition that originates in a nerve (Box 4.5). They may result from an intrinsic lesion (primary neuritis or secondary polyneuropathy) or from an extrinsic cause (compression). They may also vary in quality and in intensity. In orthopaedic medicine the variation lies between numbness and real pins and needles. It is very often described as 'tingling'.

The moment the patient mentions the presence of pins and needles, the examiner should go into detail and ask the following questions:

- What brings on the pins and needles?
- What makes them disappear?
- How far proximally do they extend?
- Where exactly are they felt?

In entrapment neuropathies, knowledge of what brings the pins and needles on will show whether a compression phenomenon or the release phenomenon is acting (see pp. 26–27). For example, pressure on a small distal nerve gives rise to paraesthesia and analgesia in the cutaneous area of that nerve during the time of compression (e.g. meralgia paraesthetica). However, when a nerve trunk or nerve plexus becomes compressed, the paraesthesia are felt in a larger area, corresponding with the territory of that nerve and occur only after the compression has ceased (e.g. thoracic outlet syndrome). Nerve root compression results in segmental pain and paraesthesia felt within the corresponding dermatome (e.g. sciatica). Multisegmental bilateral paraesthesia indicates a lesion in the spinal cord.

It must be remembered that the site of compression always lies proximal to the proximal extent of the paraesthesia. They are usually felt in the distal part of the extremities. The more accurately the patient describes the area, the more distal the compression lies.

A paraesthesia-like feeling, especially vague tingling, may be experienced in some circulatory conditions, such as Raynaud's syndrome, but this is usually accompanied by changing of the colour of the skin in the distal part of the limb.

Functional disability

Often, functional disability is complained of. It comprises limitation of movement, internal derangement, weakness and incoordination and instability.

Limitation of movement

When limitation of movement is mentioned, its nature will have to be determined during the functional examination: limitation of active movements only, or limitation of both active and passive movements, and in this case whether it is of the capsular or of the non-capsular type. End-feel at the end of the passive movements and the relationship between pain and end-feel must also be ascertained (see pp. 73–74).

Internal derangement

Symptoms caused by internal derangement are irregular in nature. There are moments when the joint feels normal and that the patient is able to do everything, and other occasions when the joint does not work well. Typical symptoms are sudden twinges, shifting pain, giving way of the limb, locking of the joint and a feeling of insecurity.

If the answer to the question 'Does the joint lock?' is positive, further inquiry should make clear in what position locking occurs and how it is released. For example, a knee that locks in extension and unlocks spontaneously suggests a loose body, and one that locks in flexion and has to be unlocked manipulatively is a meniscal problem.

Weakness

This symptom should lead the examiner to concentrate during the examination on both active and resisted movements to see if the weakness is physically apparent or not. If weakness is confirmed, the distinction has to be made between a lesion in the muscle itself (e.g. atrophy or rupture) or in the nervous system, which is more often the case.

Incoordination and instability

These complaints are indications that something is amiss with either deep (proprioceptive) sensibility, the vestibular system or the cerebellum.

Further questions

Other questions, if appropriate, are asked about similar symptoms, past or present, in other parts of the body, especially other joints (see Box 4.6). If the answer is positive, conditions such as rheumatoid arthritis, spondylitic arthritis, Reiter's disease and gout should be suspected and further examination is required.

Box 4.6

Inflammatory disorders

Rheumatoid pattern	Reactive pattern
• Several joints	• Few joints
• Small joints	• Large joints
• Symmetrical	• Asymmetrical

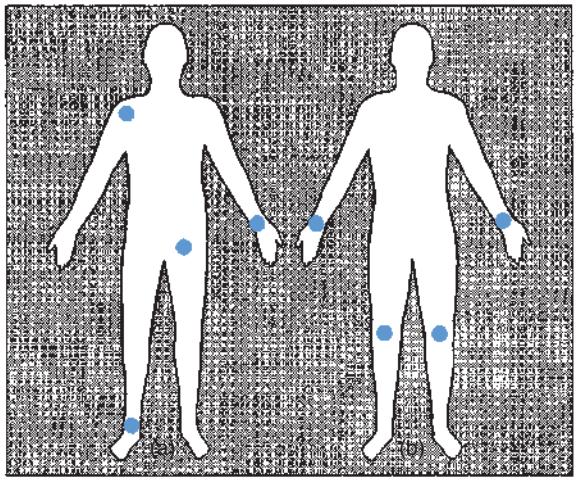


Fig 4.3 • Patterns of: (a) reactive arthritis; (b) rheumatoid arthritis.

Disorders of rheumatoid type (rheumatoid arthritis, lupus erythematosus, systemic sclerosis, dermatomyositis) are characterized by the symmetrical joint involvement, usually of the small joints (e.g. metacarpophalangeal joints). Arthritis of reactive type (e.g. peripheral joint involvement in ankylosing spondylitis, ulcerative colitis, Reiter's disease, sarcoidosis or psoriatic arthritis) affects a few large joints (e.g. shoulder, hip or knee) asymmetrically (Fig. 4.3).

Questions about the general state of health are asked to find out whether there is the possibility of a serious disorder (e.g. cancer).

The patient should also reveal present medication, and a doctor or therapist who considers manipulation should make sure that the patient is not taking anticoagulants: these are a contraindication because of the danger of haemorrhage.

Inquiries should also be made about previous treatments, which may give some idea of the chance of success of the proposed therapy. Previous surgery, its timing and indication are noted – it is not impossible that the present condition is the outcome of previous intervention (Box 4.7).

Box 4.7

Summary of history

     • expanding pain
   - Recurrences
4. Actual symptoms:
   - Pain
   - Paraesthesia
   - Functional disability: • limitation of movement
     • internal derangement
     • weakness
     • incoordination/instability
5. Further questions

Inspection

Inspection begins the moment the patient enters the room. If gait is disturbed, the way of walking may be diagnostic. An experienced examiner usually has the analytical ability to recognize, for example, the following typical patterns: a subluxated meniscus at the knee; a 'tennis leg'; the elderly patient with arthrosis of the hip; acute lumbago; a spastic gait; the patient with parkinsonism; a Trendelenburg gait; a drop foot; a ruptured Achilles tendon; and finally the patient with a non-physical condition.

Further features may be noted while the history is taken. A normally seated patient should have at least 90° flexion at hip and knee which is later confirmed on functional examination. The face may reveal the extent of pain or may disclose parkinsonism. The attitude in which a limb is held during the inquiry may be informative. Finally, the way the patient takes off clothes and shoes can provide further information on disability.

Deformities or deviations are easily seen: for example, in acute torticollis or in lumbago, the patient stands with the head or the lumbar spine held in deviation, usually towards one side. Real deformities can be the result of one or more fractures. Pathological fractures of a vertebral body lead to angular kyphosis or, if they occur at several levels, to a 'shortened' patient. Every examiner knows the typical kyphosis of adolescent osteochondrosis. Other examples are genu valgum and varum, which may be physiological up to a certain age but are pathological in adults. The presence of a deformity is not always relevant. It is quite possible that it has nothing to do with the presenting condition. A short leg or a long-standing scoliosis are very often seen but occur in asymptomatic as well as in symptomatic patients.

Soft tissues, such as skin and muscles, may show abnormalities. The colour of the skin may be different from that of other parts of the body: red in inflammation, blue when a haematoma is present or when a venous disorder has developed, white in arterial problems. Visible muscle wasting may be obvious. If swelling is present, the examiner should ascertain whether it is general and diffuse or localized.

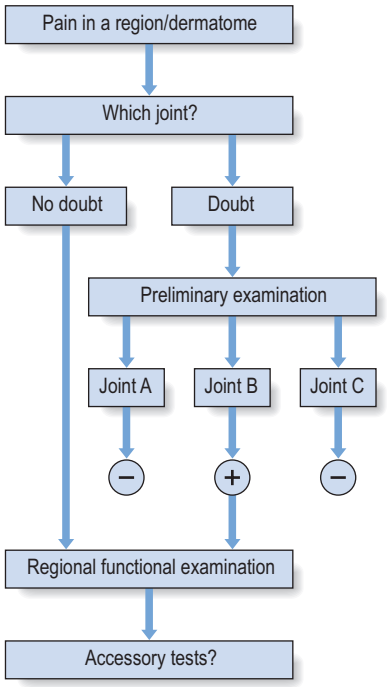

Fig 4.4 • Role of the preliminary examination.

An inflammatory condition may show quite spectacular signs such as redness of the skin, swelling and warmth.

Preliminary examination

After having taken the history and amassed evidence from inspection, the examiner should have an idea of which part of the body the symptoms originate from. Regional examination follows. When the history alone is not diagnostic, so that doubt over the origin or localization exists, a quick survey of the tissues forming the relevant segment may be necessary.

This 'preliminary' examination (Fig. 4.4) includes tests for the different joints. For example, the preliminary examination for pain down the arm includes tests for the cervical spine, shoulder girdle, shoulder, elbow, wrist and hand (Table 4.1).

When some tests are positive and indicate that the lesion lies about a certain joint, this joint will then be tested more rigorously. When no abnormalities are found, it is assumed that the lesion lies outside the moving parts. If all movements hurt, or when the patient presents a contradictory pattern, the question of a psychogenic disorder arises.

Functional examination

In lesions lying within the locomotor system, pain is brought on mainly by tension. Therefore, during examination the different tissues are selectively put under tension and the results noted.

As the function of the different tissues is well known, functional testing is really an exercise in applied anatomy. This indirect approach to diagnosis is purely mechanical.

Table 4.1 Movements tested in the preliminary examination of the upper limb

Root	Region	Type
C1	Neck movements	Active Resisted
C2–C4	Shoulder movements	Active Resisted
C5	Arm movements Shoulder	 Active Resisted
C6–C7	Elbow Wrist	Passive Resisted Resisted
C8	Thumb	Resisted
T1	Fingers	Resisted

The examination used is standardized, which permits a systematic search for *signs* in such a way that, with a minimum of tests, maximum information is obtained. Too many tests in the standard examination can confuse the examiner and make interpretation very difficult.

This does not imply that the diagnosis will always be reached after the standard functional examination. It may sometimes be necessary to add accessory tests (see pp. 66–67).

Procedure

The purpose of functional examination is to reach a decision on *which structure* is affected. However, even that may be insufficient. In a patient with a shoulder problem it is not enough to say that there is a lesion in the brachial biceps muscle: is it in the long head or the short head? In a lesion of the long head, is it localized in the bicipital groove or in its intra-articular course or at its insertion at the glenoid? Therefore, once the structure at fault is known, the next step must be to determine exactly *where, within that structure*, the lesion lies.

Examination is usually performed on both sides. Certainly, if the range of a passive movement is assessed, it has to be compared with the contralateral normal joint. When muscle strength is evaluated, comparison with the non-affected side is again necessary.

The patient as well as the examiner should adopt a good position from which to start. When passive movements are performed, the examiner must make sure that they can be done until the end of range (if present) is reached: movement should not be limited by the examiner's body, or by the couch or even by clothing. For resisted movements, which are done isometrically, the examiner's position must be such that the examiner can exert more power than the patient can. It may be of interest to put the patient in front of a mirror so that reactions can be observed.

The movements that are used to test the different structures should be 'pure' ones, i.e. testing only one structure or

Box 4.8

Aims of testing active movements

- To ascertain patient's willingness and ability
- To determine range
- To assess muscle power

one group of structures at a time. This facilitates subsequent interpretation.

Questions asked during examination should be as neutral as possible. The examiner must not impose on the patient an expected answer. Questions such as 'Does this movement hurt?' or 'Is this painful?' should be avoided. It is better to say 'How is that?' and ask the patient to report anything experienced. It must also be understood that the examiner is looking for tests that elicit the symptoms or, if they are constant, those that influence them.

Movements

The functional examination contains active movements, which are not always necessary, passive tests and movements against resistance. Positive tests are always repeated on the opposite side in order to compare the normal with the abnormal.

Active movements

Active movements are mainly used to determine quickly the area from which symptoms originate and what structures to test in detail with passive and/or resisted movements (Box 4.8).

Examination by active movements goes against the principle of trying to test one structure at a time. When a limb is actively moved, muscles, tendons, ligaments, bursae and capsule are all put under stress. In consequence such tests are non-specific and therefore not always necessary. However, they can be of interest because they suggest what the patient is able and willing to do. In most cases, they also give an idea of the range of movement possible (normal, limited or excessive) and of muscle power. They are always executed first to provide a criterion with which to compare subsequent passive and resisted movements.

When a normal range is later found on passive testing and normal muscle strength is apparent when tested against resistance, there is no reason for any abnormality or restriction of active movements. Thus if, in these circumstances, it is claimed that the active movement cannot be done, there must be refusal, either involuntary (psychogenic) or voluntary (intention to deceive). There are, of course, organic lesions where a discrepancy exists between active and passive or resisted movement but only within certain limits. For example, a mononeuritis of the long thoracic nerve, leading to weakness of the serratus anterior muscle, can make full active elevation of the arm impossible even though the passive range and muscle power of the shoulder are normal. A further example is total rupture of the Achilles tendon, in which resisted plantiflexion is weak and active movement impossible despite the range of passive movement at the ankle remaining unaltered.

Active movements are usually required when the spine (cervical, thoracic and lumbar), the shoulder girdle and the shoulder are examined but they may also be tested at any other joints if they can supply additional information.

Passive movements (Fig. 4.5)

These tests are meant to examine the inert tissues. The information they give is precise, provided they are performed correctly. The patient should completely relax the muscles and let the examiner do the movement. It is important to realize that non-inert tissues may also be stretched by the manœuvre: if this gives rise to pain, it must be determined whether there is a 'contractile tissue pattern', in which case active contraction in the opposite direction will also be painful (see pp. 77).

The criteria for passive testing are pain, range and end-feel (Box 4.9).

Pain

The patient must understand that the examiner is looking for 'the' pain – the reason for presentation – and that each time this pain is evoked or influenced a response is required. When straight-leg raising is performed in a patient with low back pain radiating down the posterior aspect of the thigh, the examiner must make sure that the sensation felt during the test is the exact pain complained of and not just a tight feeling in shortened hamstring muscles.

Pain evoked by a certain movement requires the further information of exactly *where* it is and *at what stage of the movement*. Pain may come on at a certain moment but the movement is not necessarily limited. For example, straight-leg raising may become painful at 60° but continue to full range without increased discomfort. Excessive gentleness may fail to elicit information. Passive movements must be performed as comfortably as possible for the patient but, if a proper answer can only be obtained by pushing a bit harder and thus hurting the patient, this should be done. It would be a diagnostic error to interpret a perfectly full movement as being limited by a few degrees, if the movement was stopped because of pain. The same applies to a painful arc. This may be so uncomfortable that the patient cannot get beyond it by active movement. If an arc is suspected, a harder push during passive movement may succeed and show its presence. Interpretation would be totally different: on the one hand, limitation of movement and, on the other hand, full range with a painful arc.

The presence of joint signs in root lesions is a misleading phenomenon. When a cervical or lumbar nerve root becomes compressed as the result of a disc protrusion, passive movement in a neighbouring joint may occasionally affect the root pain. Thus passive movements for the shoulder joint may hurt at the end of range so focusing attention on the shoulder. As pain of cervical origin is also felt down the arm the picture becomes very confused. The same occurs in lumbar root pain; passive hip movements are not limited but they may influence the pain when they are brought to full range – they are

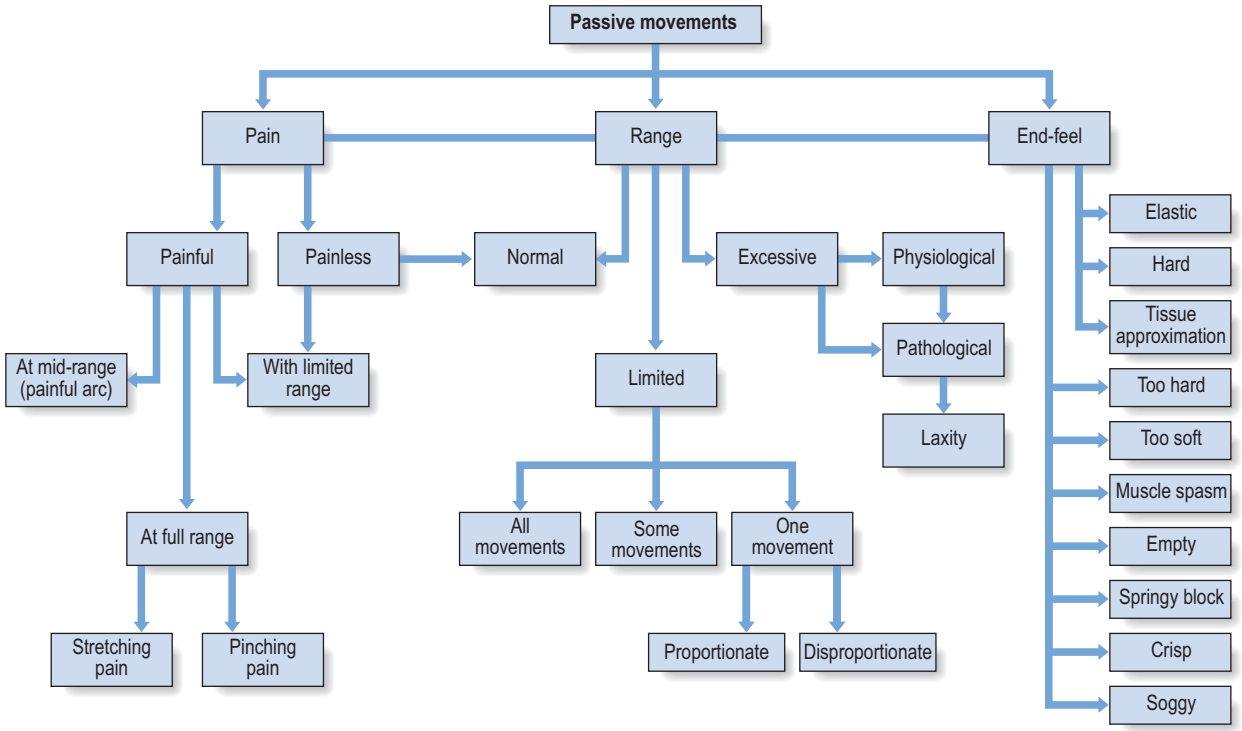

Fig 4.5 • Passive movements.

Box 4.9

Aims of testing passive movements

- To assess pain
- To determine range
- To characterize end-feel

probably capable at their extreme of altering the tension on the nerve roots in a minor way, analogous to straight-leg raising.

Amplitude

The range of movement is noted and is always compared to the unaffected side. The response should be interpreted in the light of the patient's age and general condition.

Limited movement requires the examiner to ascertain whether the limitation is in all directions or only in some directions or in one direction only. If only one movement is reduced, a 'proportionate' or a 'disproportionate' limitation may be present (see p. 76).

Pain at full range suggests that the pain is provoked by stretching or pinching of the affected structure. The localization of the pain will very often be indicative.

Excessive range may be pathological but laxity is sometimes purely physiological: for example, most women can hyperextend the elbow. When a joint moves further than is normally accepted, great care must be taken that the symptoms are not too readily ascribed to that phenomenon. Hypermobility with a normal end-feel is usually not of significance.

End-feel

This is a term typical of Cyriax. It describes the sensation that the examiner experiences at the end of the passive movement. The hand that performs the passive movement is not only motor but also sensory. When the movement comes to the end the examiner should assess the sensation. When no limitation is present the end-feel is at the end of the normal range. When limitation exists, the end-feel is judged at the end of the possible range.

End-feel is diagnostically important as it gives an idea of the structure or condition that stops the movement.[23] In addition it has therapeutic consequences. Especially during attempted spinal manipulations, the sensation imparted to the operator's hand will indicate whether or not to proceed. Likewise, in the shoulder or hip, the decision whether to undertake capsular stretching depends on end-feel.

For accurate judgement of the nature of end-feel, experience is required. Passive movement should be executed with extreme gentleness, especially during the final degrees of range. The moment resistance is first noted, the rate of movement is reduced so that the feeling can be assessed before movement comes to a complete stop. In normal circumstances each joint movement has a characteristic end-feel, which can be considered as 'physiological'. In pathological conditions, end-feel may change. The examiner should know what the normal feeling of each (passive) movement of a joint is like in order to be able to judge every change in end-feel.

Physiological end-feel

This can be hard, elastic or related to tissue approximation:

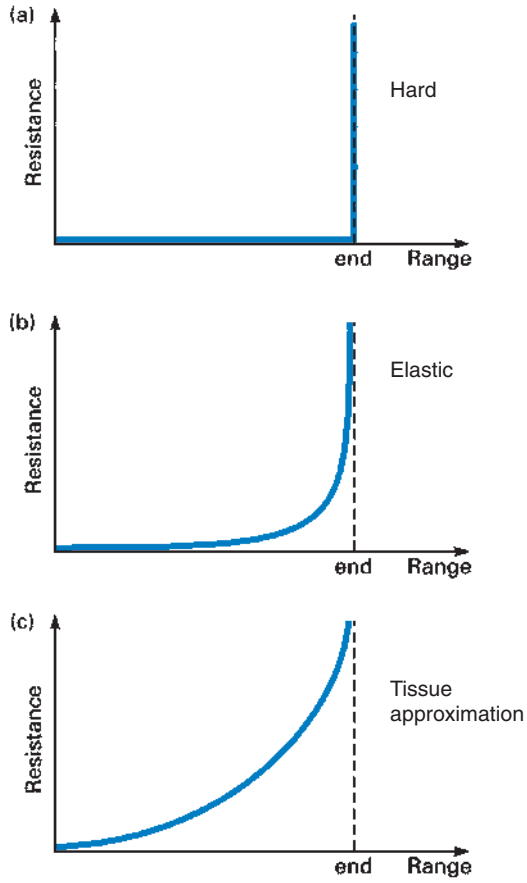

Fig 4.6 • Hard (a), elastic (b) and soft tissue approximation; (c) end-feels.

- *Hard*: the movement comes to an abrupt stop, either because two bony surfaces meet (bone-to-bone end-feel) or because a ligamentous structure prevents further movement (Fig. 4.6a). Extension of the elbow has a bone-to-bone end-feel, because the main factor that stops the movement is the engagement of the olecranon process in the olecranon fossa. Extension of the knee also has a hard stop, though less clearly direct than the elbow; here, the main structure that stops movement is the posterior cruciate ligament, which does not stretch.
- *Elastic*: at the end of range the examiner feels resistance but further stretching over a few degrees is possible (Fig. 4.6b). The feeling is one of two pieces of tough rubber being squeezed together or of a piece of thick leather being stretched. This end-feel is typical of a normal joint capsule and is felt during most rotation movements in shoulder, elbow, hip, knee, cervical and thoracic spine. The tern 'elastic' has the same meaning as 'capsular'.
- *Tissue approximation*: this end-feel is normal in those movements where extra-articular soft tissues engage against each other (Fig. 4.6c). Flexion at elbow and knee give this 'soft', 'muscular' end-feel. At the elbow the muscles of the forearm come in contact with the biceps and at the knee the calf muscles engage against the hamstrings. This 'extra-articular' end-feel does not occur in patients with poorly developed muscles: they present an 'articular' end-feel, either hard or elastic.

Pathological end-feel

A number of types of end-feel are pathological.

- *Too hard*: the normal elastic, or tissue approximation, end-feel may become harder when the quality of the tissue that stops the movement alters under the influence of pathological conditions. This change very often accompanies limitation of movement because of capsular contracture, osteophytic outcrops of bone, myositis ossificans or a malunited fracture close to the joint. Dependent on the condition, the end-feel may vary from a slight increase in hardness (early arthrosis) to a bony block (ankylosing spondylitis). The latter forms a contraindication to further stretching (i.e. during manipulation).
- *Too soft*: in those instances where a hard end-feel is expected, the movement may come to a soft stop. This is especially the case in a loose body blocking a movement as may happen at the elbow: extension is limited by a few degrees with a soft end-feel.
- *Muscle spasm*: this involuntary muscular contraction usually indicates severe disorder. The muscles contract with a sudden, vibrant 'twang' even when the movement is performed very gently. This is reflex protective spasm and may happen in acute conditions, such as arthritis in the acute stage. It may also be a sign of more serious lesions such as recent fracture (e.g. scaphoid fracture at the wrist) or secondary deposits (e.g. in a cervical vertebra). Such an end-feel is always an absolute contraindication to manipulation.
- *Empty*: movement may be so painful that the patient begs the examiner to desist. The latter feels that further movement would be possible because there is no organic resistance but stops the movement because of the perceived pain or out of sympathy for the patient. Further forcing would result in active voluntary muscular contraction. This situation always indicates a serious problem. Acute bursitis, extra-articular abscess or neoplasm is a possibility, but there is nothing wrong with the joint itself. This end-feel may also indicate laxity in a joint or a non-organic lesion. In the latter case there is initial strong resistance, which yields to sustained pressure, disclosing a full range of motion.
- *Springy block*: this finding always indicates internal derangement: when part of an intra-articular cartilaginous tissue displaces, it may prevent a full range of movement which leads to a rebound at the extreme of the possible range. The commonest examples are a displaced meniscal fragment in the knee and a buckled end-plate in the lumbar spine.
- *Crisp*: this is typical for a disc protrusion and is best felt in the cervical spine. The feeling is the result of small involuntary muscular contraction at the end of the possible range, known as 'muscle guarding'. The condition is not acute, as a result of which there is no real muscle spasm.

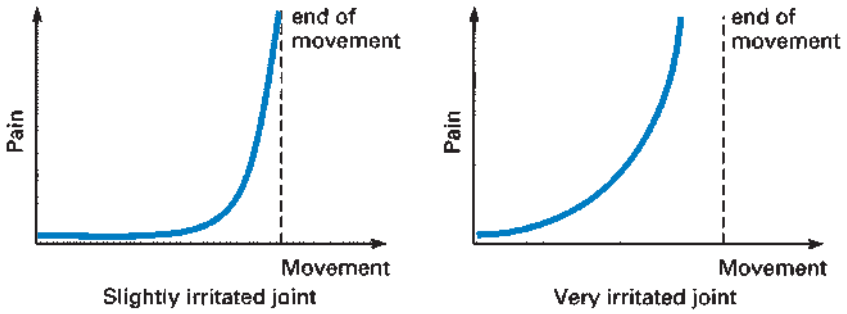

Fig 4.7 • Relationship between pain and end-feel.

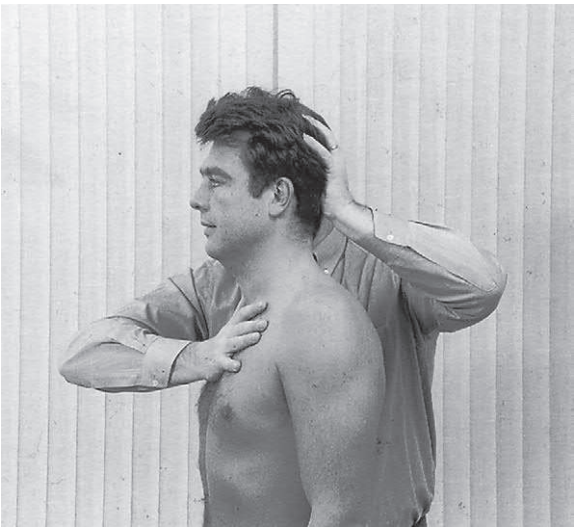

Fig 4.8 • Resisted extension of the neck.

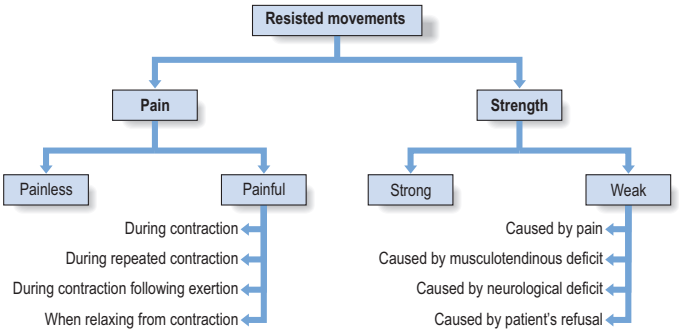

Fig 4.9 • Resisted movements.

- *Soggy*: this end-feel is seldom encountered and can be situated somewhere between a soft and an empty feeling. It is typical of rheumatoid arthritis in the upper cervical joints and is a strong contra-indication to manipulation.

Relationship between pain and end-feel

It is also important to look for the relationship between the moment of appearance of pain and that of the end-feel. Usually the pain comes on at the same time as the end of range is sensed (Fig. 4.7). Earlier pain implies that the joint is in a very irritated state which has therapeutic implications.

Resisted movements

Movements against resistance are performed isometrically. The joint is put in a neutral position and should not move when resistance is applied. This method ensures that stress on inert tissues is minimal or absent.

The position of the examiner must be such that the force exerted by the patient can be resisted. A maximal contraction is asked for and held for a few seconds. Counterpressure is therefore taken by the other hand at the opposite side. For example, to test resisted extension of the neck, one hand is put on the occiput and another hand on the sternum (Fig. 4.8).

Box 4.10

Aims of testing resisted movements

- To assess pain
- To determine muscle strength

Similarly, to test resisted flexion, one hand is placed on the forehead and the other between the scapulae.

The criteria when testing against resistance are pain and strength (Box 4.10).

Pain

In a lesion that lies in the contractile tissue, the pain should be elicited during the contraction. In mild disorders the test may initially be negative but repetition of the movement may eventually provoke symptoms. Similarly, slight muscular or tendinous problems may give pain only during exertion and resisted movements may remain painless. If pain cannot be elicited by repetitive contractions, the patient should be seen and tested in the circumstances when pain is experienced. The resisted movements may then be found positive.

There are cases of tendinitis in which the pain is only felt when the patient relaxes after muscle contraction. This is not uncommon and can also be interpreted as a positive resisted movement.

A positive answer on resisted movement is usually only one – but the most important – part of a 'contractile tissue pattern'

in which the passive movement that stretches or pinches the affected part is also painful.

The examiner must be aware of inert tissue lesions that can become painfully squeezed or moved by muscular contraction (e.g. gluteal bursitis).

Strength

The movement should be strong, but weakness may occur and an experienced examiner will immediately have an idea of what is the cause. It may be the result of pain; in that instance, the examiner feels a sudden cessation of power – the patient stops the contraction when the pain is felt. This often happens in partial muscular or tendinous ruptures when sufficient fibres are torn to diminish strength.

In total contractile tissue ruptures, there will not be pain but complete absence of muscle power. This pattern is completely different from a neurological weakness. Here there still is a force that has to be overcome: the examiner is stronger than the patient and so can push the patient's limb away while still feeling continuing resistance. The latter can vary from an almost normal sensation – slight paresis – to very little (scarcely detectable) force – complete paralysis. This may be the result of a lesion that has completely stopped motor innervation or it may be a consequence of the patient's refusal to undergo the manœuvre.

Accessory tests

After a well-balanced basic functional examination, interpretation of the pattern that emerges should, in most cases, make it possible to single out the tissue at fault. Difficulties are, of course, encountered and further accessory testing is then required to reach a precise diagnosis, to positively confirm an existing but tentative diagnosis or to disclose the precise point affected within the structure.

An important feature is that a distinction should be made between standard functional examination and accessory tests. The basic examination is always done in its entirety, whereas the accessory tests are applied selectively (Box 4.11).

It is wrong to do accessory tests without a prior idea of the nature of the problem, and in the hope that more tests would automatically provide more complete information. On the contrary, the more tests the more confusing the picture may become and in the end the 'wood cannot be seen for the trees'. Accessory tests therefore should be goal-oriented. They are performed in the following circumstances.

Box 4.11

Aims of accessory tests

- To differentiate within a group of structures
- To confirm a tentative diagnosis
- To unravel a difficult pattern
- To extend a negative examination
- To make a differential diagnosis
- To understand unusual signs

After testing a group of structures

When a resisted movement has tested a group of structures, further differentiation is sometimes necessary to find in exactly which structure the lesion lies.

In 'tennis elbow', resisted extension of the wrist is painful. To find out whether the lesion lies in the extensors of either the wrist or of the fingers the test is repeated with the fingers held actively flexed, so inhibiting the finger extensors. A negative answer implicates the wrist extensors, which can then be differentiated by executing resisted radial and resisted ulnar deviation: when resisted ulnar deviation hurts, the extensor carpi ulnaris is at fault; whereas if resisted radial deviation is painful, the lesion clearly lies in one of the radial extensors of the wrist – true tennis elbow. Whether the tendinitis is situated at the extensor carpi radialis longus or brevis cannot be found by further testing – palpation is called for.

The same applies to the hamstring muscles. A muscular or tendinous lesion about the knee will give rise to pain on resisted flexion. Differentiation between either (a) the femoral biceps or (b) the semitendinosus and semimembranosus is achieved by testing resisted external and internal rotation. Positive lateral rotation incriminates the biceps and medial rotation draws attention to the other two muscles. Palpation identifies exactly where the lesion lies.

To confirm a tentative diagnosis

An accessory test may help, especially in uncommon conditions, to confirm a tentative diagnosis. For example, when the diagnosis of mononeuritis of the spinal accessory nerve has been suspected, weakness on resisted scapular approximation will show the diagnosis to be correct.

In difficult cases

A clinical picture can sometimes be difficult to interpret and accessory tests may then resolve doubt. When pain is thought to be due to squeezing of a structure, diagnostic traction may help to confirm this. For example, in difficult cases of internal derangement of the cervical spine, pain and/or paraesthesia can be temporarily abolished by applying manual or mechanical traction. Traction on the arm can diminish pain in subacromial bursitis.

When the functional examination is negative

A negative examination does not necessarily mean that a lesion is absent. There may be a problem in a neighbouring tissue which was not systematically tested in the standard examination. A negative shoulder examination, for example, invites the examiner to test the coracobrachialis muscle. In anterior knee pain a negative examination is followed by tests of the patello-femoral joint.

In differential diagnosis

Different conditions may give rise to similar positive answers. An accessory test can then help to elucidate which structure is at fault. For example, limitation of external rotation at the shoulder is the primary sign of anterior capsular contraction as well as of a subcoracoid bursitis. Passive external rotation with the arm held in abduction will be positive in a capsular lesion and negative when a bursitis is present.

A test for distant pain can be performed when a lesion lies in a long bone. When a fracture is suspected on the dorsal aspect of a rib, pressure on the anterior aspect or on the sternum may provoke the pain. This technique can also be used to differentiate a rib problem, a lesion in an intercostal muscle or at a costovertebral joint.

When unusual signs are found

Discrepancies between individual findings on functional examination may suggest an unusual and possibly serious lesion, a psychogenic problem or an attempt to deceive. In the former, the patient is sent for further specialized examination. When neurosis or deception is suspected, the patient is subjected to a number of accessory tests: additional movements that cannot possibly influence the alleged symptoms or repetition of tests in other positions. The opportunity for the patient to make mistakes is thus presented, which in a positive way can confirm the examiner's suspicion (see online chapter *Psychogenic pain*).

Palpation

Palpation can be a very useful aid to diagnosis when performed at the right moment. However, it is frequently done too early in the examination, with the risk of an incorrect diagnosis. When, after functional testing, the examiner has interpreted the different movements and the pattern that emerged, and still thinks that more information could be forthcoming about the lesion, palpation is undertaken. Abnormal sensations that are imparted to the hand in a stationary as well as in a moving joint are sought.

Palpation of the stationary joint

During palpation of a motionless joint (Fig. 4.10a) the examiner may assess temperature (either warmth or cold), swelling, synovial thickening or structural changes. Palpation may also elicit tenderness.

Warmth

Warmth is best palpated with the dorsum of the hand and may be diffuse or localized. Spurious warmth can be the result of a rubefacient ointment or of a bandage that has been removed just before examination. Otherwise, warmth always indicates activity. The lesion may be osseous (e.g. fracture or metastases) or articular (e.g. arthritis, haemarthrosis, loose body, or a disorder of a meniscus or ligament) or tendinous (e.g. rheumatoid-type tendinitis). A purely mechanical tendinitis will not cause any warmth. When the warmth occurs suddenly and twinges are also present, this indicates persistent subluxation of a fragment of cartilage. The heat may or may not diminish when the joint is kept still. Sometimes (e.g. in loose body) the warmth may be elicited merely by the examination.

Cold

When the extremity feels cold an arterial problem is suspected. Palpation will then follow for arterial pulsations. Cold may also occur during an attack of sciatica, especially that which causes muscular weakness. When the foot becomes cold only after exertion, the probable cause is an iliac thrombosis. The cause may also be neurological.

Swelling

Swelling is the result of an articular reaction to a lesion and may be localized or generalized. Swelling that came on after injury may be the outcome of haemorrhage or effusion. If it is caused by bleeding, the joint fills up within a few minutes; effusion develops over a few hours. Blood also fluctuates: the swelling moves *en bloc*. The presence of pus is exceptional and indicates an infection with microorganisms. Periarthritic oedema may pit. In a localized swelling, its consistency should be ascertained: a soft swelling indicates subcutaneous clear fluid or a thickened bursa, a fluctuating mass may result from a haematoma or from a mucocele and a hard but still fluctuant swelling is typical of a cyst or a ganglion. When the consistency is bony the cause is usually a callus, a bony subluxation (e.g. capitate bone at the wrist or cuboid bone in the midfoot), an osteophytic outcrop or any other bony deformity which results from a destructive process (e.g. osteitis deformans, neoplasm).

Thickening of the synovial membrane

This is found in rheumatoid, bacterial or inflammatory arthritis (e.g. gout, tuberculosis, gonorrhoea, Reiter's disease, ulcerative colitis, spondylitic arthritis or psoriatic arthritis). It is absent in mechanical conditions, such as traumatic arthritis, post-immobilizational arthritis and arthrosis. To palpate capsular thickening, the examiner has to seek the reflexion of the membrane where it overlies a bony prominence.

Gaps

A gap may be palpated at the site of the rupture of a muscle or tendon.

Tenderness

Palpation for tenderness is sometimes performed to determine the exact localization of a lesion. For this purpose, it is done only in a structure that has already been found, by clinical examination, to be affected and only when it is within reach of the finger. Eliciting tenderness is only necessary when, after clinical examination, the diagnosis still lacks precision. When a localizing sign has been found, palpation is of course

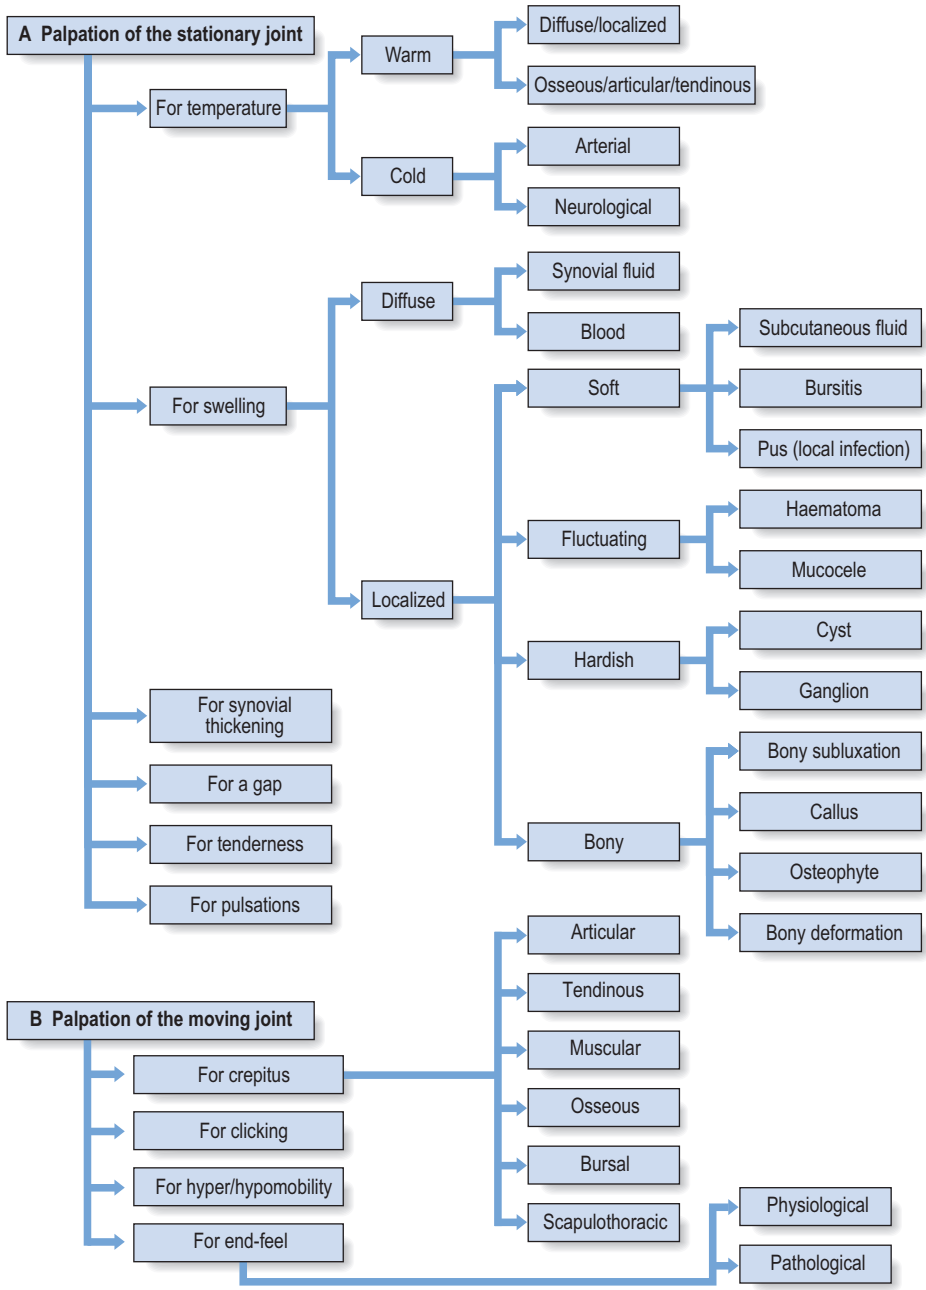

Fig 4.10 • Palpation of (A) the stationary and (B) the moving joint.

superfluous. To search for tenderness is of much more value in a distal joint (wrist, hand, ankle, foot) than in a proximal joint (trunk, shoulder, hip), because the localization of the pain is much more accurate.

Difficulties may arise when two tissues overlap and when no certainty exists whether the lesion lies in the superficial or a deep structure. This situation arises most in the chest and abdomen. To ascertain whether the tenderness lies in a superficial or a deep muscle or in another structure (e.g. a viscus), palpation is performed during contraction and relaxation of the superficial muscle. Greater pain when the superficial muscle is tense suggests that the muscle is at fault, the converse that deeper structures are affected.

Other misleading phenomena are the presence of either a 'referred' tenderness or an 'associated' tenderness.

Localized, deep referred tenderness may occur within a painful region, for example, as the result of compression of the dura mater usually by a small displaced fragment of the intervertebral disc. This phenomenon is described in Chapter 1 and can be very deceptive unless the examiner is familiar with the rules of pain reference.

Associated tenderness is a very well-localized tender area very close to the site of the lesion. There is a relation between the two because both pain and tenderness disappear when the patient is cured. Associated tenderness is most common at the wrist and the elbow. In de Quervain's disease – tenovaginitis

of the abductor longus and extensor brevis muscles at the wrist – the styloid process of the radius is extremely tender, as is the posterior aspect of the lateral epicondyle in tennis elbow, especially when the lesion lies at the tenoperiosteal origin of the extensor carpi radialis brevis.

Negative palpation does not necessarily mean that the diagnosis is wrong, except perhaps in very superficial lesions, because there are tissues that are not explicitly tender when affected (e.g. the supraspinatus tendon).

Pulsation

Palpation for pulsation in the arteries may have an important diagnostic value and is indicated when symptoms are mentioned or signs are found that point to a vascular condition (e.g. claudication, a cold limb, or blue or white skin).

Palpation of the moving joint

Next, the moving joint is palpated. The examiner may either experience crepitus or clicks, or can assess end-feel or mobility (see Fig. 4.10b).

Crepitus

Crepitus always indicates a pathological situation. It can often be heard and can also be felt by the palpating hand placed on the moving part during active or passive movement. There are circumstances in which the crepitus is only felt during a movement against resistance. Crepitus may be articular, tendinous, muscular, osseous or bursal.

Articular crepitus

Crepitus which originates from the joint surfaces gives an idea of their ability to glide over one another. Fine crepitus indicates slight roughening and occurs in mild arthrosis or in long-standing rheumatoid arthritis. The latter gives rise to the characteristic 'silken' crepitus. Coarse grating is felt in advanced arthrosis and results from considerable fragmentation of the cartilaginous surface. In severe arthrosis the cartilage has wholly worn through which leads to intermittent creaking of bone against bone ('cogwheel' phenomenon).

Tendinous crepitus

Crepitus in relation to a tendon establishes tenosynovitis. Fine silky crepitus occurs in acute mechanical cases as the result of a traumatic roughening of the tendon surface and of the inner aspect of the tendon sheath. Coarse crepitus is felt in chronic rheumatoid or tuberculous tenosynovitis.

Muscular crepitus

This is observed in two situations only:

- Tenosynovitis of the two extensors and of the long abductor of the thumb in the distal part of the forearm is usually accompanied by crepitus that can be felt locally. The crepitus is, however, sometimes felt throughout the muscle bellies, possibly as far up as the elbow (see p. 524).
- Localized crepitus is usually felt in a lesion at the musculotendinous junction of the tibialis anterior muscle.

Osseous crepitus

A fracture may crepitate when the limb is moved and the two ends of the fractured bone move against each other but, except in pathological fractures, an attempt to elicit crepitus usually causes so much pain that it should not be done.

Bursal crepitus

Subdeltoid bursitis is the characteristic situation. Some time after a bursitis with effusion has subsided, creaking on moving the arm can be felt (see Shoulder, p. 333).

Scapulothoracic crepitus

This is unique. The posterior thoracic wall can become roughened at an area just beyond the lateral edge of the iliocostal muscle, with localized crepitus felt on shoulder movement (see the online chapter *The shoulder girdle: Disorders of the inert structures*.

Clicks

Clicks can be produced in several ways. Certain tests on clinical examination or certain manœuvres during a manipulative session may provoke movement of an intra-articular fragment of cartilage. This often happens when a loose body is present in a joint (e.g. knee or elbow) or when a meniscus subluxates (e.g. knee or jaw) or a fragment of disc moves (e.g. spinal joints). Clicking during a manipulative manœuvre is of interest in that it is often associated with an improvement of the physical signs, clearly indicating that a block to movement has been removed. In ligamentous laxity (as can be seen in subluxation of the clavicular joint, in capsular overstretching of the shoulder, or in rupture of the medial collateral ligament at the knee), a click is produced when one bone moves in relation to its fellow. Irrelevant clicks also appear, for example painless clicking of a costal cartilage or a patellar click during active extension of the knee.

End-feel

End-feel can be assessed when a passive movement comes to a stop. It is either physiological or pathological and has important diagnostic and therapeutic consequences (see pp. 64–65).

Hypermobility and hypomobility

These are terms that are currently used by osteopaths and manual therapists.[24–25] During their so-called 'segmental examination' they claim to be able to feel the difference in mobility between different, mostly spinal, joints.[26] To establish hyper- or hypomobility would afford an excellent guide to the level of the lesion *if* it were always at the joint in which the fault lay, which is not in fact the case. Moreover, these findings are so subjective that they are not verifiable or reproducible. It has been shown on different occasions that even experienced osteopaths or therapists cannot agree about the findings.[27–31] The main mistake, however, consists in attributing diagnostic significance to such differences in mobility. When movement

in a hypomobile or hypermobile joint strongly evokes the patient's symptoms, this has to be considered as the best criterion and clearly shows where the lesion must lie. However, when the abnormal mobility does not elicit the known symptoms, the problem clearly has nothing to do with the hypermobile joint.[32–34] Furthermore, there are no universal standards to determine abnormal mobility. What is normal for one person can be abnormal for another. Hypermobility can be physiological up to a certain level, especially in women, and hypomobility can also be considered as normal, particularly in the elderly. When hypermobility gives rise to symptoms, then and then only can it be considered as pathological. The terms 'laxity' and 'instability' are then used. The end-feel will add greatly to this conclusion.

Diagnostic infiltration or aspiration

Diagnostic local anaesthesia

When faced with lesions of the locomotor system, a diagnostic infiltration with a weak local anaesthetic is extremely valuable and most effective in confirming the diagnosis. There is no other comparably effective test. By using infiltration in every suitable case, the physician makes the patient the judge of the correctness of the diagnosis.

Between 2 and 10 ml of a weak local anaesthetic (e.g. procaine 0.5%) is infiltrated at the assumed site of the lesion. Five minutes later the movements that were previously positive are retested. This allows the patient to determine whether the infiltration has altered the pain. When the tests have become completely or partly negative, the exact site of the lesion has clearly been reached, confirming the diagnosis. When the tests are still as painful or as limited as before, the wrong place was infiltrated, i.e. the diagnosis is wrong.

This approach is useful in the following circumstances:

- When the examiner is not certain about a diagnosis or when the examiner wants positive confirmation of a tentative diagnosis, the induction of a local anaesthetic may help.
- For lesions in the extremities, infiltration is particularly useful and gives reliable answers. However, it is not useful on the posterior aspect of the trunk: paraspinal infiltrations may give temporary relief but have no diagnostic value.
- In difficult cases this approach may be the final 'court of appeal'.

Aspiration

From the diagnostic point of view it is often important to aspirate a swollen joint or a diffuse extra-articular swelling in order to ascertain what sort of fluid is present.

Technical investigations

It should be stressed again that there still remains a huge discrepancy between discovered anatomical changes and existing pain and disability. During the last decades the medical profession has focused on, and been fascinated by, techniques of imaging that can clearly show existing anatomical aberrations. However, very often, these anatomical changes are not the source of the pain because they appear to exist also in large groups of symptomless individuals. For example, the prevalence of herniated lumbar discs in a normal asymptomatic population ranges from 35%–50%.[35–41] Evidence of cervical discopathy is also found in asymptomatic subjects[42–44] and there is not always good concordance between the different imaging techniques.[45] In the shoulder, echography can discover partial thickness and full thickness ruptures of the rotator cuff even in large asymptomatic groups.[46–49] The finding of asymptomatic anatomical changes in knee joints during arthroscopy is not uncommon.[50,51]

In orthopaedic medicine, technical examinations are not routinely performed but are instead used only when necessary to refine the clinical diagnosis, to exclude certain lesions or to clarify differential diagnosis. They are always undertaken when the history and/or functional examination have revealed warning signs (Box 4.12).

The clinician should not ascribe too much diagnostic importance to technical investigations – a positive answer does not always identify with certainty the condition present. The reverse also holds: a negative picture does not always mean that there is nothing wrong. Knowing when to ignore a positively or negatively misleading picture comes only from proper clinical examination (see Box 4.13). The latter always remains the most important of the tools available and it is far more dangerous to omit a proper clinical examination and rely on technical investigations than to do the reverse.

Later chapters outline when and when not to fall back on technical investigations and complement the clinical findings.

Interpretation

Interpretation is only possible if the clinical examination has been performed correctly: a detailed history, followed by inspection and a careful functional examination. Every part of the examination may be important, and consequently a complete examination should be carried out on each occasion. Cyriax stated 'Omission of part of this examination, because the diagnosis seems obvious or to save time, is the common source of error'.[52] Examining patients may become a routine and repetitive, with the same features being frequently encountered so that it is tempting to omit that part of the examination

Box 4.12

Technical investigations

Only when necessary:

- To refine the clinical diagnosis
- To exclude certain lesions
- To clarify differential diagnosis
- When warning signs are present

Box 4.14

Patterns found in clinical examination for suspected soft tissue lesions

Active movements are positive

- In combination with passive movements
- In combination with resisted movements
- In isolation:
  Limitation of active movements only
  Presence of a painful arc
  A 'snap' occurs
  A 'crack' is heard

Passive movements are positive

- Limitation of range:
  The capsular pattern
  Non-capsular patterns
- Full range
- Excessive range
- No movement possible

Resisted movements are positive

- In combination with passive movements
- In isolation
- In combination with other resisted movements

No movements hurt

which is expected to be negative. By doing this, the presence of a double lesion can easily be overlooked or, even worse, the signs of an uncommon (possibly serious?) disorder (one of the classic 'warning signs') may be missed.

The functional examination gives positive answers balanced by negative ones, the latter corroborating the former. A pattern is found, which may be capsular, non-capsular, muscular or partly or fully articular, and this has to be interpreted so that logical conclusions of incontestable validity are drawn. Interpretation requires experience because examination is subjective and such features as weakness, end-feel and resistance can only be interpreted by comparison, which needs time and patience.

In practice one of a number of patterns can emerge (see Box 4.14).

Impairment of active movements

In combination with impairment of passive movements

The response to active movements (Fig. 4.11) may correspond with that found on passive testing. When an active movement is found to be *painful*, passive movement in the same direction will usually be more painful. In this case, the passive movement must be considered as the important one and the response to it is used for interpretation (see pp. 73–77). When the active movement is *limited*, passive movement is usually also restricted, although it should be possible to go a little further in the limited direction.

In combination with impairment of resisted movements

When an active movement *hurts* and the same movement performed against resistance is also painful, the latter has to be considered as being most important (see pp. 77–78). *Limitation* of an active movement and not of the corresponding passive one indicates gross weakness. The same movement performed against resistance usually also proves to be weak. Sometimes, however, other (accessory) tests against resistance must be done to uncover the lesion.

In isolation

One or more active movements are limited but are full range on passive movement

This occurs when one or more muscles are out of action. The resisted movements aimed to test the same muscles will also be weak. Weakness is quite often encountered in orthopaedic medical disorders. It may be of organic type or functional type (Fig. 4.12).

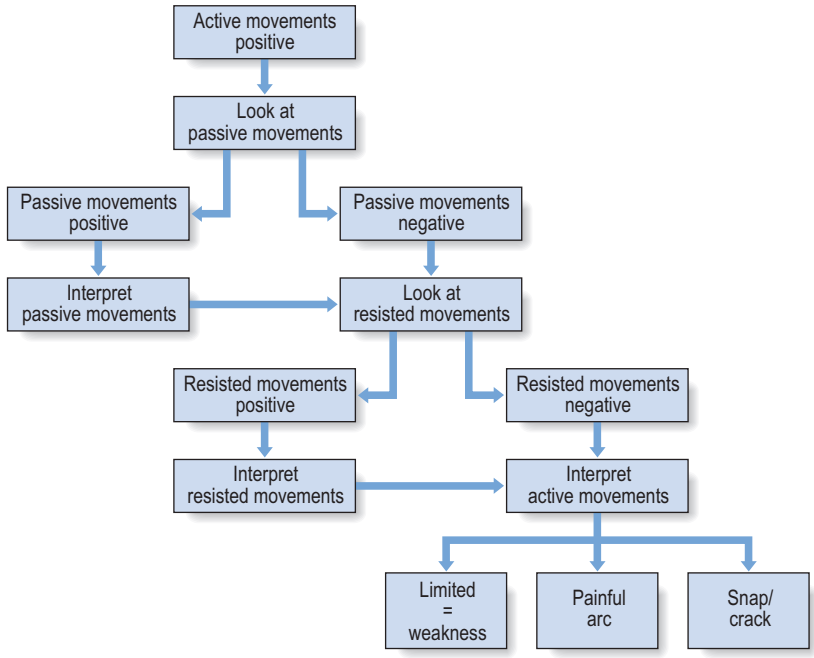

Fig 4.11 • Response to active movements.

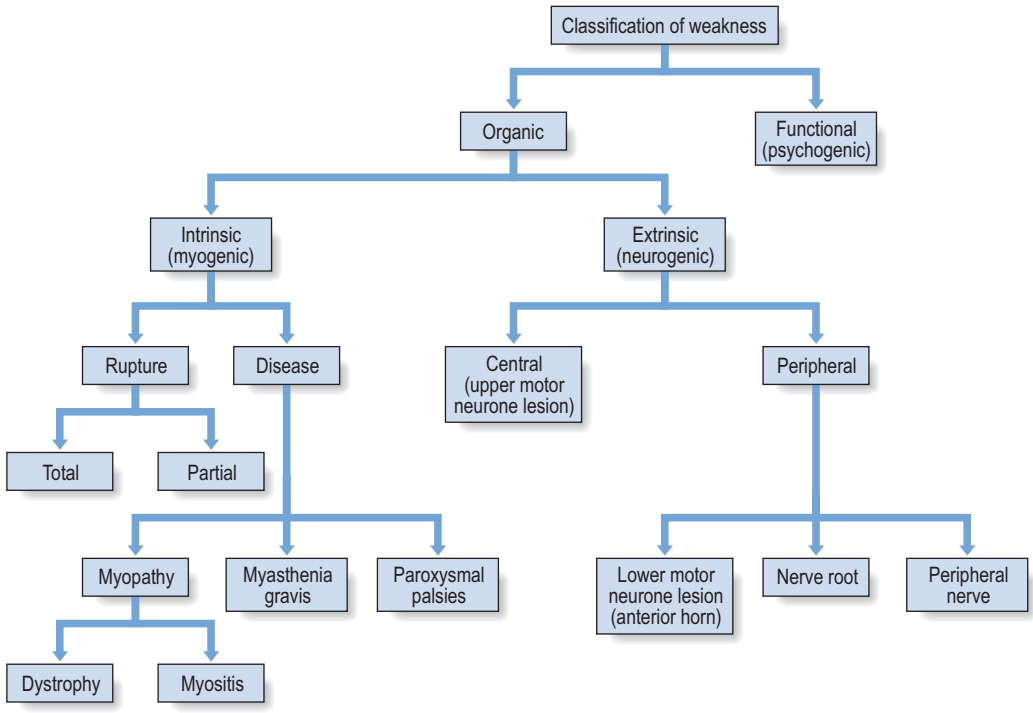

Fig 4.12 • Classification of weakness.

Functional palsies are mostly psychogenic. Organic palsies are the result of either an anatomical pathological condition or of a physiopathological (usually biochemical) lesion. The cause may be intrinsic or extrinsic.

Intrinsic (myogenic) lesions are the result of either a structural disorder, such as a severe partial or a total rupture of muscle or tendon, myopathy (e.g. muscular dystrophy or myositis) or a biochemical disorder (e.g. myasthenia gravis or paroxysmal palsies). Extrinsic (neurogenic) lesions may be either central or peripheral (Table 4.2).

Central palsy

A central palsy is the result of a lesion of the upper motor neurone (i.e. the corticospinal and/or corticonuclear tracts), caused by a vascular condition, a tumour, trauma or disease (e.g. encephalitis or multiple sclerosis) in the region between

Table 4.2 Differences between central and peripheral palsies

Central	Peripheral
Muscular hypertonus	Muscular hypotonus
Hyperreflexia	Hyporeflexia
No muscular atrophy	Muscular atrophy
Upper skin reflexes disappear	
Lower skin reflexes appear	

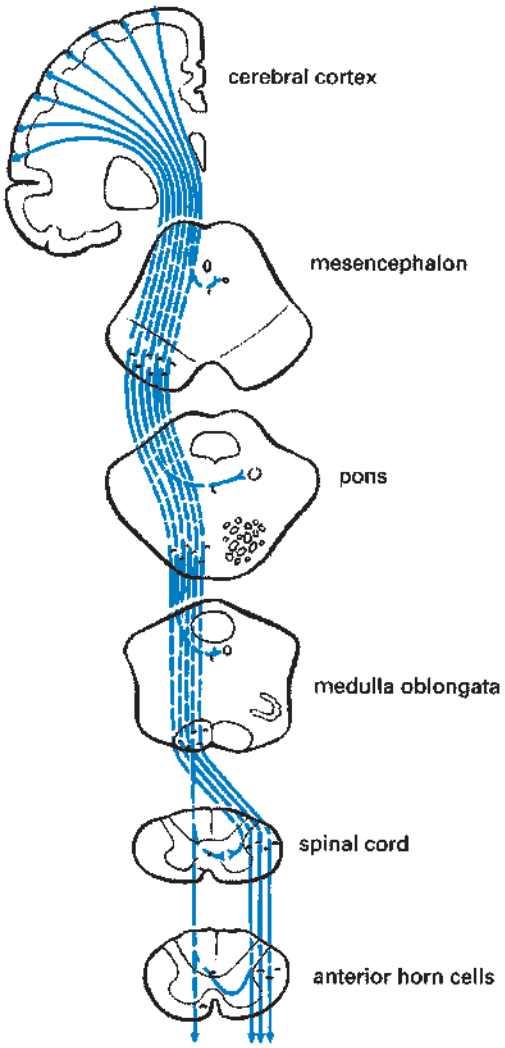

Fig 4.13 • Corticospinal tract (pyramidal tract).

the cerebral cortex and the spinal cord (Fig. 4.13). Hemiplegia, monoplegia, paraplegia or quadriplegia follows, characterized by muscular hypertonus, hyperreflexia, disappearance of the upper skin reflexes and appearance of abnormal skin reflexes (e.g. the Babinski reflex). Because the cells in the anterior horn of the spinal cord are not affected, there is no muscular atrophy apart from some slight wasting because of the patient's inactivity.

Peripheral palsy

A peripheral palsy may have its origin in the cells of the anterior horn of the spinal cord (nuclear palsy or lower motor neurone lesion). Typical anterior horn disorders are acute anterior poliomyelitis, giving rise to asymmetrical paralysis of the proximal muscle groups, and degenerative conditions such as chronic anterior poliomyelitis and amyotrophic lateral sclerosis (ALS), which cause symmetrical bilateral paralysis starting in the distal muscle groups.

Anterior nerve root lesions (radicular palsy) give rise to segmental paralysis or paresis. Nerve root palsy is usually preceded by severe segmental pain.

When a peripheral nerve or nerve trunk is affected, only the muscles innervated by that nerve are weak. When a plexus is affected, the weakness is more extensive. The clinical features are muscular hypotonus, hyporeflexia and atrophy.

A painful arc is present

The moment the patient shows a painful arc the examiner knows that the lesion lies in a position that is subject to compression. Interpretation is on anatomical grounds: the examiner knows what structures can and cannot become momentarily compressed (see later chapters on specific joints).

A snap occurs

When this is present, the patient usually mentions it as a previous occurrence. It may be detected at examination, especially on active movements.

A snap may be felt when a tendon catches against a bony prominence and then slips over it. Examples are the shoulder ('snapping shoulder'), if the long head of biceps slips in and out of the upper end of the bicipital groove as the result of rupture of the transverse humeral ligament; the ankle ('snapping ankle'), when the peroneal tendons are loose in their groove on the posterior surface of the fibula and slip forwards over the malleolus; and the hip, when the greater trochanter catches against the edge of the gluteus maximus muscle. Snapping is not necessarily painful. Therefore, when a patient complains about a joint that also snaps on certain movements, the cause of the pain and the snapping are not always related.

A crack is heard

Joints may crack when they are brought to the end of range, either actively or passively. The cause is the momentary formation of an intra-articular air bubble from the synovial fluid as a result of the partial vacuum created by traction. This often happens in the finger joints and is also very common in the spinal facet joints during manipulation.

Impairment of passive movements

Positive passive movements in combination with negative resisted movements draw attention to the inert structures, although they do not unconditionally exclude a lesion of contractile tissue (see Fig. 4.14).

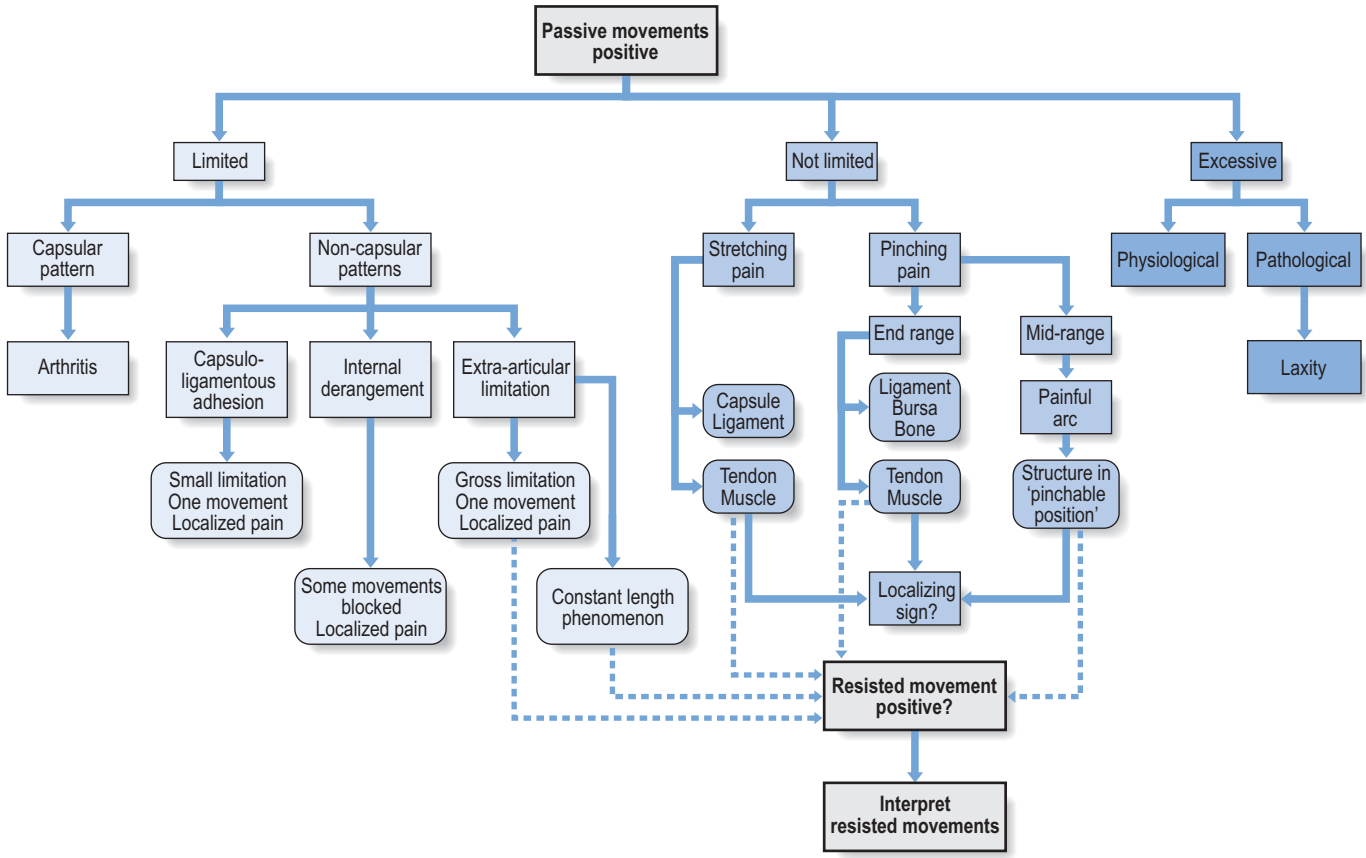

Fig 4.14 • Positive passive/negative resisted movements.

Limited range

Limitation in the literal sense of the word can only be detected on passive testing. Although a patient may present with limitation on active movement, this does not necessarily mean that the joint cannot move to its full range. The examiner should meticulously check whether a movement really is limited. Even the slightest decrease in range has significance. When one or more passive movements are limited the major question arises: 'Is this limitation in the capsular proportions or not?' Or, in other words, 'Is there a capsular pattern present or is the pattern non-capsular?'

The capsular pattern

> The capsular pattern = Arthritis

In a peripheral joint, a lesion of either the fibrous capsule or of the synovial membrane with which it is lined gives rise to limitation of movement, to a characteristic proportion. It does not matter whether the irritation is synovial only (as in recent sprain or haemarthrosis), capsular only (as in arthrosis) or both (as in rheumatoid arthritis) – the same pattern results. This limitation of movement to a proportion typical for the joint capsule is initially caused by a protective mechanism (muscle spasm) and later by fibrous contracture. This pattern of limitation always indicates that a lesion of the whole joint is present. The condition is called capsulitis, synovitis or arthritis, the latter being the best name as it clearly indicates involvement of the entire joint.

This phenomenon is easy to check in clinical daily practice but is difficult to explain. In acute cases the muscles clearly contract in a way that anticipates the situation that might be created when later the capsule 'contracts'. So there must be an in-built mechanism in the brain which acts in imitation or in correspondence with the normal evolution of the movement.

The capsular pattern varies from joint to joint. It is not clear why some joints limit in certain directions and other joints in other directions. In arthritis of the shoulder it consists of a certain degree of limitation of scapulohumeral abduction, more limitation of external rotation and less limitation of internal rotation. A capsular lesion in the hip by contrast manifests itself with most restriction of internal rotation and less limitation of flexion, abduction and extension, external rotation remaining full range. There are joints in which the capsular pattern includes complete absence of certain movements: the joint is fixed in a certain position. Examples are the subtalar joint, which fixes in full valgus, and midtarsal arthritis in which the joints are fixed in full abduction and external rotation.

The full articular pattern

At the spinal joints, a similar situation is found. When the whole intervertebral joint complex is affected a full articular lesion exists which gives rise to a pattern comparable to the capsular pattern in peripheral joints. However, the lesion is not always capsular and therefore is better described as a 'full articular' pattern, which covers all possible conditions.

Joints not spanned by muscles

Where muscles are not present to cause any limitation of movement, joints are supported by ligaments only. Restriction of movement caused by irritation of the capsule (synovitis) is not possible. There is pain only at the extremes. This phenomenon is found at the acromioclavicular, sternoclavicular, sacroiliac, sacrococcygeal and lower tibiofibular joints, and also at the symphysis pubis.

Limitation with a bony block end-feel

Slight painless limitation of movement with a bony block end-feel occurs in neuropathic arthropathy. The movement causes an ache in gross osteophytosis, myositis ossificans or a malunited fracture.

Non-capsular patterns or partial articular limitation

When the limitation of movements in a certain joint does not correspond to the capsular pattern of that joint, the lesion is clearly not capsular, which means that it does not affect the entire joint. So arthritis is not present.

In contrast to the capsular pattern a non-capsular pattern is less well defined, but for each joint different patterns may occur, all of which do differ from the capsular pattern (see Fig. 4.15).

Partial articular pattern

In the spine the term *partial articular pattern* is more appropriate, indicating that only part of the intervertebral joint complex is affected.

Non-capsular conditions fall into three main categories.

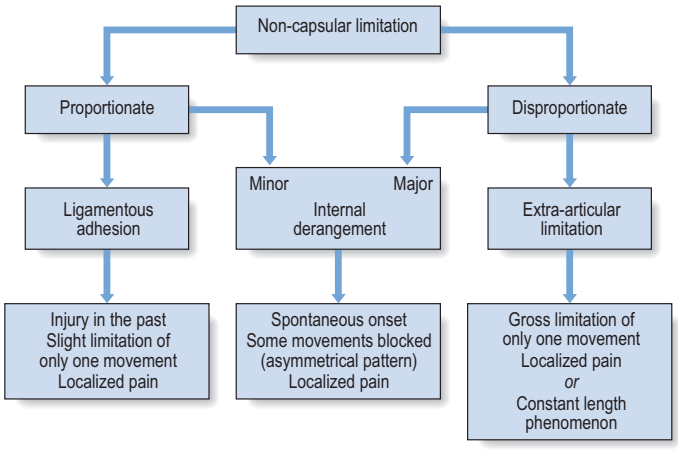

Fig 4.15 • Classification of non-capsular limitation.

Ligamentous adhesions

When a post-traumatic ligamentous lesion heals in the absence of movement macro-adhesions may form (ligament to capsule or underlying bone), which impair function.

One movement is usually limited by localized pain but others may be painful at their extremes. The limitation is *proportionate*: slight restriction in one direction – the one that stretches the affected part of the ligament – and full range in other directions.

Typical examples are the medial collateral ligament of the knee and the lateral ligaments of the ankle. At the knee, flexion is usually 10–15° limited, with pain very localized over the course of the ligament. At the ankle, the combined movement of plantiflexion and inversion is slightly restricted and the tender spot lies in the affected ligament (anterior talofibular, calcaneofibular or calcaneocuboid).

Internal derangement

When fragments of cartilage or bone become loose in a joint, the clinical picture is of internal derangement. The knee is the most common site followed by the spinal joints, the wrist and the jaw and less so the hip, the elbow or the tarsal joints.

Displacement comes on quite suddenly and blocks part of joint movement with localized pain on one aspect and limitation of some movements but not others.

Two different types of limitation occur:

Proportionate derangement. When the displaced fragment is small and lies in such a position that it does not greatly hinder the function of the joint, restriction of movement is also small by comparison with normal movement. The picture may very well mimic the proportionate limitation in ligamentous adhesions but the absence of an injury and the short history exclude this possibility. A typical example is the loose body in an arthrotic knee: flexion is 15–30° limited and the pain is felt at the inner side.

Disproportionate derangement. A large displacement causes gross limitation of movement in some directions and full or almost full range in other directions – an asymmetrical pattern. This is a well-known clinical picture in acute lumbago. Two or three trunk movements are totally blocked and one movement, usually one lateral flexion, is scarcely limited.

Extra-articular limitation

A tissue outside the joint may be damaged and prevent movement in one direction only. A *disproportionate* limitation is then seen: one movement is grossly limited and all other movements are of full range. Such disproportion is only possible when the tissue that causes the limitation lies extra-articularly. In some cases it does not allow stretching, in others it is resistant to compression. Rupture of some muscular fibres (in the quadriceps or in the calf) is followed by localized muscle spasm which prevents stretching. In acute subdeltoid bursitis, gross disproportion is also found between the very limited scapulohumeral abduction and the slight limitation of both rotations.

The 'constant-length' phenomenon. In this phenomenon the degree of limitation of a movement in one joint depends on the position in which the adjacent joint is held. This is only

possible when the structure that prevents stretching spans the two joints. Straight-leg raising is a typical example, with the hamstring muscles spanning the hip and knee joints. The amount of flexion at the hip depends on the position of the knee: when done with the knee extended the movement stops when the hamstring muscles become tight, but flexion of the knee allows full flexion at the hip. Another example is Volkmann's contracture: the fingers cannot be extended without flexing the wrist.

Full range

When no limitation of movement exists on passive testing, the picture may be difficult to interpret. The site of pain usually helps to determine whether it is caused by stretching or by pinching of the affected tissue (Fig. 4.16).

Pain is elicited on stretching

Pain at the extremes of several movements may be found in those joints that are not spanned by muscles. As the capsule of these joints does not have muscular protection the passive tests stretch the ligaments. When, for example, the acromioclavicular joint is affected, the extremes of passive movements at the shoulder are painful.

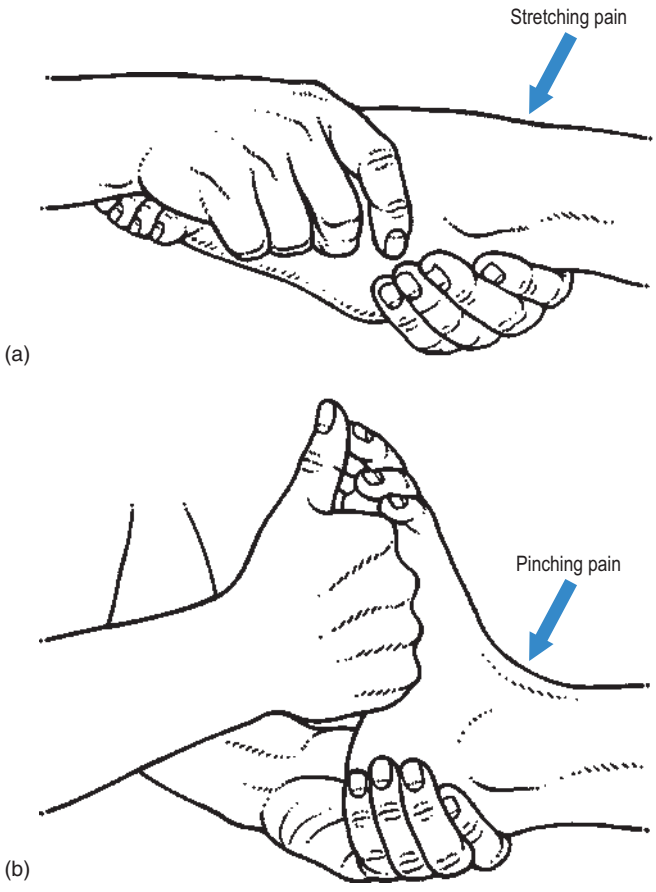

Fig 4.16 • (a) Pain on stretching, (b) pain on pinching.

When only one passive movement causes pain as a result of stretching, the examiner should think in terms of a ligamentous, tendinous or muscular tissue being stretched. In the last of these, resisted movement in the opposite direction is also painful – the 'contractile tissue pattern' (see below). However, an early arthritis in shoulder and hip may, for a short period, show pain at the end of one movement only.

Pain is elicited on pinching

Pinching of a tender tissue may happen at the end of range or at mid-range. In both cases, the pain is the result of the same mechanism. When a passive movement elicits pain at *full range* but the main test result is a resisted movement, this sign sometimes has localizing value. This is seen for example at the shoulder in supraspinatus and subscapularis tendinitis, at the elbow in biceps tendinitis, at the hip in rectus femoris tendinitis and at the heel in Achilles tendinitis. For more details, see the appropriate chapters.

In other cases, logical thinking based on anatomical grounds is required to find out what structure has been painfully pinched. It may be an inert structure (bone, capsule, ligament) or a contractile structure (muscle, tendon). The latter will, of course, show with pain on resisted movements as well. Palpation may then often help to determine the exact localization and local anaesthesia can be used to confirm this.

Pain felt somewhere near *mid-range* in a movement, either passive or active, is called a 'painful arc'. The pain is absent when the movement starts, appears at a certain moment during the movement and disappears again before the end of range is reached. To be called 'painful arc' the pain should disappear at either side of the arc. An arc indicates that the affected structure becomes momentarily compressed between two bony surfaces. Only some structures in the body lie in a position that they can cause a painful arc. It is quite common at the shoulder and in the lumbar spine.

Sometimes the painful arc can be considered a *localizing sign*: its presence shows exactly where the lesion lies. In supraspinatus tendinitis the presence of a painful arc indicates that the lesion lies at the superficial aspect of the tenoperiosteal insertion of the tendon into the greater tuberosity of the humerus, and a painful arc accompanying the signs of a subscapularis tendinitis shows the lesion to lie at the upper part of the insertion at the lesser tuberosity.

Excessive range

Hypermobility is seen in capsuloligamentous laxity and is then a pathological finding. However in some circumstances excessive range can be purely physiological (e.g. passive elbow extension in most women). The matter is considered earlier in this section under *palpation*.

No movement is possible

This is not often encountered but it may result either from a severe muscle spasm, protecting a very acute or irritated lesion or from fibrous or bony ankylosis.

Impairment of resisted movements

In combination with impairment of the passive movements

If a movement against resistance is painful, passive movement in the opposite direction is usually also painful. This is the 'contractile tissue pattern'. When the lesion is tendinous there is a full range of movement. In muscular rupture, the movement that stretches the muscle may be not only painful but also limited because of a localized protective muscular spasm of the fibres around the breach. This phenomenon helps to differentiate between a tendinous and a muscular lesion.

In isolation

One resisted movement is positive

This indicates one muscle or one muscle group is involved. In the latter case, one or more accessory tests are necessary to find the muscle or tendon at fault. For example, resisted extension at the wrist tests the extensors of fingers and wrist; repetition of the test with the fingers held actively flexed distinguishes between finger extensors and wrist extensors. Radial and ulnar deviation against resistance differentiates between the radial extensors (extensor carpi radialis longus and brevis) and the extensor carpi ulnaris.

In combination with impairment of other resisted movements

Two resisted movements are positive

This can occur when two contractile structures are affected or, more probably, when one muscle is affected which combines the two functions. The brachial biceps muscle produces both flexion of the elbow and supination of the forearm. A lesion in this muscle leads to both movements being positive. At the shoulder, the combination of positive resisted external rotation and resisted adduction of the shoulder draws attention to the teres minor, which combines these functions.

Three or more resisted movements are positive

When this occurs, the chance that there is a lesion in a contractile tissue is much less. It is more logical to think of either transmitted stress to a very painful space-occupying lesion, such as a tumour, metastases, abscess or very irritated bursa, or a psychogenic problem.

All resisted movements are positive

This excludes a musculotendinous lesion and has the same interpretive significance as multiple resistance. The examiner should also make sure that the patient does not misinterpret the questions: a hypersensitive patient may equate effort with pain and say that every movement against resistance is painful. Careful comparison of both sides is helpful in avoiding misinterpretation.

Table 4.3 Relationship of pain and strength in resisted movement

Pain	Strength	Disorder
–	Normal	–
+	Normal	Contractile tissue
–	Weak	Nervous lesion Complete rupture
+	Weak	Serious lesion Partial rupture

Pain develops on repetition

Pain developing on repetition of a movement may be indicative of an arterial problem leading to intermittent claudication.

Relationship of pain and strength

Resisted movements test for strength and pain. The patterns that emerge are usually a combination of strength or weakness and the presence or absence of pain. In practice, four combinations may occur (Table 4.3).

Painless and strong

Negative resisted movements – no pain and normal strength – exclude a lesion of a contractile tissue. This axiom is often neglected. For example, patients with pain and local tenderness in the trapezius area are often diagnosed as having a 'trapezius syndrome'. The clinical examination, however, shows the trapezius muscle to function normally. In this case there is no reason to incriminate the muscle. Pain and tenderness are clearly referred, usually from the cervical spine. Another example is when a patient has pain over the long head of the biceps but the tests for that muscle are completely negative, then it is apparent that the muscle is normal and the pain is referred.

Painful and strong

When the resisted movement causes pain but the patient is capable of exerting normal strength, the condition must be a minor lesion in a contractile structure. The possibilities are a muscular strain, a lesion at the musculotendinous junction, a tendinous problem (tendinitis, tenovaginitis or tenosynovitis) or a lesion at the tenoperiosteal junction. Typical examples are supraspinatus tendinitis at the shoulder, lesion of the extensor carpi radialis brevis at the elbow (tennis elbow), tenovaginitis of the extensor pollicis brevis and abductor pollicis longus at the thumb (de Quervain's disease), infrapatellar tendinitis at the knee or peroneal tenosynovitis at the ankle.

Painless (or constant pain) and weak

The patient is either pain-free or in constant pain. The test against resistance, although weak, does not elicit or alter the pain. This is usually the result of a nervous condition, either extrinsic or intrinsic. Dependent on the severity of the lesion the weakness detected may vary from very moderate to complete paralysis.

Complete rupture of a muscle or a tendon also leads to a painless total loss of strength (see earlier).

Painful and weak

This combination suggests a major lesion. The movement is painful and its strength is reduced, either because the muscle is functioning poorly or because the attempt to use it increases the pain sufficiently to inhibit full contraction. This pattern occurs in serious disorders, such as fracture or metastases. Usually there are also articular signs. When after an 'ankle sprain' resisted eversion proves painful and weak, a fracture of the tuberosity of the fifth metatarsal bone is suggested. Metastases in the upper femur or in the cervical spine give rise to weakness in resisted movements of the hip or the neck.

If only one movement is painful and weak and the joint moves normally, a partial rupture of a muscle or tendon is probably present, although a severe tendinitis may cause an identical picture.

Positive resisted movements in lesions of non-contractile structures

There are three situations in which muscular contraction causes pain in the absence of any musculotendinous lesion.

The first is a bony lesion (e.g. fracture or metastases) close to the insertion of a muscle or tendon: when the muscle is tested against resistance, the contraction causes pull at the site and the test is painful and possibly associated with weakness. Stress fracture of the pubic bone causes pain felt on resisted adduction of the hip and in an anterior upper rib fracture contraction of the pectoralis major muscle hurts.

The second is compression of a tender structure by a contracted muscle belly which is often encountered in the buttock where an irritated gluteal or trochanteric bursa can be compressed by contraction of the gluteus medius muscle.

The third is in patients with psychological problems, when resisted movements are quite often more painful than passive or active ones (see online chapter *Psychogenic pain*).

Absence of pain on functional testing

For a given region a negative functional examination, including accessory functional tests, implies that the pain is referred. Other parts of the locomotor system from which the pain might originate are then examined. When nothing is found, the lesion is clearly non-orthopaedic, most probably nervous but possibly visceral. Also small bony lesions (e.g. osteoid osteoma) along the shaft of a long bone may cause localized pain without influencing the function of an adjacent joint.

Warning

Every patient with a clear pattern of symptoms in the absence of positive signs on clinical examination should be referred for more specialized investigations.

Summary

The interpretation of resisted passive movements is summarized in Figure 4.17.

Diagnostic difficulties

Very slight pain

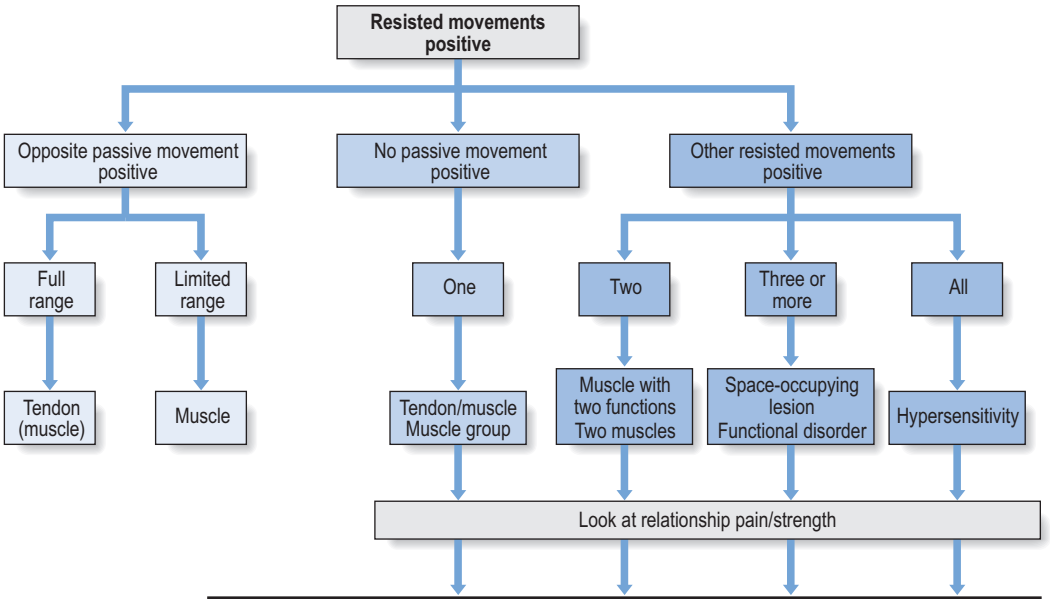
When the patient has very little pain, examination can be totally negative. Palpation is very dangerous in these cases for the reasons mentioned earlier. It is better to re-examine 1–2 weeks later. If spontaneous recovery has not taken place, it is likely that some signs will have developed. Another way to proceed is to seek to provoke signs by having the patient exercise sufficiently to produce symptoms. Clearly a diagnosis is impossible as long as signs are absent.

Very severe pain

Certain conditions are so painful that it is hard for the patient to state accurately where and when pain is felt. Functional testing and its interpretation are also difficult, either because excessive physical signs are presented or because the patient cannot move and is opposed to carrying out potentially diagnostic manœuvres. Severe pain may interfere with the ability to cooperate so that, for example, a resisted movement cannot be done properly. After an injury, swelling and/or haematoma may also render palpation impossible: for example, in the first days after an ankle sprain the condition may be so acute that no clear pattern emerges on examination; lumbago may be so painful that any movement becomes impossible. History is then of great importance, particularly the presence or absence of warning signs. The number of conditions that can provoke such severe pain is limited and the examiner must try to interpret the symptoms in the light of the realistic possibilities.

Non-orthopaedic disorders

Some neurological, vascular or visceral disorders may cause diffuse pain which resembles the symptoms of a lesion of the locomotor system. A patient who complains of vague pains, especially in the trunk, but has negative findings on locomotor and soft tissue examination should be referred for further neurological, vascular or internal examination.



Pain	One contractile tissue	Double lesion Space-occupying lesion	Space-occupying lesion	Space-occupying lesion
Pain and weakness	Partial rupture Fracture Space-occupying lesion			Fracture Serious disorder Space-occupying lesion Functional disorder
Weakness	Complete rupture		Neurological lesion: peripheral nerve or nerve root Gross neurological lesion Functional disorder	

Fig 4.17 • Interpretation of resisted and passive movements.

Difficult clinical pictures

Conditions affecting the spinal column may give rise to vague, diffuse pain felt somewhere in the trunk. If the anterior longitudinal ligament becomes affected in ankylosing spondylitis, pain may be referred to the sternum or to the epigastrium. For those who are not familiar with the phenomenon of dural pain, the extensive and vague radiation of multisegmental pain can be very confusing.

A patient may present the symptoms and signs of a genuine, although minor, lesion which is overshadowed by psychogenic features. The picture is correct in quality, but grossly excessive in quantity. The examiner recognizes the truth within the patient's story but finds that it is interwoven with unlikelihoods and improbable signs are mixed up with the genuine findings (see online chapter *Psychogenic pain*).

The occurrence of a double lesion is not so uncommon and it quite often does not cause a problem, especially when the two conditions can be clearly distinguished because they cause pain in different places or show different sets of signs. Interpretation is more difficult when they lie close together or when the symptoms and signs of one clearly dominates. The examiner can make a diagnosis based on those symptoms and signs that are understood and wait until one problem is solved before attempting to interpret the remaining features. It is indeed a sound principle never to treat two conditions at the same time. The choice of which to treat first can be based on several criteria: pain, frequency, importance and the 'approachability' of the lesion. It is logical to try to improve the more painful lesion first. If doubt exists as to which structure is at fault, the condition that is statistically more common is treated. A problem in a joint – usually arthritis – is dealt with first. Finally, when it is known that one condition can be more quickly treated than another, this condition is treated first.

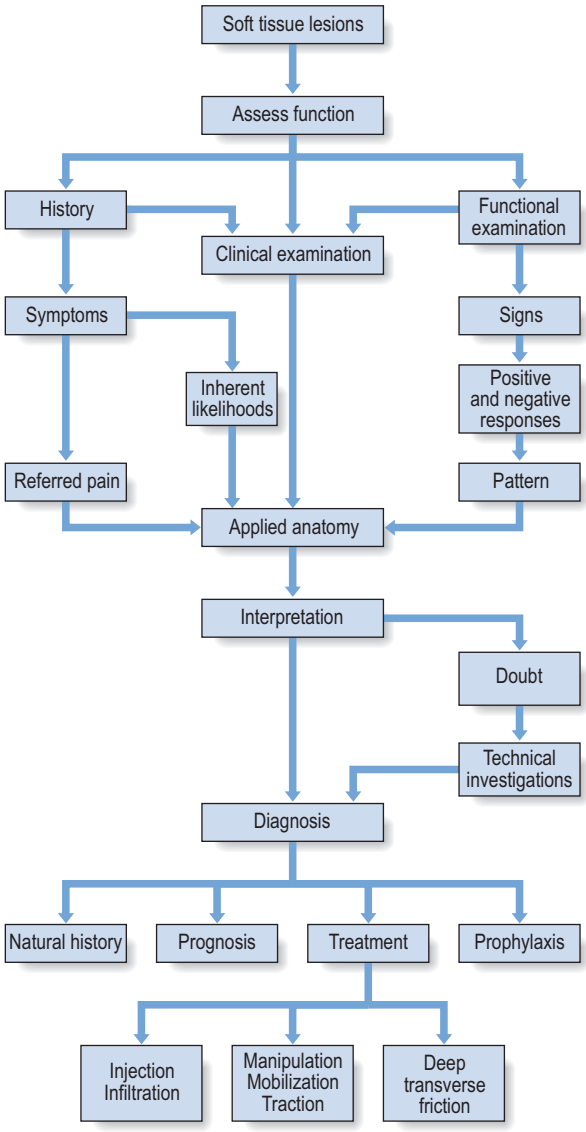


Fig 4.18 • Clinical approach in orthopaedic medicine.

The clinical approach in orthopaedic medicine is summarized in Fig. 4.18.

Psychogenic problems

Introduction

Cyriax had a straightforward opinion about treating orthopaedic problems:

- All pain arises from a source
- All treatment must reach the source
- All treatment must exert a beneficial effect on it.

It is obvious that the method of treatment will depend largely on the existing type of disorder.

In orthopaedic medicine, disorders may be grossly categorized as follows:

- *Traumatic* – an injury resulting either from one single trauma or from multiple small traumas, the so-called overuse injuries
- *Inflammatory* – rheumatoid: poly- or monoarticular, infectious, traumatic
- *Degenerative*
- *Internal derangement* – loose bodies and displaced menisci in peripheral joints and intervertebral disc displacements in the spine
- *Functional disorders* – instability, weakness, proprioceptive disturbances
- *Psychogenic pain* – there is no existing functional or anatomical explanation for the pain.

However, most 'disorders' have a combined aetiology: traumatic inflammation or repetitive internal derangement may lead to functional instability or to weakening of the proprioceptive reflexes; long-standing functional disorders may lead to psychogenic decompensation.

Before any form of treatment is undertaken, precise diagnosis is mandatory; it is the type, extent and position of the disorder present which determines treatment. Therefore training in orthopaedic medicine must put great emphasis on how to reach a proper diagnosis. It is more difficult and requires considerable delicacy of approach to teach and learn how to diagnose and so to propose therapy chosen on logical grounds, than it is to instruct and learn treatment techniques. Other aspects must also be taken into account: how much pain can the patient bear? To what extent does the lesion interfere with normal activities? How eager is the patient to receive a quick

cure? And what is the patient's attitude towards certain therapeutic methods such as corticosteroids and manipulation?

Orthopaedic medicine based on a detailed functional examination requires more knowledge, skill, time and effort from the physician than just to order technical investigations, but leads to greater professional interest, more appropriate diagnosis and a higher degree of patient satisfaction. Clear diagnosis and consequent selection of treatment on logical grounds also leads to better understanding between doctors and therapists. Because the two groups work with the same types of patient, they must share a common approach. Therapists should no longer be regarded purely as technicians who listen to the physician and carry out orders. On the contrary, they should be aware that they have diagnostic and therapeutic responsibilities. Their opinion must be taken seriously and is important to avoid unnecessary delay in achieving a satisfactory outcome.

Techniques

The treatment techniques used in orthopaedic medicine thus depend entirely on the type of disorder. The different types of treatment we describe are:

- *Manipulation techniques* (rapid, small-amplitude, thrusting passive movement – also called 'grade C mobilization') are used to reduce small cartilaginous displaced fragments both in the spine and in peripheral joints (loose bodies). Manipulation is also called for to restore normal mobility in a joint restricted by ligamentous adhesion and in subluxation of bones.
- Gentle *passive mobilizations* (grade A and B mobilizations) are used to stretch capsular adhesions and to improve the function of ligaments and tendons. In the treatment of traumatic injuries they are often used in combination with deep transverse massage.
- *Active movements* and proprioceptive training are needed in the treatment of functional disorders and instability. In the treatment of minor muscular tears they are very useful in avoiding the formation of abnormal intralesional adhesion formation.
- *Injection and infiltration techniques* are used to reduce traumatic or rheumatoid inflammation. They are most valuable in arthritis, bursitis, ligamentous and tendinous lesions and in neurocompression syndromes.
- *Deep friction* is a very useful technique in treating traumatic and overuse soft tissue lesions. The rationale for using deep friction (which is in fact a form of soft tissue mobilization) is supported by experimental studies of the past several decades that confirm and explain the beneficial effects of activity on the healing musculoskeletal tissues (see Connective tissue).

Repair and remodelling of healing tissues respond to cyclic loading and motion.[1] Early motion and loading of injured tissues is not without risk, however, and excessive loading can inhibit or stop healing. Deep transverse friction imposes cyclic loading without bringing too much tension on the healing longitudinal structures of tendon or ligament and can therefore be considered as beneficial.

Deep transverse friction

Deep transverse friction (although the word friction is technically incorrect and would be better replaced by 'massage') is a specific type of connective tissue massage[2] developed in an empirical way by Cyriax.[3]

Transverse massage is applied by the finger(s) directly to the lesion and transverse to the direction of the fibres. It can be used after an injury and for mechanical overuse in muscular, tendinous and ligamentous structures.[4–6] In many instances the friction massage is an alternative to infiltrations with steroids. Friction is usually slower in effect than injections but leads to a physically more fundamental resolution, resulting in more permanent cure and less recurrence. Whereas steroid injection is usually successful in 1–2 weeks, deep friction may require up to 6 weeks to have its full effect.

The technique is often used before and in conjunction with mobilization techniques. In minor muscular tears, friction is usually followed by active movement, in ligamentous tears by passive movement and in tendinous lesions by active unloaded movements until full resolution has been achieved.

It is vital that transverse massage is performed *only at the site of the lesion*. The effect is so local that, unless the finger is applied to the exact site and friction given in the right direction, relief cannot be expected.

Over the years, and unfortunately enough, the technique has developed a reputation for being very painful for the patient. However, pain during friction massage is usually the result of a wrong indication, a wrong technique or an unaccustomed amount of pressure. Friction massage applied correctly will quickly result in an analgesic effect over the treated area and is seldom a painful experience for the patient.

Mode of action

Transverse massage should be used empirically for what it is and what it achieves; there is no scientific proof for any postulates about the underlying mechanism of action.

Only a few studies exist,[7,8,9] and more research is urgently needed. However, experienced therapists know in what kind of soft tissues they can expect good results with transverse massage and where the technique does not work. Transverse massage either is effective quickly (after 6–10 sessions) or not at all. Advice on indications, contraindications and modalities of the technique that are given in this book rely solely on the experiences of the authors and not on scientific research.

However, although the exact mode of action is not known, some theoretical explanations have been put forward. It has been hypothesized that friction has a local pain-diminishing effect and results in better alignment of connective tissue fibrils.

Relief of pain

It is a common clinical observation that application of local transverse friction leads to immediate pain relief – the patient

experiences a numbing effect during the friction and reassessment immediately after the session shows reduction in pain and increase in strength and mobility. The time to produce analgesia during the application of transverse friction is a few minutes and the post-massage analgesic effect may last more than 24 hours.[10] The temporary relief at the end of a session may prepare the patient for treatment with mobilization not otherwise possible, such as selective rupture of unwanted adhesions.

A number of hypotheses to explain the pain-relieving effect of transverse massage have been put forward:

- Pain relief during and after friction massage may be the result of modulation of the nociceptive impulses at spinal cord level: the *gate control theory* (see Ch. 1). The centripetal projection into the dorsal horn of the spinal cord from the nociceptive receptor system is inhibited by the concurrent activity of the mechanoreceptors located in the same tissues. Selective stimulation of the mechanoreceptors by rhythmical movements over the affected area thus 'closes the gate for pain afference'.
- According to Cyriax, friction also leads to increased destruction of pain-provoking metabolites, such as Lewis's substances. This metabolite, if present in too high a concentration, provokes ischaemia and pain.[3]
- It has also been suggested that prolonged deep friction of a localized area may give rise to a lasting peripheral disturbance of nerve tissue, with local anaesthetic effect.
- Another mechanism through which reduction in pain may be achieved is through diffuse noxious inhibitory controls, a pain-suppression mechanism that releases endogenous opiates. The latter are inhibitory neurotransmitters that diminish the intensity of the pain transmitted to higher centres.[11–13]

Effect on connective tissue repair

Connective tissue regenerates largely as a consequence of the action of inflammatory cells, vascular and lymphatic endothelial cells and fibroblasts. Regeneration comprises three main phases: inflammation, proliferation (granulation) and remodelling. These events do not occur separately but form a continuous sequence of changes (cell, matrix and vascular changes) that begins with the release of inflammatory mediators and ends with the remodelling of the repaired tissue (see Ch. 3). Friction massage may have a beneficial effect on all three phases of repair.

Friction stimulates phagocytosis

It has been suggested that gentle transverse friction, applied in the early inflammatory phase enhances the mobilization of tissue fluid and therefore increases the rate of phagocytosis.[14]

Friction stimulates fibre orientation in regenerating connective tissue

During maturation, the scar tissue is reshaped and strengthened by removing, reorganizing and replacing cells and matrix.[15]

It is now generally recognized that internal and external mechanical stress applied to the repair tissue is the main stimulus for remodelling immature and weak scar tissue – with fibres that are oriented in all directions and through several planes – into linearly rearranged bundles of connective tissues.[16] Therefore, during the healing period, the affected structures should be kept mobile by normal use. However, because of pain, the tissues cannot be moved to their full extent. This problem can be solved by friction. Transverse friction massage imposes rhythmical stress transversely to the remodelling collagenous structures of the connective tissue and thus reorients the collagen in a longitudinal fashion. Friction is thus a useful treatment to apply early in the repair cycle (granulation and beginning of remodelling stage): the cyclic loading on and motion of the healing connective tissues stimulates formation and remodelling of the collagen.[17]

Friction prevents adhesion formation and ruptures unwanted adhesions (Fig. 5.1)

In that transverse friction aims to achieve transverse movement of the collagen structure of the connective tissue, crosslinks and adhesion formation are prevented. In the early stages of proliferation when crosslinks are absent or still weak, friction must be very light so as to cause only minimal discomfort. Therefore, in the first day or two following an injury, friction is given with slight pressure only and over a short duration, e.g. 1 minute.

At a later stage when strong crosslinks or adhesions have formed, more intense friction is needed to break these

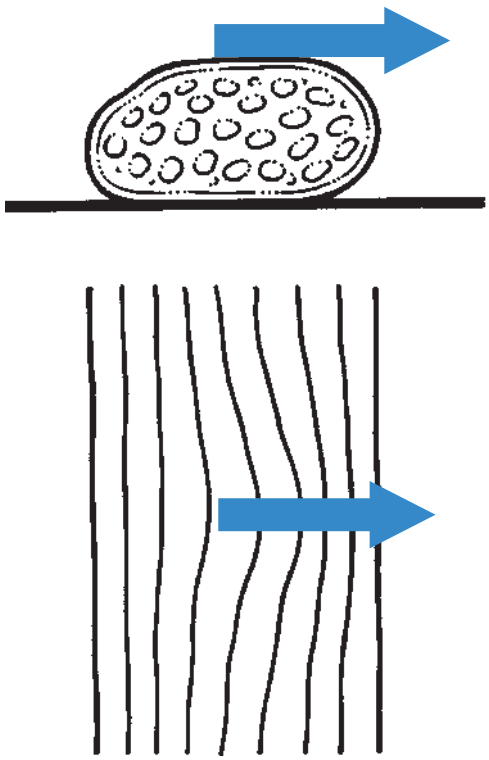

Fig 5.1 • Friction achieves a transverse movement between longitudinally arranged collagenous fibres.

down.[18–21] The technique is then used to soften the scar tissue and to mobilize the crosslinks between the collagen fibres and the adhesions between healing connective tissue and surrounding tissues. This, together with the local anaesthesia produced, prepares the structures for mobilizations that apply longitudinal stress to the structures and rupture the larger adhesions.

Friction induces traumatic hyperaemia

Forceful deep friction produces vasodilatation and increased blood flow to the area. It may be hypothesized that this facilitates the removal of chemical irritants and increases the transportation of endogenous opiates, so causing a decrease in pain. Such a forceful friction, resulting in hyperaemia is only desirable in chronic, self-perpetuating lesions.

Indications

Diagnosis

The reduction in pain achieved after a few minutes of localized transverse friction may be very helpful to define the exact location of the lesion. In muscular, tendinous or ligamentous lesions, a few minutes of massage on the suspected area results in diminished pain on testing immediately thereafter, so confirming the diagnosis as accurately as an infiltration with local anaesthesia.

Preparation for mobilizations and manipulation

Transverse massage is often applied before and in conjunction with other mobilizing techniques. In muscular lesions, friction is given before active or electrical contractions on an unloaded muscle. The purpose is to allow broadening of the muscle and so the prevention of adhesion formation between adjacent muscle fibres and/or bundles.

For reasons of pain relief, transverse massage is usually required before manipulative breakage of ligamentous adhesions is performed. This may be indicated in chronic ligamentous lesions at knee and ankle.

Deep and thorough friction also precedes manipulation of the elbow in type II tennis elbow. The technique is used for its desensitizing and softening effect which makes the manipulation more tolerable.

Therapy

Muscle bellies

Friction is given to a healing muscle belly after contusion, in minor muscular tears and in so-called 'myosynovitis'. In minor muscular tears the friction is often part of combined treatment because it is usually applied after an infiltration with local anaesthesia and is followed by active contractions.

The aim of treatment in muscular tears is to allow the torn fibres to heal in such a way that normal increase in breadth on contraction remains possible, a characteristic that can be disturbed by abnormal adhesion formation. Transverse friction aims to achieve a transverse sweeping movement over the longitudinal muscular fibres without pulling on the tear, so to prevent (in the early stage) or to break down (in the chronic stage) adhesion formation between the individual fibres and between individual fibres and the surrounding connective tissue. It is obvious that to break down crosslinks in a chronic stage, the friction can be given forcefully and for a duration of 15–20 minutes, whereas in more recent lesions the technique must be applied more gently and for a shorter duration. Friction to a muscle belly is always given with the muscle well relaxed.

In recent tears, especially in the large muscles of the lower limb, friction is followed by active or electrical contractions with the muscle in a position of maximal relaxation and without weight bearing, so that tension does not fall on the healing breach.

To avoid early recurrence, friction is given for 1 week after all clinical tests have become negative. During the period of treatment, all movements or activities that bring on pain should be avoided by the patient.

Theoretically, friction can be used for all muscle belly lesions. However, some lesions respond so well to local anaesthetic infiltration that friction is not used. This is the case in type IV tennis elbow (lesion at the muscle belly of the extensor carpi radialis). On the other hand, sometimes no alternatives exist to treatment with deep transverse friction (Box 5.1). A lesion of the subclavius or intercostal muscles for instance can be treated only by deep transverse friction.

Musculotendinous junctions

It is a common clinical experience that all musculotendinous junctions (containing both muscular and tendinous fibres) throughout the whole body can be treated only by deep transverse friction. It would seem that no alternatives exist: local anaesthetics, so curative for some lesions of muscle bellies, and steroids, so effective for tenoperiosteal lesions, have not the slightest effect on musculotendinous lesions, whereas deep transverse friction usually has.

Tendons

All overuse tendinitis can be treated by deep massage except for the tenoperiosteal origin of the extensor carpi radialis brevis (type II tennis elbow), which is best treated by an infiltration with corticosteroid or, in refractory circumstances, sometimes by manipulations.

Box 5.1

Muscle belly disorders that can be treated only by deep transverse friction

Subclavius
Brachialis
Supinator
Adductors of the thumb
Interosseus muscles of the hand
Intercostal muscles
Oblique muscles of the abdomen
Interosseus muscles of the foot

Tenosynovitis also usually responds well to deep transverse massage. In this condition, occurring in long tendons with a sheath, inflammation and roughening of the gliding surfaces of both tendon and sheath give rise to pain and sometimes to crepitus. Friction rolls the sheath around the stretched tendon, so facilitating functional movement between the tendon and its sheath. The technique is useful in both acute and chronic lesions.

Lesions at the tenoperiosteal insertion can be treated either with corticosteroid infiltrations or with deep transverse massage. Corticosteroid suspension quickly converts an inflamed and painful scar into one free of inflammation. However, the recurrence rate is rather high, between 20% and 25%.[3] The aim of the massage is to get rid of the self-perpetuating inflammation by breaking up the disorderly scar tissue and adhesion formation by converting it into properly arranged longitudinal connective fibres. This takes longer but once cure is achieved there will be less of a tendency towards recurrence. It may therefore be a policy to start treatment with infiltrations but if the trouble recurs after a few months to substitute with massage.

As a rule, however, friction is always selected as the treatment of choice in athletes or when the tendon is weakened (partial rupture). It cannot be denied that repeated use of corticosteroids, even in small doses and correctly applied, temporarily weakens a tendinous structure. Steroids also take away inflammation and pain, so giving the patient the false impression of being cured. The combination of a weakened tendon and abolition of pain can be disastrous – rupture may ensue.

There exist also a few conditions that seem to respond only to deep transverse friction. Steroid infiltrations are useless here. This is so in tendinous lesions of the interosseus in the hand and at the quadriceps expansion at the patella.

Lesions in the tendinous body, either traumatic or resulting from overuse, are contraindications for infiltration with corticosteroids. Ruptures have been reported after intralesional steroid infiltrations of long tendons and therefore deep frictions are the treatment of choice here.[22,23]

It is obvious that during the whole period of treatment of tendinitis, tenosynovitis or tenovaginitis, the patient must avoid all activities that provoke the pain, especially the loading of the affected contractile tissue.

Ligaments

Transverse massage is an excellent treatment in acutely sprained ligaments, especially in ligaments of the knee and ankle. The background, mode of action and technique differ considerably and depend on the stage of the lesion.

It has been explained (see Ch. 3) that early mobilization is extremely important for swift and full recovery of ligamentous sprains. However, in advocating this, one main difficulty is encountered: the intensity of the initial inflammatory reaction. The slightest movement causes pain which forces the patient to immobilize the joint and the ligaments. However, during immobilization, regenerating fibrils quickly start to form randomly organized scar tissue, leading to crosslinks and adhesion formation. This problem can be solved by gentle transverse frictions. Rhythmic movement across the inflamed ligament eases the pain and the tissue can be moved to and fro in an imitation of its normal behaviour.

In recent cases the friction need not last long nor be very vigorous – 1 or 2 minutes of daily gentle transverse sweeping movement over the regenerating fibrils is enough. As pain diminishes over subsequent days friction is progressively increased to about 4–5 minutes for 2 or 3 days and finally to a full duration of 15–20 minutes. From the third day, friction is followed by passive and active movements within the limits of pain to maintain normal gliding of the ligament over adjacent bones. When the lower limb is involved, the patient should be instructed to walk as normally as possible but without provoking too much pain.

In chronic ligamentous lesions, frictions are also used but in a totally different way. Here adherent scar tissue has formed abnormal attachments as the result of healing during a period of insufficient movement. As a result of the reduced mobility of the ligament, vigorous use of the joint re-sprains the ligament and in due course leads to recurrent sprains.

Treatment will consist of rupturing the adhesions by manipulation, for which vigorous deep friction to the site of the adhesions prepares the ligaments. The massage weakens and desensitizes the structure, making the forced movement practicable and painless.

Experience has shown that particular ligamentous lesions can be treated only by friction. This is the case for the posterior carpal ligaments at the wrist and the tibiotalar ligaments.

Joint capsules

Deep transverse friction can be applied to the capsules of the trapezium–first metacarpal joint, the temporomandibular joint and the cervical facet joints. The indication is traumatic arthritis or osteoarthrosis. Results are fair, provided the arthrosis is not too advanced. Indications and contraindications to friction are outlined in Table 5.1.

Contraindications

Ossification and calcification of soft tissues

Extensive ossification in muscles, tendons, ligaments or capsules is a bar to all active treatment. However the minor calcifications that may occur after a sprain can be managed by

Table 5.1 Indications and contraindications to friction

Indications	Contraindications
Diagnostic difficulties	Ossification and calcification of soft tissues
Preparative massage	Bacterial and rheumatoid-type tendinitis, tenosynovitis and tenovaginitis
Therapeutic massage:	Skin problems such as ulcers, psoriasis or blisters
• To muscle bellies	Neighbouring bacterial infection
• To musculotendinous junctions	Bursitis and disorders of nerve structures
• To tendons	Haematoma, if large
• To ligaments	
• To joint capsules	

friction. In supraspinatus tendinitis, calcification is regarded as responsible for complaints when the insertion is very tender to touch and a radiograph shows calcification. These findings are a contraindication to friction. In contrast, when calcification is present in the absence of severe tenderness, transverse massage can be given.

Bacterial and rheumatoid-type tendinitis, tenosynovitis, tenovaginitis

All types of bacterial and rheumatoid disorders, no matter at what stage of inflammation, are absolute contraindications to friction.

Skin problems such as ulcers, psoriasis and blisters

When normal skin has been abraided – sometimes by friction – massage should not be given. In skin disorders, it must be abandoned when stable skin–finger contact becomes impossible and friction aggravates the skin problem.

Neighbouring bacterial infection

Because these may be reactivated by or may extend if friction is used, it must be postponed until the infection has resolved.

Bursitis and disorders of nerve structures

When bursitis is mistaken for a tendinous or ligamentous disorder and friction is given, the problem will either increase or, at best, the pain will remain unchanged – it certainly will not improve. Friction to a nerve is also harmful.

Haematoma

A haematoma in a muscle belly or after an ankle sprain is not a contraindication to friction. Even if the haematoma is the result of deep friction, treatment may be continued unless the effusion is large.

Technique

Introduction

Transverse massage is not an easy technique. In order to produce results, three conditions must be satisfied.

First, the therapeutic movement should be applied to the exact site of the lesion which may occupy only a very small volume of tissue. In other words, an identification of the site to within 1 cm must be achieved which relies entirely on clinical diagnosis and palpation of the lesion, based in turn on anatomical knowledge. In some instances it will be necessary to palpate carefully the entire structure at fault so as to find the point that reproduces the patient's pain.

Secondly, friction should be applied transversely across the longitudinally orientated fibres, with sufficient sweep to reach all the affected tissue and firmly enough to produce movement between the individual connective tissue fibres of the affected structure.

Third, the movement can only reach deeply seated structures if the deep friction technique of Cyriax is used; that implies attention must be paid to different elements such as the position of the patient and of the therapist's hand, which fingers are used, the amount of pressure, the duration and frequency of the sessions. The patient's skin and the therapist's finger must move as one, so that the deep layers of the skin move over the affected fibres. Therefore all cream, ointments, powder or any other procedure, such as previous heat, that makes the skin sweat, must be avoided. Six to 12 treatments are normally necessary. Except in acute ligamentous disorders they are not given more often than every other day because otherwise the site of the lesion may still be too tender from the previous treatment to permit adequate massage.

Position of the patient

The patient's position must be *comfortable* because it must be maintained for up to 15–20 minutes. Sitting or lying is preferable.

The lesion must be brought *within finger's reach*. In some structures this can be easily attained but others such as the supraspinatus insertion and the anterior aspect of Achilles tendon, require more specific positioning of the patient.

In addition, positioning must place the affected structure under the *required amount of tension*. Full relaxation is necessary for a muscle belly in order not only to treat its surface but also to access a deeply seated lesion. Tendons with a sheath must be kept taut otherwise friction will be ineffective between tendon and sheath. The same applies in ligamentous lesions, which are also placed in tension but within the limits of pain.

Position of the therapist and the hands

The bodily position of the patient should be the most comfortable and least tiring for the therapist. Working height is of chief importance, so an adjustable high–low couch is ideal. To have some economy of effort the therapist should adopt a position that utilizes body weight to a maximum. Usually this is standing and with the patient on a slightly lower plane. The therapist should avoid flexed positions. The shoulder should also not be in abduction because this quickly leads to pain and cramp in the neck and shoulder girdle.

Massage is performed by the whole arm and is not just an activity of hand and digits. Movement is generated in the shoulder and conducted via elbow and forearm to the digits. One set of muscles is used to apply force and another to provide movement, for example pressure with the fingers, movement with the arms. Digits, hand and forearm should generally form a straight line and are kept parallel to the direction of movement.

The majority of friction techniques are performed in two phases: *an active movement*, usually as a result of flexor muscular activity and a *passive movement*, when the arm and hand are returned to the starting position. At the end of the passive phase there should also be a moment of rest during which the therapist fully relaxes the muscles.

The hands can be used in a variety of ways depending on the tissues to be treated and the surface worked on. The wrist and metacarpophalangeal joints should be kept in an almost neutral position. The interphalangeal joints are slightly flexed to avoid traumatic arthritis.

Three main techniques can be distinguished.

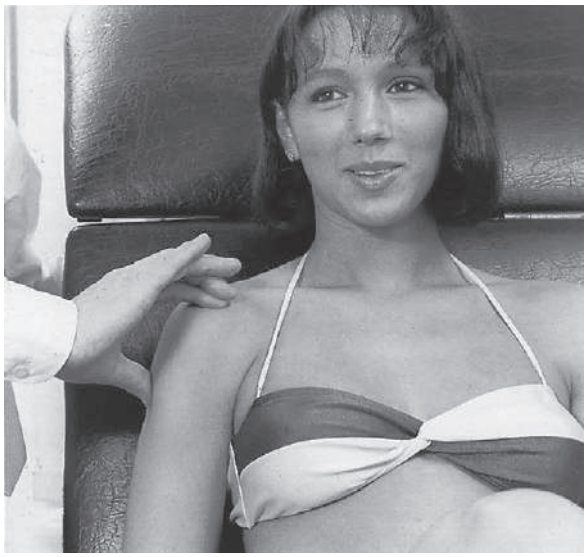
To-and-fro movements

These are used in the treatment of dense, round or flat collagenous bundles (tendons or ligaments) and in the treatment of tenosynovitis. The active phase is a sweep with the tip(s) of one or two digits across the tendinous structure. During the passive relaxation phase the finger is returned to the starting position, without losing contact between finger and skin. Movement is with the arm; friction is given by use of the pulpy part of the finger (Fig. 5.2). In large lesions, as in peroneal tendinitis, two or three adjacent fingers are used together. In deep-seated lesions as in tendinitis of the long head of biceps in the bicipital groove or at its insertion on the radius or in infraspinatus tendinitis, the thumb performs friction.

Counterpressure is usually provided to enable a good sweep. The finger(s) applying counterpressure and stabilization are most important in bringing those applying friction into the right position and also determining the direction of the friction. The thumb is used (to give counterpressure) when the sweep is performed by a movement of the index reinforced by the middle finger or the middle finger aided by the index finger. When the thumb does the massage, counterpressure is from the fingers (Fig. 5.3). The most common way of applying friction around a round edge on a flat surface is to use the index reinforced by the middle finger. Sometimes the opposite is done: the middle finger is reinforced by the index. Sometimes counterpressure is not given, for example in friction to the quadriceps expansion or intercostal muscles.

Pronation–supination

This technique is often used where the lesion is difficult to reach: the anterior aspect of the Achilles tendon, popliteus tendon and the dorsal interossei of the metacarpals. Massage



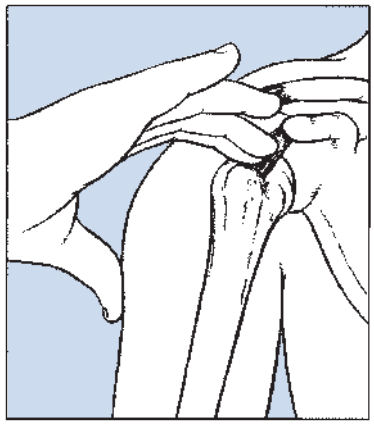


Fig 5.2 • Friction to the supraspinatus tendon: counterpressure is by the thumb.

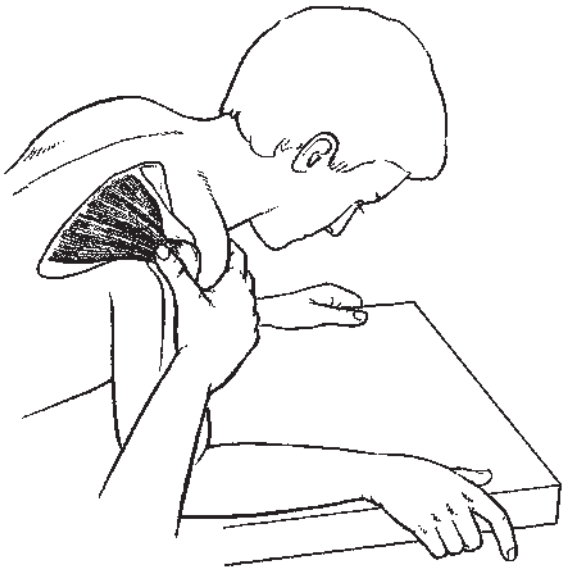

Fig 5.3 • Friction to the infraspinatus tendon: counterpressure is by the fingers.

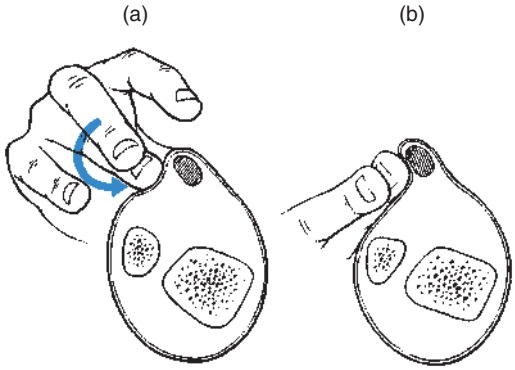

Fig 5.4 • Active phase of pronation–supination friction technique to the anterior aspect of the Achilles tendon. a, starting position; b, end of supination (active) movement.

is performed with the pulpy part of the third finger (long finger), reinforced by the index finger. The long finger is used because its long axis is the prolongation of the axis of pronation–supination rotation of the forearm (Fig. 5.4).

The active phase is usually on supination. No counterpressure is given. Caution is taken not to move the finger on the skin but rather to move the skin and the fingertip as a whole. The passive phase is the pronation movement that brings the frictioning finger back to the starting position without losing contact with the skin.

Pinch grip

This is the normal technique for a muscle belly. The pinch is between the thumb and the other fingers. The muscle is fully relaxed. The fingers are placed at one side of the affected area and the thumb at the opposite side (Fig. 5.5). By drawing the fingers upwards over the affected area, the therapist feels the muscle fibres escape from the grip until only skin and subcutaneous tissue remain.

During the passive phase the fingers are slightly relaxed and moved downwards into the previous deep position where the same movement starts again.

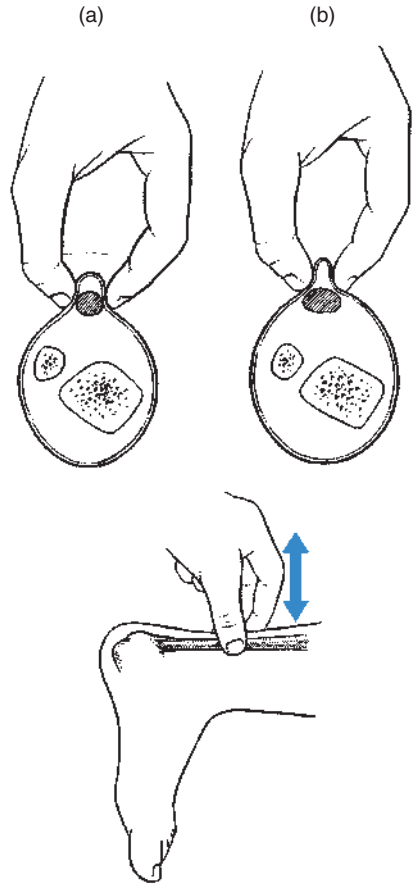

Fig 5.5 • Pinch grip friction to the Achilles tendon. a, starting position; b, end of active phase.

Sometimes the same technique is used in tendinous lesions, for example, at the sides of the Achilles tendon.

No movement between finger and skin is allowed

Deep friction can only be effective when skin and subcutaneous fascia are moved over tendon ligaments or muscles. No movement is allowed between the therapist's finger and the

patient's skin. If movement occurs between finger and skin, blistering soon takes place and usually indicates faulty technique. Sometimes it can be avoided by keeping the skin dry by the use of 95% alcohol in water and/or by placing a piece of cotton in between the finger and the skin.

In the obese, subcutaneous soreness and/or ecchymosis may occasionally occur and sometimes a nodule may form. For this reason the finger should not be in continuous contact with the same area but should displace the skin slightly to one or other side, before pressure is applied.

Direction of friction must be transverse to the tissue fibres

Longitudinal massage improves the circulation of blood and lymph but has no effect on musculoskeletal lesions. On the contrary, because lesions of tendons, muscles and ligaments are normally caused by a longitudinal force, longitudinal massage can possibly be harmful in that it may separate the ruptured ends further. To restore and/or maintain full mobility of a lesion, massage must be given across the fibres, so moving all fibres in relation to each other. To achieve this, the therapist must have a good anatomical knowledge of the direction of the fibres.

Sweep

The main goal of friction is to move fibres in relation to each other and adjacent structures. Enough sweep must be given to the friction for this purpose, so the frictioning finger starts at the far side of the lesion, glides over it and ends at the near edge. Pressure alone, however hard and painful it may be, is totally ineffective. Adequate sweep is sometimes limited by the amount and elasticity of the overlying skin. Initial displacement of skin over the lesion from the near to the far side may help increase sweep and reduce the risk of blistering.

Amount of pressure

Over recent decades, friction has been held in some disrepute in that it was perceived by some as synonymous with very painful treatment. Though it cannot be claimed as wholly pain-free, the pain should not be unbearable. When excessive pain is provoked, this is usually the result of a failure to understand the meaning of the term 'deep', which means 'as deep as needed to reach the lesion'. Many therapists misinterpret this in such a way that they feel that they always have to work hard physically, which obviously leads to pain and may do more harm than good.

The amount of pressure applied depends on three elements:

- *The depth of the lesion*: that friction must always reach sufficient depth to move the affected fibres in relation to their neighbours and sometimes the underlying bone or capsule, increased pressure must be applied to deeper structures.
- *The 'age' of the lesion*: recent sprains and injuries require only preventive friction because crosslinks or adhesions have not had time to form. In long-standing cases more pressure is needed to get rid of these. However, pressure should always be associated with movement and should not replace it because pressure alone is both painful and ineffective.
- *The tenderness of the lesion*: in severely inflamed lesions that are very tender to touch, friction with the usual amount of force may be very painful. Pain can be avoided by starting with a minimal amount of pressure – just enough to reach the lesion – and progressively increasing the force as treatment proceeds.

In order to avoid painful sessions of deep transverse friction it is good practice to grade its application. Begin with a sweep that is gentle and continue this for a few minutes; some numbness of the treated area follows which allows slight intensification of the amount of pressure, which in turn leads to more numbness. Finally, it will be possible to give effective massage that is practically painless to the patient.

Duration and frequency

Friction is usually given for about 10–20 minutes and, because of tenderness, on every second day. The ideal timing of the next treatment is when local tenderness caused by the previous session has resolved. If tenderness persists after 2 days, the pressure used during friction should not be diminished but the interval between sessions must be increased.

Massage immediately after a ligamentous sprain or a minor muscular rupture may be applied daily for the first week but should be of very low intensity and short duration.

Treatment is stopped once the patient is pain-free during daily activities and functional tests are totally negative. Local tenderness may persist longer but disappears spontaneously because it is the outcome of repetitive hard pressure. However, in a minor lesion of a muscle belly, massage is continued for 1 week after full clinical recovery to prevent recurrence (see Table 5.2; see also Box 5.2).

Passive movements

Treatment by passive movement is otherwise known as *mobilization*. It cannot be performed by the patient and requires the intervention of a therapist. Depending on its velocity and the range of movement that is aimed for, it can be graded as A, B and C *mobilization*:

- Grade A mobilization is a passive movement performed within the pain-free range.
- Grade B mobilizations are passive movements performed to the end of the possible range. The latter is indicated by an end-feel. All stretching and traction techniques are grade B mobilizations.
- Grade C mobilization is a minimal thrust with a high velocity and over a small amplitude. It is performed at the end of the possible range, i.e. the moment the therapist has reached the end-feel. Another word for grade C mobilization is *manipulation*.

Table 5.2 Transverse massages/modalities

Indication	Duration (min)	Pressure	Frequency	Combined treatment
Diagnostic	15–20	High	Once	
Acute ligamentous	30 sec	Very low	Daily	Effleurage before and active movement after the treatment
Subacute ligamentous	3–10	Low	Daily–3 times/week	Passive grade B movements after
Chronic ligamentous	15–20	High	3 times/week	Passive grade B movements after
Ligamentous adhesions	15–20	High	Once	Before manipulation (grade C mobilization)
Tendinitis – tenoperiosteal	15–20	Grading	3 times/week	Relative rest – unloaded active movement
Tenosynovitis	15–20	Grading	3 times/week	Relative rest – unloaded active movement
Musculotendinous	15–20	Grading	3 times/week	Relative rest – unloaded active movement
Myosynovitis	15–20	Grading	3 times/week	Relative rest – unloaded active movement
Muscular tear – acute	5–10	Low	Daily	Procaine infiltration before and active unloaded contractions after treatment
Muscular tear – chronic	10–15	High	3 times/week	Active unloaded contractions after treatment
Capsular lesions	15–20	Grading	3 times/week	

Box 5.2

Summary of deep friction technique

1 Position of the patient must:
be comfortable
bring lesion within finger's reach
be appropriate for the type of structure at fault:
- tendon/ligament under tension
- muscle belly: relaxed

2 Position of the therapist must:
be comfortable
facilitate economy of effort:
- alternating active and passive phases
- using large muscles

3 Use of the hand:
To-and-fro movement
Pronation/supination
Pinch grip

4 Use of the fingers:
Counterpressure
Friction using the fingers

5 Other points:
Fingers and skin move as one unit
Direction of friction must be transverse
Sufficient sweep must be used
The pressure must be appropriate
Duration and frequency must be appropriate

Indications

Grade A mobilizations

To promote healing of injured connective tissue

Passive movements within the pain-free range are usually called for in the treatment of injured connective tissue. A comprehensive literature evaluation and meta-analysis of experimental studies of the past several decades have demonstrated that regeneration of injured connective tissue is significantly better with the application of continuous passive motion. If the healing tissues are not loaded, regeneration results in unstructured scar tissue. Under functional load, the collagen fibres are oriented in a longitudinal direction and the mechanical properties are optimized.[24]

Grade A mobilizations are therefore applied early in the treatment of sprained ligaments to promote orientation of the regenerating fibres. They are given in conjunction with gentle transverse massage and within the pain-free range. Care should be taken not to bring the fibres under longitudinal stress in order not to disrupt the healing breach. The movements are of short duration but repeated often.

Distractions at the shoulder

Grade A mobilizations are also used on the capsule of the shoulder in stage III arthritis when stretching and intra-articular steroids are contraindicated (see Ch. 14). In this condition, long-standing stimulation of the nociceptors has increased neuro-sympathetic activity, giving rise to vasoconstriction, muscle spasm and pain.

Gentle and rhythmical grade A movements are performed in such a way that the fibres are stretched longitudinally, stimulating the mechanosensor mechanisms in the joint and so

inhibiting somatosympathetic reflexes that are co-responsible for the increased inflammation of the joint.

Deformity correction

Some cases of lumbago show persistent spinal deviation even after the pain has ceased. A quick thrust manipulation so effective in relief of pain is not effective in correcting the remaining deformity, but sustained translatory gliding in the opposite direction is most helpful. The movement is performed slowly and care is taken to keep the gliding within the pain-free range (see Ch. 40).

Reduction of an intra-articular displacement in a peripheral joint

When a meniscus or some other piece of intra-articular cartilage (with or without an osseous nucleus) becomes displaced and locks a joint, the logical treatment is either to remove it or manœuvre it into such a position that the joint can again move freely over a normal range. The technique needed for the latter is usually a series of manipulative movements which normally contain elements of traction combined with movements of rotation and flexion or extension. In general, these are first performed in the less painful direction of movement and repeated several times with progressively increasing force.

Unlike manipulations in the spine, the manœuvre to reduce an intra-articular loose body is not a grade C mobilization because the movement is not performed at the end of range nor does it contain a 'thrust' element. The flexion–extension movement is over a wide range and stops before the end-feel is reached. The rotation movements are performed to the end of range where end-feel is sensed by the therapist. The 'manipulation of an intra-articular displacement in a peripheral joint' is therefore a combination of grade A and grade B mobilizations.

Grade B mobilizations

To maintain a normal range at the joint

Paralysed muscles may lead to a loss of normal range of motion of the corresponding joint. This can be avoided by gently stretching the capsule, starting as soon as possible after the onset of paralysis. The approach should also be considered for joints that have been injured or subjected to surgery. In such circumstances, there may be the paradox that immobilization is needed for a fracture to heal but that movement is required to prevent loss of capsular elasticity. Often the problem can be solved by adapting the technique of capsular stretching so that it does not influence the site of the fracture.

To stretch the capsule of a joint

Grade B mobilizations may be required to stretch the joint capsule in non-acute arthritis and in early osteoarthrosis. The technique will be further referred to as *capsular stretching*. Capsular stretching is particularly useful in shoulder and hip joints but is applicable in all 'non-irritable' capsulitis. The condition is characterized by:

- a limitation in the capsular pattern (see Ch. 4)
- demonstration of a hard-elastic end-feel to restricted movements (see Ch. 4).

In the very beginning of arthritis, muscle spasm forces the joint to be held in a position of ease, so restricting movement in some directions more than in others (see Capsular pattern, Ch. 4). Immobilization and inflammation cause disordered deposition of collagen fibres in the joint capsule and lead to the formation of capsular adhesions, which in turn are responsible for more restriction of movement and pain. *Stretching* aims at restoring mobility and function by breaking micro-adhesions and producing elongation of the shortened capsule. To be applicable, however, the ligamentous end-feel must be reached before the protective muscle spasm begins. To be successful, the therapist should therefore be able to differentiate between an elastic and a spastic end-feel.

The technique is a slow and steady pressure, performed at the end of range over about 30 seconds to 1 minute with as much force as is reasonable for the patient to bear. Tension is slightly diminished for a few seconds, so affording the patient some respite, and then again increased. From time to time the procedure is completely interrupted. If tension is released too quickly, some pain may be felt and it is therefore wise to bring the limb back into neutral position under traction. The technique is not painless. The stretching causes some micro-ruptures, which result in an inflammatory response and after-pain that lasts for a few hours.

Normally, capsular stretching is given for 15–20 minutes, three times a week. The therapeutic effect is slow.

Capsular stretching can be preceded by application of heat, either through short-wave diathermy or ultrasound. This can relieve some pain and seems to lower the viscosity of the collagenous tissue, allowing more movement for less force. *In vivo* studies on the effects of heat on ligament extensibility have shown that sustained force applied after elevating tissue temperature produced significantly greater residual elongation.[25,26]

Manipulation of a joint capsule under anaesthesia is a grade C mobilization and is only considered for postoperative intra-articular adhesions. A joint that has been manipulated under anaesthesia requires daily intensive mobilization immediately afterwards in order to prevent the formation of new intra-articular adhesions.

To stretch a muscle

Children with short calf muscles can be helped by sustained stretching. The procedure consists of a series of alternating passive stretchings and active contractions. Stretching is maintained for about 8–10 seconds and is followed by full relaxation and active contraction of the muscle. These alternating movements are performed six to eight times per session, preferably daily but at a minimum of three times a week. The earlier the stretching is started, the better the result. Above the age of 15 not much improvement can be expected.

Traction

Traction is used to separate articular surfaces from each other and can be employed in two ways: as an accessory to manipulation or as the sole treatment. Reducing a displaced fragment is obviously easier when the bone ends between which it lies are pulled apart. If the fragment projects beyond the articular edge, tautening of the ligaments and capsule also provides a

centripetal force. In that traction diminishes the pressure on the fragment, pain decreases, which allows the patient to relax the muscles more.[18] In the cervical and thoracic spines, traction is a built-in safety measure for protecting the spinal cord during manipulation (see below) although the use of traction for this purpose and at these sites does not imply that manipulation can be performed on a basis of 'try and see what happens' without a proper diagnosis.[27]

In the spine, traction is used as the sole treatment only in nuclear disc protrusions, which are rare at the cervical and thoracic levels but are more common in the lumbar area. Spinal traction is always mechanical and is performed with the help of a harness (lumbar or low thoracic) or a sling (cervical or upper thoracic). Spinal traction distracts the intervertebral disc spaces. It also pulls the apophysial joints apart and slightly widens the intervertebral foramina.[27–31] At the same time, negative intradiscal pressure is produced with centripetal 'suction' on any protrusion. The posterior longitudinal ligament is tightened, which may help reduce a displaced fragment. All these elements are helpful in the progressive reduction of a nuclear disc protrusion. Reduction of herniated bulges has been demonstrated on epidurography[31–33] and on CT scan[34] during and after traction. The effect of traction depends on the amount of force applied, the length of time per session, the interval between each session and the total number of sessions.[35]

Grade C mobilizations

Grade C mobilizations or manipulations are forceful passive movements, performed at the end of range. Spinal manipulations are mainly to interrupt discodural or discoradicular contact. At the peripheral joints the purpose of a manipulation is to rupture unwanted adhesions between bone and ligament or bone and tendon or to reduce small bony subluxations in the wrist or foot.

Rupture of ligamentous adhesions

Small ligamentous adhesions sometimes develop between a healing ligament and bone. They usually result from a sprained ligament that has been immobilized during the healing process. The usual presentation is at the lateral ligaments of the ankle and at the medial collateral ligament of the knee. The clinical features are local pain during exertion and a small limitation of movement in one direction only. The adhesions can be ruptured by a high-velocity, small-amplitude thrust manipulation, after preparation of the affected ligament with intensive deep transverse friction.

The joint is stretched as far as possible in the limited direction and manipulated with a single firm thrust, during which a typical 'snap' is often heard. Harm is not caused to the ligament nor to the other parts of the joint because the adhesions bear the brunt of the force. The manipulation is almost painless and after-pain is not to be expected. A successful manipulation should achieve an immediate result. Active movements during the following days to maintain function should be highly encouraged.

Rupture of tenoperiosteal adhesions

In type II tennis elbow (tendinitis of the attachment of the extensor carpi radialis brevis), adherent and disorganized scar tissue causes a self-perpetuating inflammation. The manipulation aims to rupture the adhesions and produce a permanent elongation of the tendon. The high-velocity manœuvre is preceded by thorough deep transverse friction in order to numb and to weaken the spot. The manipulation is performed only once per session; 10–15 sessions may be required to achieve a result.

To reduce a bony subluxation

A subluxation of one of the carpal bones or of the cuboid bone can easily be reduced by digital pressure combined with translatory movement during traction.

Manipulation of the spine

Spinal manipulative therapy is a major part of treatment techniques in orthopaedic medicine and is discussed thoroughly below.

Contraindications to forced movements

Contraindications to spinal manipulations are discussed later in this chapter.

Capsular inflammation

Forced movements should not be performed when signs and symptoms of capsular inflammatory activity are present. These are spontaneous pain, pain especially at night, wide reference of pain, inability to lie on the affected side at night or to bear weight on the affected side. Local warmth and effusion are other pointers of a highly inflamed joint. However, if these symptoms and signs are present but the rest of the clinical examination demonstrates internal derangement (e.g. knee, hip, ankle), manipulation is indicated and can safely be performed.

Muscle spasm

Grade C mobilizations should never be applied to a joint that is protected by a muscle spasm. Grade B mobilizations may be used unless the end-feel of the movement that is intended to be forced through is also spastic.

Severe osteoporosis

Grade B mobilizations, for instance stretching of the shoulder or hip joint in elderly people, should always be carried out with caution for fear of fracturing the humerus or the neck of the femur.

Joints and ligaments not under voluntary tension control

Mobilization is also contraindicated for those joints and ligaments on which the tension is not under voluntary control. This is the case for the acromioclavicular, the sternoclavicular and the sacroiliac joints and the sacrococcygeal ligament.

Manipulation of the spine

Introduction

Spinal manipulative therapy includes all procedures of mobilizing or adjusting the spine by means of the hands. As in the peripheral joints, grade A and B mobilizations are movements of low velocity with varying amplitude but remaining within physiological limits and within the patient's tolerance and control.

A manipulation or grade C mobilization usually implies a single thrust of high velocity performed at the end of a passive movement after the 'slack' has been taken up, and over a small amplitude. It goes beyond the physiological limit but remains within the anatomical range. Precision of the movement and control of the applied force are required.[36] Spinal manipulative therapy is a valuable method in the treatment of mechanical spinal disorders. Although it has not been scientifically validated, some studies have shown beneficial effect.[37–40] However, its potential benefit should not be overestimated and the indications must be well defined and based on a sound clinical diagnosis. It must never be done as a test to see if it is effective. Therefore it should not be used on all those with back and neck pain although it may well cure a proportion who actually require it. To use McKenzie's words:

> *Even if you have a hammer in your hand not everything you see is a nail. Therefore indiscriminate use of spinal manipulative therapy must not be made if the criticisms that have been justifiably levelled at chiropractice and osteopathy are to be avoided. The development of postgraduate courses in manipulation is welcome, although some have overvalued the benefits of manipulative therapy. All who undertake manipulation have experienced the feeling of pride and joy in producing cure. It is the duty of those who have more experience of the benefits and limitations of manipulative therapy to moderate the understandable enthusiasm of those entering the field – a few successes may quickly lead to the temptation to manipulate every patient for any disorder.*[41]

Manipulation either helps quickly or not at all. Therefore if improvement does not occur after one or two sessions, manipulation is not likely to be successful and it is pointless to continue with it.

Historical note

Manipulation is as old as medicine and embraces both medicine and mankind in general. In recent times, the medical aspect has become structured and different methods have been developed which are subject to controversy and competition.

Osteopathy

The concept of osteopathy was introduced by A. T. Still (1828–1917) and developed out of frustration with traditional medicine. His ideas were based on two principles: (1) the body has within itself the processes to combat all disease, and (2) the cause of all disease is dislocated bones, abnormal ligaments or contracted muscles with consequent mechanical pressure on blood vessels and nerves.

Diagnosis is mainly based on palpation for restricted spinal mobility and treatment consists of a manipulative system in which joints are forced by a distant leverage. Cure is sought for all kinds of visceral and musculoskeletal disorders.[27]

Chiropraxy

This method was started in 1885 by D. Palmer. It is based on a revision of techniques that originated with Hippocrates and is also influenced by osteopathy. Chiropraxy was long regarded as maintaining osteopathic dogma in its most primitive form and having a strong commercial character.

Chiropractors also claim to cure visceral diseases via the musculoskeletal system. Diagnosis is made on palpation for vertebral displacement and manipulative pressure is applied directly to the bone.

Orthopaedic medicine

This term describes the system of diagnosis and treatment of musculoskeletal lesions introduced by J.H. Cyriax. It is the system on which this book is based. Diagnosis rests on careful history and functional examination. Treatment depends mainly on the type of lesion, and manipulation is applied only when indicated. In spinal manipulation, Cyriax proposed a fixed set of high-velocity, small-amplitude thrusts performed at a certain distance from the lesion and, characteristically for this method, usually under strong traction. The objective of Cyriax's spinal manipulative techniques is to alter the discodural or discoradicular interaction by moving a displaced cartilaginous fragment away from the sensitive dura mater and dural nerve sleeve. Spinal rotation manipulations apply a torsion stress throughout a whole part of the spine, not at just one level. With an intact posterior longitudinal ligament and annulus fibrosus, some of this torsion force exerts a centripetal force by suction on the protruding disc material.[42] This effect is not confined to one level and full reduction is not absolutely necessary for pain relief, in that when contact between dura and disc has ceased the problem is frequently solved.

Manual therapy

Treatment is characterized by rhythmic repeated movements within the physiological range. Oscillatory techniques had already been used by E. Cyriax (father of J.H. Cyriax) but were more widely employed by Maitland and later slightly changed by the different schools of manual therapy (Cyriax:[3] p. 40). Pressure is applied to what is believed to be the appropriate level.

Orthopaedic medicine technique

Before any manipulation is done an exact diagnosis must be made. The decision to manipulate is followed by choice of the correct manœuvre. The patient is put in a comfortable position and the manipulator adopts a stable stance. The floor and shoes should not be slippery, so that there is no risk of inappropriate movement.

Attention must be given to the following general matters, which are important for all manipulations.

Traction during manipulation

Most types of spinal manipulation in orthopaedic medicine are performed under traction. For the cervical and thoracic spine, traction is applied by the manipulator with the help of a fixing belt or by one or two assistants. At the lumbar level, traction is usually already built into the manœuvre. Traction facilitates the reduction of a displaced fragment and provides an important safety element against the possibility of a protrusion contacting the spinal cord during manipulation.

End-feel on taking up the 'slack'

All spinal manipulations are performed over only a small amplitude. Therefore all 'slack' must be taken up by moving the vertebral joints passively to the end of the normal passive range of movement. At this stage it is absolutely necessary to have a clear idea of the end-feel, which is nominally elastic for the entire spine. An end-feel that does not correspond with this – muscle spasm, or hard or empty end-feel – is an absolute contraindication to any manipulation and the manœuvre is not continued.

Final thrust

Immediately after the slack has been taken up in the surrounding tissues, a minimal amplitude, high-velocity thrust is given to affect the target tissue. The velocity is of great importance because tissues loaded quickly are stiffer so that the manœuvre will affect only the displaced fragment of disc and will not damage the surrounding structures.[43]

The amount of force used for the final thrust depends mainly on the patient and manipulator in that a tall manipulator will have to use less force in a small patient and vice versa.[44] The length of the lever (see later) is also important. The force should always be kept reasonable and may be progressively increased, according to the immediate result.

The manipulation thrust is often accompanied by an audible 'pop'.[29,45] Although it is a common belief that pops or clicks are provoked by the formation of a temporary vacuum, as occurs in small peripheral joints put under traction,[46–48] this is not definitely established for the spine. An alternative and more likely explanation is movement of cartilaginous fragments, as may be heard during manipulation for a loose body in the knee or hip. If the clicks were simply the result of the collapse of a vacuum they should also be – but are not – heard during mechanical traction, in which the traction force is much higher.

Leverage

The amount of force used depends on the length of the lever. If for example a rotation of the lumbar spine is forced via the shoulder and pelvis, the lever offered by the shoulder is the same length as that offered by the pelvis, so an equal amount of force must be used by both hands. But if the femur is used instead of the pelvis, the length of the pelvic lever doubles. The hand on the shoulder must apply double the amount of force that is used on the knee. The longer the lever, the less force is needed.

Reassessment

After each manœuvre the patient is assessed, the criteria of success being the absence of symptoms and the restoration of pain-free movement. The patient and not the manipulator is the arbiter.[49] Depending on the immediate outcome, the therapist decides whether to repeat the same manipulation, probably with increased strength, to try another manœuvre or to refrain from further manipulation.

It should be appreciated that after successful manipulation the anatomical lesion is still present: a piece of cartilage, although put back in place or into a neutral position, persists and may redisplace. For this reason, those who undertake manipulation should note the results obtained and what manipulations were used, in case of recurrence.

Figure 5.6 outlines the assessment of spinal lesions and their manipulation.

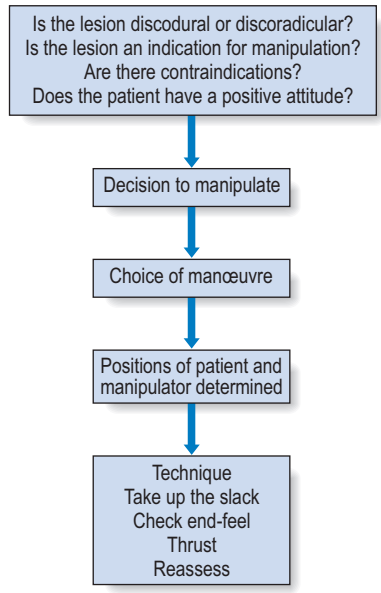

Fig 5.6 • Spinal manipulation.

Selectivity of a manipulative treatment

Selectivity must be considered both in diagnosis and therapy.

Selectivity of diagnosis

Osteopaths and manual therapists claim to have developed the clinical skills to localize by palpation the exact site of fixation, and are therefore able to perform the manipulation at the required level. Diagnosis is mainly based on segmental mobility tests: joint play, springing test or tests of passive physiological movements. Movement can be tested by exerting local pressure at one side of a vertebra while counterpressure is applied to the contralateral side of the vertebra above or below. For the lumbar spine, it can be done with the patient on the side with both hips flexed to 90°. Small movements of the thighs cause the lumbar spine to flex or extend which can be detected by palpation of the spinous processes.

Other practitioners look mainly for palpable soft tissue changes, such as local subcutaneous thickening or exquisite tender spots (trigger points) in muscles, ligaments (iliolumbar,

sacroiliac) and over bony prominences. All these are considered to be important diagnostic and therapeutic factors.

The great variability in the extent of spinal stiffness between subjects, or at different levels within the one subject, makes the determination of areas of abnormally increased stiffness difficult. Increased stiffness may in fact be a normal variant and bear no relationship to the patient's presenting symptoms. Few of those advocating segmental mobility tests have seriously examined the value of their tests. They have generally presumed that the tests were useful because their patients got better.[50] However, several studies have failed to demonstrate the reliability of these tests.[51–62] Therefore it must be made clear that judgement of small changes in the range of movement of a segment, in the absence of full restriction of movement, remains a very subjective finding, which depends mainly on the personal conviction of the examiner rather than on objective measurements. Moreover, in soundly based tests, findings must be reproducible and must show correspondence when performed by other investigators. In the establishment of 'joint play' the inter-observer discrepancy is too large to be acceptable.[63] In 1973, Cyriax attended a demonstration in which five therapists, all of whom specialized in mobility testing, examined over a period of a few minutes a patient with a neck problem. There was no agreement between these specialists about the level of the lesion (C2, C3, C4, C5, C6 or T2), or about the direction of restriction (see Cyriax:[64] p. 108). Similarly, a patient who had congenital fusion of the sacroiliac joints was examined by 10 manipulators. Each had his own diagnosis, such as left anterior sacrum, right anterior sacrum and bilateral posterior sacrum, although 'the tests were very positive' for all of them (see Maigne[65] and Cyriax:[64] p. 363).

Even if it were possible to identify with certainty localization of the hypomobile segment, the question remains as to whether this is also the site of the lesion. Studies have shown that frequently the lesion does not lie at the joint where motion is restricted but at one which appears to be normal.[55] Moreover, other disorders such as osteophytosis, congenital fusion and ankylosing spondylitis all give rise to restricted movement which is usually painless.

Selectivity of manipulation

Manipulation is often accompanied by immediate relief of symptoms and signs which, since success has been obtained, is logically taken as absolute confirmation of the precision of diagnosis and treatment. Such a deduction may be – and often is – totally wrong. The only thing proved is that the manipulation was efficacious. The erroneous reasoning that successful manipulation necessarily confirms the diagnosis has been and is still today an important argument for the false belief of some schools that manipulation can cure all kinds of disorders even including visceral diseases. A typical example is pectoral pain, resulting from a thoracic discodural interaction which is misdiagnosed as angina. The patient goes to an osteopath who manipulates the thoracic spine and the pectoral pain ceases immediately. Both patient and manipulator, misled by the wrong diagnosis, will believe that the manipulation has altered autonomic tone and cured the angina, whereas what it actually did was interrupt the discodural interaction.

In orthopaedic medicine most manœuvres used are non-specific long-lever manipulations. These include all procedures in which a force is exerted on a part of the body some distance away from the area where it is expected to have its beneficial effect. Levers may include the shoulder, transverse processes and parts of the skull, pelvis or thigh (Frymoyer *et al*:[45] p. 1594). Although some criticize the crudity of long-lever high-velocity manipulation it should be realized that it is not elegance, impressiveness, specificity or technical difficulty which count but effectiveness and safety. Furthermore, the use of a lever enables the manipulator to reach the lesion more effectively. During the preparative phase – on taking up the slack – all the normal joints are brought to their anatomical end position except for the joint that is blocked. When the additional thrust is given, the final extra pressure falls inevitably first and to the greatest degree on the deranged joint. The manœuvre thus becomes specific even though in general the techniques are regarded as non-specific.

Long-lever manipulations are in full contrast to what are called 'specific' short-lever high-velocity manipulations. Here the goal is to act specifically at what is believed to be the level of the lesion. The spinal segment and the facet joints adjacent to the lesion are locked by moving the spine to the physiological limit of passive movement and a high-velocity small-amplitude thrust is given to the short vertebral lever (transverse process or spinous process) in the specific direction that will liberate the restricted movement. However, it is technically not possible to lock all other joints and then to manipulate at just one level (Cyriax:[64] p. 108). It was even demonstrated that by mobilizing the sacroiliac joints after locking of the lumbar spine, the largest movement took place between L4 and L5.[66] Furthermore, if diagnosis fails to be absolutely right, how can there be certainty as to the exact level of the lesion to work on? Fortunately for those who employ 'specific' short-lever manipulations, these are much less specific than they think, because the manipulations actually cover a much larger part of the spine and so unintentionally also include the lesion.

Specificity is a false attribute. The methods that claim to lead to specific localization in both diagnosis and treatment are scientifically unacceptable. Claims of specificity are made in order to give prestige to manipulators who claim to feel something that cannot be felt. Manual therapists, chiropractors and osteopaths over-complicate their teaching and often create excessive patient dependency, instead of providing the patient with independence. Indeed, patients are encouraged to return at regular intervals for pointless prophylactic adjustment.[41] We support R. McKenzie's conclusion that demystification of spinal manipulative therapy is an urgent priority.[41] Chiropraxy, manual therapy and osteopathy, however, thrive by creating the impression that there is something complex and exclusive about the practice of passive end-range motion that only experts in these practices can understand or have the skills to feel. The belief is strong that expertise in the understanding and delivery of spinal manipulative therapy requires 3 or 4 years' training. The main advantages of the methods discussed in this book are that the manipulations are much simpler and at least as effective as those advocated by chiropractors, osteopaths and manual therapists. Non-specific long-lever manipulations are quickly effective, do not take long to perform and are

simple to learn. Moreover, they can take only about 180 hours of tuition, provided that the student has already gained qualifications in medicine or physiotherapy.

Mode of action of spinal manipulation

To date, the mode of action of manipulation has not been totally clarified, although many different models have been put forward. All pose unsolved questions, lack objective confirmation and are subject to dispute. Different attitudes towards spinal disorders determine theories and explanations.[67]

Those who believe in 'posterior facet joint' syndrome as a frequent source of back pain, believe that manipulation corrects a posterior joint dysfunction, in which either a minor subluxation of a facet together with an entrapment of the synovial fold, or of part of a small intra-articular meniscus, is held responsible, both of which may give rise to a blocked vertebral joint (Kirkaldy-Willis:[29] p. 296; Mathews and Yates[68]).

Others suggest that manipulation ruptures periarticular connective tissue adhesions or that it abolishes a muscle spasm.[69] In our opinion, a manipulation does not directly affect muscle spasm; instead, the latter disappears secondarily when the underlying problem is solved.

It has also been suggested that manipulations influence the mechanism of cutaneous pain tolerance as the result of release of endorphins, or that stimulation of mechanoreceptors of the facet joint capsules, ligaments and annulus fibrosus influences the neurophysiological gate that controls the perception of pain.[70] This could conceivably abolish pain immediately after manipulation but does not explain longer term improvement.

Some believe that manipulation may move an inflamed nerve away from the herniation[71] or that relief is achieved via a return to normal of neurogenic reflex activity.[42,72]

We strongly believe that spinal pain is the result of disc protrusion that gives rise to a conflict between the posterocentral or posterolateral rim of the disc and the pain-sensitive dura mater or dural nerve sleeve, and that a displaced fragment of an intervertebral disc can be moved by manipulation.[42,73–76]

This was the hypothesis of Cyriax[3] (see his pp. 38–50) and Maigne[77] and has been supported by the observations of Mathews and Yates,[68] who have shown by epidurography that in acute lumbago small lumbar disc protrusions diminished in size after manipulation. Manipulative interruption of contact, moving the displaced cartilaginous rim away from sensitive structures, is the objective for relief of pain and is best obtained by a non-specific long-lever, high-velocity manipulation.

Indications for spinal manipulation

Spinal manipulation is useful for all annular disc protrusions in the absence of any contraindications or of any signs or symptoms that indicate that manipulative reduction would not succeed. All these factors may vary for the cervical, thoracic and lumbar spine, and the indications are discussed in detail in later chapters.

Contraindications to spinal manipulation

All effective treatments are potentially dangerous and therefore possess contraindications. Although manipulative techniques are not hard to learn, years of experience are needed to learn when to manipulate, when not, and what sort of manœuvres to use.

Contraindications to manipulation are bleeding disorders, softening of bone, rheumatoid conditions, neurological deficit and danger to the spinal cord.

Box 5.3

Anticoagulants contraindicate spinal manipulation

Coumarin derivatives:
- Heparin
- Warfarin
- Phenprocoumon
- Acenocoumarol

Indandione derivatives:
- Diphenadione
- Phenindione

Bleeding disorders and anticoagulant use

When normal clotting of blood is not guaranteed, as in congenital or acquired (liver disease) bleeding disorders or because of the administration of anticoagulants (Box 5.3), spinal manipulations are potentially dangerous. Disastrous results can follow, such as intraspinal haemorrhage with the formation of a haematoma that may lead to sensory and motor deficit, to paraplegia, quadriplegia or death.[78] For this reason, a coagulopathy is an absolute contraindication to spinal manipulations. Manipulation can be safely performed only after blood clotting tests have returned to normal.

Spinal tumours, unstable fractures, vertebral infections and severe osteoporosis

(see Grieve:[27] p. 829)

These all result in weakening of bone with risk of further damage by manipulation. Long-lever manipulation is not safe in severe osteoporosis.

Rheumatoid arthritis, psoriatic arthritis, Reiter's syndrome and ankylosing spondylitis

The first three of these may be associated with ligamentous laxity and gross destruction of the joint with subsequent instability. Manipulation must not be undertaken. The same applies for the inflammatory stage of ankylosing spondylitis. In the unlikely event of a patient with this disorder developing a disc lesion, manipulation is not at all safe, especially in the cervical spine, where luxations, fractures and cord compression have been described.[79]

Neurological deficit and spinal cord compression

Segmental neurological deficit is characterized by disturbance of either motor function, with impaired reflexes and/or muscular weakness, or sensory function, with diminished sensibility. The two may be combined. Segmentally referred pins and needles due to compression of the sensory fibres of a nerve are not regarded as neurological deficit and are therefore not a contraindication. In neurological deficit, manipulation is usually

without value because deficit suggests a large protrusion that cannot be reduced. This opinion is not universally supported,[80,81] and some still manipulate when minor neurological signs are present. However, in all instances where progressive neurological deficit is present, manipulation must not be done.

A similar rule applies in cord compression or cauda equina syndrome when a very large posterocentral protrusion threatens the spinal cord or the cauda equina. This is true not only for obvious signs but also in the presence of even the slightest symptoms, such as extrasegmental pins and needles or pain in the S4 dermatome.

Hypermobility

In several schools of thought on manipulation, too much emphasis is placed on hypermobility. Although it is true that special attention must be given to hypermobility in the cervical spine, it is not important elsewhere. A hypermobile joint may move further than an ordinary joint, but once extreme range is reached it stops in exactly the same way as does an ordinary joint. More often the disc fragment itself is hypermobile, which may lead to frequent recurrences. This circumstance does not contraindicate manipulation but calls for extra measures to achieve stabilization, for example by infiltration with ligament sclerosant (see Cyriax:[3] p. 38).

For the cervical spine a history of frequent disc problems, alternating from one side to another, may be suggestive of hypermobility. When doubt exists the following tests may be useful: spinal flexion with putting the palms flat on the floor with knees straight, passive apposition of the thumb to the flexion aspect of the forearm, passive hyperextension of the fingers parallel to the external surface of the forearm and hyperextension of the elbow and/or of the knee of 10° or more. If one or several of these are positive hypermobility is likely.[82] Also, when the end-feel on passive rotation, extension or on preparation for a straight-pull manipulation is too elastic, further manipulation must cease.

Spinal manipulation under anaesthesia

Spinal manipulation should never be done in an unconscious patient. First, anaesthesia is unnecessary. Second, the final warning of potential danger offered by increased pain or abnormal end-feel on taking up the slack is completely lost, as is clinical assessment after each manœuvre. Consequently, complications are more frequent after manipulation under anaesthesia.[83]

Patients who have difficulties in relaxing during manipulation may benefit from being given diazepam before a session.

Evaluation of the effectiveness of spinal manipulation

Although several studies, mainly done on the lumbar spine, support the view that many patients benefit from spinal manipulation,[39–41,84–87] agreement on the effectiveness and the role of manipulation in spinal disorders is still lacking. Reports from clinical trials are not always clear and the effects of manipulation are often difficult to interpret[88] because of a small number of patients and their selection by symptoms rather than diagnosis. To make trials scientifically valuable a precise definition of manipulation is necessary – a record of which types of technique have been used and for what type of disorder and its duration. It should also be said that a double-blind randomized trial on spinal manipulation is not possible because of the absence of a placebo and the obvious knowledge by the patient and operator of what is being done.

Sims-Williams published a clinical trial on 94 patients with non-specific lumbar pain, who took part in a trial in which placebo physiotherapy was compared to Maitland mobilization and manipulation. Studies mainly showed that manipulation hastened improvement chiefly in those patients whose severity and duration of symptoms did not require specialist referral.[80,89]

Bergquist-Ullman and Larsson,[90] Coxhead *et al*[81] and Farrell and Twoney[39] found a significantly shorter duration of complaints in patients receiving manipulation.

Chrisman *et al*[91] stated that half of those suffering from sciatica showed clinical improvement after manipulation, but the improvement could not be objectively confirmed by myelography.

Hadler *et al*[86] compared the results of spinal mobilization to high-velocity thrust manipulation in patients with acute, uncomplicated low back pain and tried to exclude all elements of chronicity or compensation insurance. Patients treated by manipulation improved to a significantly greater degree and more rapidly than those treated by mobilization.

In one study, in which rotational manipulation was compared with simulated short-wave diathermy, those who received the former fared better immediately after the session.[92] However, when pain relief was compared 7 days after treatment there was no significant difference between the two groups.

In another study, 24 patients with complaints of less than 3 weeks' duration were followed. It showed that 92% of those treated by rotational manipulation were cured in less than 2 weeks.[93] Of those who received diathermy, only 25% got better in the same period of time.

A further trial in acute disc herniation compared conventional physiotherapy with manipulation and showed that the manipulated group scored significantly better.[94] All manipulated patients were able to return to work, whereas only 26% of the physiotherapy group could do so.

In a randomized clinical trial Koes *et al* compared the effectiveness of manipulative therapy, physiotherapy, treatment by the general practitioner and placebo therapy in 256 patients with non-specific back and neck complaints of at least 6 weeks' duration. They concluded that manipulative therapy showed a faster and greater improvement in physical functioning compared to the other three therapies.[95,96]

Controlled studies performed by Mathews *et al* clearly demonstrated that manipulation treatment for low back pain scored significantly higher in the subgroup with limited straight leg raising.[97,98]

Generally it can he concluded that manipulation and mobilization hasten both pain relief and the resolution of objective signs such as limitation of straight leg raising and of articular movement. Manipulation with high-velocity thrust seems to work better and quicker than more gentle mobilization techniques. The results are also better in recent-onset cases than

in those of longer duration. Manipulation helps either quickly or not at all; which means that manipulative therapy continued over a long period of time is not appropriate.

Complications of spinal manipulation

General considerations

Manipulation is, as with anything in medicine, not without danger and it must be admitted that even in experienced hands accidents may happen. Therefore manipulative treatment must never be undertaken recklessly, or on a 'hit or miss' basis.[3] Although it is probable that more accidents have occurred than have been reported, the risks must not be overstressed.[40,99] In 30 years of clinical practice Kirkaldy-Willis[29] (his p. 293) did not have one patient who was made worse by a manipulation. Dvorak and Orelli estimated that in 1 out of 400 000 manipulations severe neurological damage results, and in 1 out of 40 000 slight neurological signs appear.[100] It should not be forgotten that traditional treatment with non-steroidal anti-inflammatory drugs is also not without complications, in that they may give rise to severe gastrointestinal problems (mucosal bleeding, or reactivation of previous ulcers or initiation of new ones), haemolytic anaemia, leukopenia, thrombocytopenia and even fatal agranulocytosis, salt and water retention, albuminuria, nephritis, acute renal insufficiency, or to allergic reactions in all degrees of severity. No matter what treatment is given there will always be an inherent risk, but this should be reduced to a minimum by taking all necessary precautions.

Complications of manipulation can range from a temporary slight increase in pain to severe neurological deficit and death.

Postmanipulation pain

Immediate postmanipulation pain – which is usually not severe and is present in the whole area – can be relieved by using special techniques at the end of a manipulation session such as a lateral glide at the cervical spine or the rhythmic extension technique in the lumbar spine.

A degree of pain for a short duration – due to stretching of the muscles and ligaments – is normal in the elderly. It disappears spontaneously within 1 or 2 days. To avoid undue anxiety, patients should be warned of this. For the same reason, in older patients some manipulation-free days must be planned between sessions.

Increased pain

Worsening of the condition immediately after a manipulative manœuvre manifests by either an increase in original pain or by its movement more laterally. The implication is that the protrusion has been further displaced. This may occasionally occur in a manipulation which was perfectly performed and does not necessarily mean a poor technique. Further worsening can usually be avoided by performing a different manœuvre, very often by changing the direction of rotation. The same course is adopted when, after manipulation, pain moves to the other side – an indication that overcorrection has occurred.

Fracture

Exceptionally, manipulation may be complicated by a rib fracture, sternal fracture or fracture of a transverse process. These usually occur in the elderly and can be avoided by not using certain techniques in patients above 60 years of age.

Onset of neurological deficit

Sometimes uncomplicated root pain becomes complicated by neurological deficit, and it may occur after a manipulation that was correctly performed, but which has resulted in the protrusion being moved further laterally or the compression being increased. This event must be considered when root pain does not improve. Neurological reassessment must be done and, as a consequence, further manipulations will cease and, if necessary, epidural injections or sinuvertebral nerve blocks may be given. It is very seldom that the problem is so severe that neurosurgical intervention is needed.

Vascular interference and cord compression

Most severe problems arise from compression of blood vessels resulting in temporarily or permanent ischaemia of the cerebrum, brainstem or spinal cord, or as a result of direct compression of the spinal cord by a disc fragment or as a sequel to vertebral fracture or luxation. Para- or tetraplegia may follow, sometimes leading to death. These complications are usually encountered in the cervical spine and are extremely rare at the thoracic level. When they occur at the lumbar spine, they may give rise to a cauda equina syndrome, often followed by definite neurological features.

Risks in relation to level

The risks involved in manipulation differ at the cervical, thoracic and lumbar levels.

Cervical level

Serious neurological complications have been reported after manipulation of the cervical spine. The techniques that are blamed to cause most of the injuries are hyperextension manœuvres accompanied by excessive rotation.[45,102,103]

During a recent inquiry over a period of 2 years among 468 Californian neurologists, 55 strokes following osteopathic cervical manipulation were surveyed. Most of the patients continued to have persistent neurological deficits 3 months after the onset and about one-half were marked or severe. Nearly all of the strokes involved the posterior circulation and almost one-half were angiographically proven.[109] A Danish survey reported the incidence of cerebrovascular incidents (CVI) after chiropractic manipulation to be about 1 for every 120 000 cervical treatment sessions, manipulation to the upper neck being about four times more commonly associated with CVI than treatment of the lower neck.[110]

Neurological complications are mainly the result of a dissection of the vertebral artery[104–108]. Vertebral artery dissection (VAD) is an uncommon vascular wall condition that typically involves a tear at some point in the artery's lining and the formation of an intimal flap (see Chapter 9). The latter triggers off an arterial narrowing or even a complete obstruction of the lumen.[111,101] Although the pathophysiology of a dissecting vertebral artery is well understood, the underlying cause of intimal tears remains uncertain. Most experts link VAD to traumas of varying degrees of severity and maintain that because tearing occurs, previous trauma was necessarily involved. An article reviewing 606 cases of VAD reported that 371 (61%) were spontaneous. The remaining 39% were associated with trivial or other trauma, which included manipulation in 9% of the total cases.[112] However, VADs more commonly occur after

very minor trauma, and even everyday activities such as reversing a vehicle, coughing, vomiting, unusual sleeping positions or having one's hair washed at a beauty salon[113]. For that reason, evidence is mounting that the association between spinal manipulation and stroke is coincidental rather than causal and reflects the natural history of the disorder[114].

Thoracic level

Complications at this level are usually due to vertebral metastases or to severe osteoporosis resulting in fractures of vertebrae, ribs or sternum.

Lumbar level

The main complication is compression of the cauda equina because of a massive posterior sequestration of a lumbar disc.[115] Compression of the cauda equina complicating lumbar manipulations without anaesthesia is extremely rare, when it is considered that in the US in 1975 about 124 million office visits to chiropractors took place. Between 1911 and 1992 only 13 cases were recorded.[116] This potential complication should never be taken as contraindication to manipulation. However, anyone who manipulates must be able to recognize the syndrome immediately, so that no time is lost before surgical decompression is performed.

Measures to prevent complications

Although complications may occur and cannot be totally excluded by any means, each manipulator should try to reduce the eventuality to the lowest possible degree. It would be wrong to condemn the manipulator simply because a mishap or a complication occurred. If this was done it would mean that, instead of getting on with his work, the practitioner would forever be 'looking over his shoulder'. It is not possible to arm oneself against unpredictable events. Even if they do occur occasionally, this argument should not be used to condemn manipulation.[116]

Obviously all measures must be taken to decrease the risks as far as possible. In orthopaedic medicine the necessary steps are taken during the whole procedure, starting with the history, through clinical examination, technical investigations and ending with the manipulation itself. Safety measures and acknowledged warning signs are incorporated in each stage. These are discussed in detail in the relevant chapters and are only briefly outlined here.

History taking

Before any manipulation, history taking must be sufficiently thorough to elicit information on drug intake (anticoagulants) and the existence of other (visceral–rheumatoid) diseases. Severe pain in the absence of movement or pain worse at night may indicate that the lesion – whatever it may be – is in a highly inflamed state and unsuitable for manipulation. Expanding pain, excessive weight loss and recent operations may indicate metastases and must always be excluded. All these are severe warning signs.

Cervical root pain of more than 2 months' duration or root pain at lumbar level for over 6 months (unless there is still scapular or lumbar pain influenced by cervical or lumbar movements) does not respond to manipulative reduction. Hence no attempt to manipulate should be made.

Clinical examination

A complete clinical examination must *always* follow. In particular, in relation to the cervical spine, full attention must be paid to the end-feel on passive rotations and on extension. Even if the clinical examination suggests an ordinary disc lesion, if the end-feel shows muscle spasm is empty or if it comes to a bony hard stop, manipulation should not be done before serious disorders have been excluded. Muscle or empty end-feel may point to a disorder such as metastases, fracture or infection. A bony block end-feel implies that it is impossible to increase the range beyond this point, and therefore the lesion is unsuitable for manipulation.

A patient suffering from acute lumbago or sciatica usually cannot put weight on the joint, may suffer from constant pain day and night and on clinical examination may be found to have deviation and muscle spasm. When more severe disorders such as metastases, rheumatoid arthritis and ankylosing spondylitis have been excluded, a disc lesion is most likely and manipulation can be safely performed.

A protrusion of disc substance larger than the aperture from which it emerged – usually characterized by a neurological deficit – means that reduction is impossible. The same accounts for nuclear protrusions, which require traction.

Manipulation should never be used simply because 'no contra-indication has been discovered, no one can think what else to try, and a friend was recently relieved by this means' (Cyriax:[117] p. 31). If the diagnosis is unclear or if too many inconsistencies are found, manipulation should be avoided. Once again it should be stressed that manipulation follows only if the diagnosis of a discodural or discoradicular interaction has been established. For safety, the following must be added: 'If the diagnosis is established but it is uncertain if manipulation will work, then try. If the diagnosis is uncertain and it is unclear whether or not manipulation is safe, do not try.' (Cyriax[3]).

Radiographic appearances

Radiological changes are signs of structural alterations that usually cannot be treated, though it is of most importance to find out if they are relevant to the symptoms present. Osteoarthrosis of the spine cannot be cured by manipulation, but a manipulation can easily reduce a displaced disc fragment even in an osteoarthrotic spine.

Although the diagnosis of tumours of the lumbar spine is largely dependent on radiography examinations, it must be remembered that 30% of the osseous mass of a bone must be destroyed before this type of lesion becomes radiologically evident.[118] Therefore radiographs do not reveal early disease, and too much reliance on negative radiographic appearances can give rise to a false feeling of security. Radiographs that show no evidence of bone disease should not be taken to indicate that manipulation is safe (Cyriax:[64] p. 292). A decision to manipulate because the radiograph is normal carries a high risk of worsening the patient's condition and may even lead to disaster. The diagnosis of lesions in bone in the early stage is mainly dependent on history and clinical examination. Special attention must be paid to 'warning signs'. In several disorders, such as early invasion of bone by a secondary neoplasm, the clinical signs may precede the radiographic findings. In

doubtful cases, when routine radiography fails to support the clinical impression, a radioisotope scan must be obtained.

Appropriate technique

Manipulative techniques contain important safeguards against possible accidents. This is chiefly so for the cervical spine, in which dangerous techniques such as extension in combination with rotation should never be used.[36,119,120] Those with special interest in musculoskeletal disorders should not only read textbooks but must be prepared to take courses in order to learn the necessary theoretical and practical skills before undertaking manipulation.

Once a manipulation has started, the operator must always concentrate on the type of *tissue resistance* (end-feel) *while taking up the slack* just before the final thrust is given. If the end-feel is abnormal, he must stop immediately and must not manipulate. To push through muscle spasm protecting a joint should never be attempted.[117]

To prevent compression of the spinal cord all manipulations must he performed under *traction*.

The major aim of manipulation should always be to gain maximal benefit with the use of minimal force. Therefore it is good sense to start gently and progressively to increase the force if needed.

Each manipulation must always be followed by re-assessment. If the patient is worse, the same manœuvre should not be repeated but another manœuvre can be tried. If the latter also increases signs or symptoms, further manipulations should be abandoned.

Avoidance of overtreatment

Once symptoms and signs have cleared, treatment must be stopped. There is no sense in asking the patient to come back at regular intervals for 'prophylactic' manipulations.

Box 5.4 summarizes measures to prevent complications.

Box 5.4

Measures to prevent complications

History:
- Exclude anticoagulants
- Check for warning signs
- Ascertain duration of root pain

Clinical examination:
- Check for warning signs
- Assess end-feel
- Exclude neurological deficit

Radiographic appearances:
- Exclude structural alterations
- Do not rely on radiography alone; negative radiography does not guarantee absence of disease

When manipulating:
- Avoid dangerous techniques
- Check end-feel
- Use traction
- Start gently
- Reassess after each manipulation
- Do not overtreat

Active movements

The effects of immobilization on skeletal muscle, tendon, ligament, joint capsule and articular cartilage are dramatic and have been described thoroughly in Chapter 3. Physical activity is also the primary stimulus for the repair of musculoskeletal tissues. Therefore, most therapeutic modalities that are advocated in this book are in conjunction with movement. Active movements are defined as those undertaken by the patient via muscular contraction. In orthopaedic medicine they are not so often used as a sole therapy; their main role is in combination with other therapeutic techniques. However, there are a few situations (both therapeutic and prophylactic) where active movements play a particular role.

Simple active movements to gain or preserve normal range in a joint

A few examples make the above clear. Immobilization of the shoulder leads to the development of an arthritis with limitation of all movements in a capsular way if the shoulder is not brought daily through a full range of movement. Total rupture of the infraspinatus tendon leads to limitation of external rotation of the shoulder if the patient is not performing daily lateral rotations.

Treatment of sprains is essentially treatment with movement (see p. 48). Although the first measure is friction, passive and active movements within the limits of pain to maintain normal gliding of the ligament over adjacent bones should be encouraged. When the lower limb is involved, the patient should be instructed to walk as normally as possible but without provoking pain.

Ligamentous adhesions that have developed as the consequence of a chronic sprain at ankle or knee need to be ruptured manually: the joint is forced through its normal range of movement by a high-velocity, short-amplitude thrust manipulation (see p. 12). After the manipulation and in order to retain the mobility achieved, the patient should repeat the same movement actively and on a daily basis. After rupturing of adhesions under anaesthesia, active movements in addition to passive ones are also necessary to maintain the range that has been regained. They should be performed several times a day.

Isometric contractions

Isometric contraction is the development of tension within a muscle without significant change in its fibre length. Joint motion or work is not achieved.

In orthopaedic medicine isometric contractions are mainly performed to strengthen stabilizing muscle groups. The main example is in treatment of shoulder instability: in order to provide a firm foundation for the scapula, the muscles of the shoulder girdle (trapezius, serratus anterior, rhomboids and pectoralis minor) are strengthened by isometric training.

Isotonic contractions

Isotonic exercise is classically defined as the movement of a load at constant resistance through an arc of motion.

In orthopaedic medicine, isotonic contractions are performed in the following situations:

- *In minor muscular tears* after the lesion has been prepared by gentle transverse friction (see p. 4). The contractions are carried out with the muscle in a position of maximal relaxation and with minimal resistance so that no tension falls on the healing breach. They begin as soon as possible after the injury and are preceded by an infiltration with local anaesthesia and by transverse friction. The idea is to promote movement between adjacent muscular fibres to prevent abnormal formation of adhesions because these can disturb the normal increase in breadth on contraction.
- *To strengthen weakened muscles* as in arthritis or after local or generalized immobilization. If passive movements are limited, say by the arthritis, the isotonic exercises should be performed within the painless range to avoid increase of synovial inflammation.
- *To strengthen muscles* so they can protect joints or inert structures from being painfully overstretched. One example is the strengthening exercises of the short plantiflexor muscles and the lumbricals of the foot in the treatment of splay foot and chronic metatarsalgia. Strong muscles that contract properly at each step will take most of the body weight and relieve the metatarsal heads.

Eccentric contractions

Eccentric (lengthening) actions are characterized by elongation of the muscle during active contraction.[122] Over the last fifteen years, eccentric exercises have been promoted as treatment strategies for tendinopathies and muscle strains, especially for the lower limb (quadriceps and Achilles tendinopathy). Greater forces can be produced during eccentric contraction than during concentric (shortening) actions,[123] which leads to positive changes in tissue structure and mechanical properties. One study found that Type I collagen synthesis increased after eccentric training in a group of twelve soccer players with unilateral Achilles tendinosis, offering a possible explanation for the mechanism of tendon healing.[124] Another study described a decrease in tendon thickness and normalized tendon structure measured by ultrasound in a group of subjects with chronic Achilles tendinosis who were trained using an eccentric training protocol.[125] Systematic review of the literature revealed that eccentric exercise may reduce pain and improve strength in subjects with lower extremity tendinosis,[126,127] but whether it is better than other forms of rehabilitation has yet to be determined.

Electrical contractions

In some circumstances a strong voluntary muscle contraction is not possible. Muscles can be (temporarily) paralysed or they are affected by severe injury. In such a situation, daily application of electrical stimulation (ES) may retard the loss of muscle strength or even improve it in already weakened musculature. The gains are not long-lasting, however, and electrical stimulations should only be used temporarily while awaiting neurological recovery. ES can then be replaced by a good exercise programme.

Coordination exercises

During the last decades it has become clear that rehabilitation should not be restricted solely to procedures that improve mobility, strength and endurance but also that functional exercises allowing a better coordination of particular muscle groups should be included in the rehabilitation programme. This kind of training is particularly important in the treatment of problems of instability (e.g. in shoulder, knee and ankle).

The ability to control the position of a joint during active motions (proprioception) and to produce a voluntary muscular contraction to stabilize the joint and/or to alter the joint position so as to prevent excessive joint displacements is referred to as *reactive neuromuscular control*.

Proprioception is a specialized sensory modality that gives information about extremity position and direction of movement: stretch-sensitive mechanoreceptors within skin, capsular ligaments and tendons (see Ch. 3) are activated by tension, thus producing a muscular contraction to protect these structures at the extreme of motion.[128] This type of afferent sensory feedback is extremely important in mediating muscular control over joints and thus preventing them from overstretch and (sub)luxation.[129]

Numerous authors have recommended the training of proprioceptive skills and proper muscular coordination to re-establish the reactive neuromuscular control abilities in the joints at risk and to create a functional joint stability.[130–134] Several techniques exist, from the see-saw block or tilting board in the treatment of functional instability of the ankle to the use of dual channel electromyography biofeedback systems in the treatment of patellofemoral dysfunction[135] and glenohumeral instability.[136] However, most functional training techniques used to re-establish the proprioceptive skills make use of *eccentric training*.[137] Eccentric activation refers to the situation in which the muscle–tendon unit is lengthened while active. Small weights and multiple repetitions of the movements are used.

Proprioceptive neuromuscular facilitation (PNF) techniques can also be used to gain or improve neuromuscular stability at a joint. PNF techniques may be of value in the prophylaxis of recurrent periarticular shoulder lesions. PNF may be defined as a method *promoting or hastening the neuromuscular mechanism through stimulation of the proprioceptors*. Hence, PNF refers to the improvement of flexibility through stimulation of the nerves and muscles internally. The technique involves the use of the principles of reciprocal innervation and the stretch reflex: as a muscle is passively or actively stretched, it is brought to a point of limitation before pain develops. This is the point at which the proprioceptive organs send a message to the central nervous system to terminate the movement before further elongation occurs. At this point the muscles being stretched (antagonist) are contracted for a few seconds

at an intensity of 50% of maximum. This contraction allows for the inhibition of the muscle spindles and Golgi tendon organs and a subsequent initiation of the stretch reflex of the stretch receptors. After releasing the contraction, the muscle is stretched to a new point of limitation and held for another few seconds. The interested reader is referred to Alter's *Science of Stretching*,[138] that offers over eight PNF techniques and exercises.

Injection and infiltration

Musculoskeletal disorders such as tendinitis, minor muscular ruptures, ligamentous sprains and arthritis can usually be treated by infiltration. For an optimal effect the product administered must he put directly into the lesion and not in its surroundings. The descriptive terms 'injection' and 'infiltration' are used; each has a well-defined meaning and expresses a different way by which the product is administered. In *injection* the tip of the needle is placed in exactly the right place and all the product is deposited at one single push, as is done in an ordinary intramuscular injection. This technique is mainly used for intra-articular and caudal epidural injections. Once the tip of the needle has been brought within the joint or the epidural space, the full amount of product is put in. Local administration of a drug into a structure, as in bursitis, tendinitis, tenosynovitis, tenovaginitis, lesions of a muscle belly and also in ligamentous problems, is usually performed by *infiltration*. In this, maximal beneficial effect is obtained when all the different areas within the lesion receive some of the product. This can only be achieved if the tip of the needle is displaced several times while injecting a small amount of the product at each point. An infiltration is therefore a series of injections, given at slightly different places, within the lesion. Although the aim of all infiltrations is the same, the specific technique may vary depending on the type of lesion and its location.

In orthopaedic medicine three types of product are used: local anaesthetics, corticosteroids and sclerosant solution. Each of these has its own specific indications, contraindications and side effects. Although, in each group, several agents are available, it is better to use only one as this leads to optimal therapy.

General principles

To obtain maximal benefit with minimal side effects the following general rules must be observed.

Exact diagnosis

Any treatment must reach the lesion. Infiltrations, like deep friction, need a diagnosis accurate within a millimetre or two and must be directed to the precise site of the lesion. The steroids used in orthopaedic medicine are all suspensions of insoluble particles, so their action is mainly confined to the place where they are administered. An exact preliminary diagnosis must be made, together with proper localization of the lesion.[139]

Choice of product

Many different products are used in musculoskeletal disorders. Local anaesthetics and corticosteroids are most frequently used but occasionally a sclerosant solution containing phenol, glycerol and dextrose is needed. The type of the product, its concentration and volume depend on the structure affected, the nature of the lesion, the degree of inflammation and other additional elements such as age, activities and the general condition of the patient. Of main importance is increased liability to – or the presence of – general or local infections and allergy to the products.

A lesion of the muscle belly can be treated by infiltration of a local anaesthetic, usually procaine, whereas steroid is never used. Musculotendinous insertions do not respond to any product and therefore are never therapeutically infiltrated but are best treated by deep transverse friction. Procaine is of no curative value in tenoperiosteal insertions or periosteal attachments of ligaments; for these, steroid is used or friction is given. In lesions of the body of a tendon, steroid is never infiltrated into the tendon itself, but is put at the surface along the tendon.

For optimal results the appropriate agent at the indicated dose and concentration must be used. For example, 20 mg of triamcinolone at a concentration of 10 mg/ml means that a total volume of 2 ml is administered. This is not the same as 0.5 ml of a 40 mg/ml suspension, as the steroid administered in this way will be concentrated over a much smaller area and may not be sufficient in volume to reach the whole lesion. Moreover, a strong concentration of steroid spread over too small an area may cause an increased risk of tendinous or ligamentous rupture.

Equipment

If a certain amount of product is indicated, it should always be put into a syringe of the corresponding volume. If this is not done, infiltration may fail because of counterpressure offered by the tissue. Care should be taken to fit the needle firmly to the syringe because an infiltration into a ligamentous or tenoperiosteal insertion may demand considerable pressure on the plunger, which could lead to detachment of the syringe.

The needle to be used must be of appropriate length and be as thin as possible. These characteristics are always indicated throughout the text in subsequent chapters. An appropriate needle enables the therapist to recognize the type of tissue by the resistance it offers as the needle penetrates the structure: for example, ligaments and tenoperiosteal junctions have a totally different resistance from that of a muscle belly. Moreover, the thinner the needle the easier it is to recognize differences in resistance on the plunger during infiltration. Both types of resistance are important in giving a good indication of the localization of the tip of the needle.

The main characteristics of the needle types referred to in this book are given in Table 5.3.

Position of the patient

Before any attempt is made to infiltrate, the patient is positioned in the way that renders the lesion most accessible. For

Table 5.3 Main characteristics of needles used

Needle type*	Gauge		Length	
	G	mm	inches	mm
Preparation	19	1.1	$1\frac{1}{2}$	40
2.5 cm	25	0.5	1	25
3 cm	22	0.7	$1\frac{1}{4}$	30
4 cm	21	0.8	$1\frac{1}{2}$	40
5 cm	22	0.7	2	50
7 cm	20	0.9	$2\frac{3}{4}$	70
Spinal	22	0.7	$3\frac{1}{2}$	90

*Terminology used in this book.

each injection, the ideal positions from which to start are presented in later chapters; positions are usually the same as for deep friction. For intra-articular injections, different positions have been described. We present those which are the most simple to perform and which offer the least risk in relation to other neighbouring structures. The landmarks required and sometimes also the affected structure should be palpated and, if necessary, should be marked on the patient's skin.

Aseptic care

Careful aseptic precautions are always necessary in order to avoid, for example, a suppurative arthritis. Aseptic techniques include:

- Hand antisepsis
- Skin antisepsis at the site of insertion
- Disinfecting the rubber septum with alcohol prior to piercing it
- Using a new sterile syringe and sterile needle to draw up the fluid while preventing contact between the needle and the hands
- Removing the needle and using a fresh one for the injection
- Using a no-touch-technique: neither the tip of the needle, nor the skin at the site of insertion should be touched after skin antisepsis
- Using gloves? Gloves can only be used if an assistant handles the non-sterile packages and vials and prepares the syringes. In our opinion, the use of gloves does not add to aseptic safety, if the rules mentioned above are strictly followed.

Technique of infiltration

Two major techniques are considered here: dynamic infiltration, in which the product is injected during movement of the needle, and a static infiltration, in which the product is administered with the needle at rest.

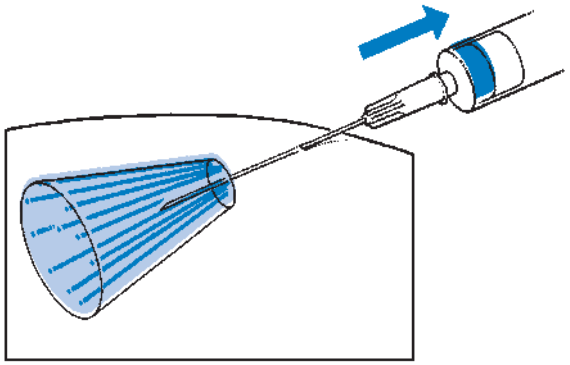

Fig 5.7 • Conewise infiltration.

Dynamic infiltration

This is used mainly when large amounts of product have to be administered in extensive lesions. Three different techniques are used, mainly conewise, fanwise and cylindrical infiltration. A further technique is used for static infiltration.

Conewise infiltration

This is the usual technique for a lesion of a muscle belly. The limb is brought into such a position that the muscle is well relaxed. The tender part is pinched between the thumb and fingers and the needle is inserted obliquely in between them until its tip passes beyond the farthest edge of the lesion. Some of the product is now administered while the needle is withdrawn until the tip is at a point just beyond the nearer border of the lesion. It is then reinserted at a slightly different angle and more product is infiltrated while the tip is again withdrawn (Fig. 5.7). This is repeated several times until the entire lesion has received some of the product. During the whole procedure, the fingers that hold the lesion verify and control the infiltration.

Cone infiltration is also used in bursitis lying within the reach of the fingers. After the lesion has been carefully defined, the needle is directed to the centre of the tender area and towards the underlying bone. The site of tenderness usually cannot be kept between the fingers. The product is infiltrated by a series of partial withdrawals and reinsertions at a slightly different angle.

Fanwise infiltration

This technique is similar to conewise infiltration but is two-dimensional. It is used in subacromial bursitis. The needle is directed towards the centre of the deep part of the subdeltoid bursa and to its full length. By a series of partial withdrawals and reinsertions in a horizontal plane, to the left and to the right from the centre (Fig. 5.8), the full amount of product is applied during withdrawal.

Cylindrical infiltration

A cylindrical infiltration is used to place the agent along the surface of a tendinous body. The tendon is first stretched to provide a stiff flat surface. The needle is tangentially inserted along the tendon between the tendon and its sheath, until the tip reaches the far edge of the lesion. During partial withdrawal as the needle traverses the surface of the tendon, constant pressure on the plunger maintains flow of the suspension. The

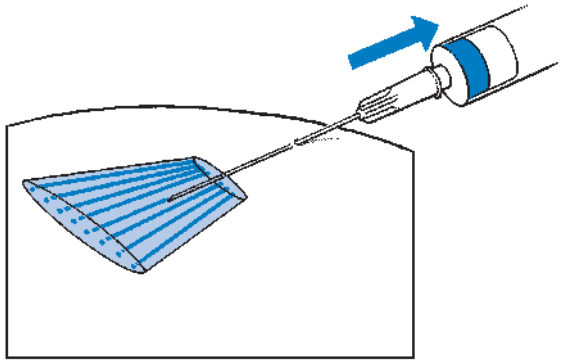

Fig 5.8 • Fanwise infiltration.

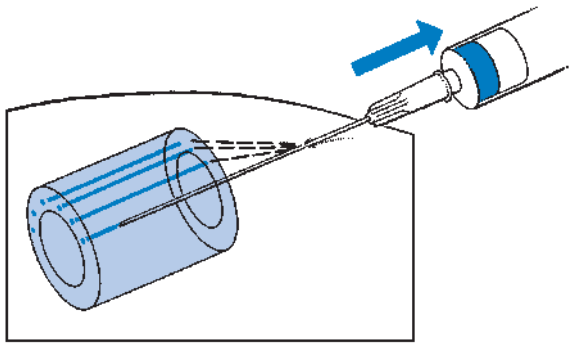

Fig 5.9 • Cylindrical infiltration.

needle is then reinserted parallel to its first position but 2 mm to one or the other side and the manœuvre repeated (Fig. 5.9). This is repeated four or five times until the full amount has been given.

Static infiltration

This technique is mainly used to put a small amount of fluid into a well-delineated area. It is indicated for tendinous insertions and ligamentous attachments to bone. These offer considerable resistance to depression of the plunger. Hence the smallest syringe must be used to provide enough purchase to force the product into the structure. When the tip of the needle lies at the exact site, a typical counterpressure is felt during insertion, just before its point hits the bone. Now a few droplets are injected with the tip of the needle in bony contact. The needle is then five to ten times partly withdrawn and inserted at slightly different angles and depths (Fig. 5.10) until the full amount has been administered and the whole lesion has been treated. The technique is sometimes referred to as *peppering*. During the entire infiltration a typical resistance is felt, much more marked than during infiltration of a muscle belly or a bursa, where resistance is minimal.

Follow-up and after-care

For maximal benefit, all infiltrations in any part of the contractile structures are followed by relative rest for 1–2 weeks. If full activity is continued without this rest, relapse is likely. When tendinous structures are infiltrated by steroid there is a second reason for rest, in that the agent may temporarily weaken the tendon.

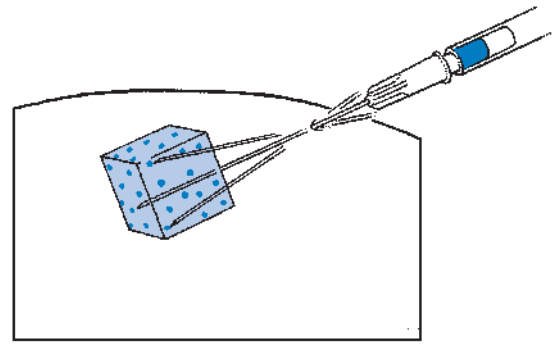

Fig 5.10 • Static infiltration.

The patient should be reassessed after 14 days and, if pain still remains, a second infiltration is given. A partial rupture of a muscle belly offers an exception to this in that it is infiltrated only once, followed next day by deep transverse friction, active exercises and electrical stimulation in the position of maximal relaxation of the muscle. Stress at the site of healing is avoided for about 3 weeks.

After infiltration into a sprained ligament, the joint is immediately used as fully as possible, allowing movements within the limits set by pain but avoiding stretching of the damaged structure. This leads to good functional results in a short period of time.

The advantage of this type of treatment is its rapid effect but on some occasions it may lead to recurrence in tendinous lesions. Recurrences are best treated by deep transverse friction.

Local anaesthetics

Cyriax first started using procaine purely for diagnosis. If the suspected lesion is infiltrated by local anaesthetic, the pain on functional testing should disappear almost immediately, so confirming the diagnosis. He was most surprised when some of those initial patients reported persistent improvement some time later. He continued to use procaine because he felt that the therapeutic results were better than with the alternative local anaesthetics. Nowadays local anaesthetics are still used for both diagnostic and therapeutic purposes.

Because prolonged action of the anaesthetic is never needed in orthopaedic medicine, adrenaline (epinephrine) is not added. In addition, vasoconstriction restricts the spread of the agent so diminishing any beneficial effect.

Types of local anaesthetic

Two major types of local anaesthetic are available: procaine and those belonging to the amide group (e.g. bupivacaine, lidocaine (lignocaine)) (Table 5.4).

Table 5.4 Local anaesthetics and their effects[141]

Name	Strength	Toxicity	Maximum dose (mg)	Latency (min)	Duration (min)
Procaine	1	1	500	5–10	45
Lidocaine (lignocaine)	4	2	200	2	60
Prilocaine	4	1, 5/4	400	2	60
Mepivacaine	4	2	350	1	100
Bupivacaine	16	8	150	2–5	360

Procaine

Procaine is an ester of para-aminobenzoic acid and was first synthesized in 1904 by Einhorn. Until 1943 it was the only anaesthetic available.[140] It is quickly and locally metabolized by an esterase, giving rise to the acid itself, which may act as an allergen. Its effect begins after 5–10 minutes and lasts approximately 45 minutes. The maximum dose used is 250 mg, which corresponds to 50 ml of a 0.5% concentration.

Although classical texts emphasize the hazard of allergic reactions, we have used procaine several times daily for over 20 years without any problems. Cyriax estimated the risk as 1 per 500 000 administrations.

The usual concentrations employed are 0.5 and 2%. Indications for 0.5% procaine are lesions of muscle bellies, most cases of chronic bursitis and caudal epidural injection. Procaine 2% is used to dissolve calcifications in tendons and bursae, and in sinuvertebral nerve blocks.

Amides

Newer local anaesthetics are the amides. They are metabolized in the liver and seldom give rise to allergic reactions. We use lidocaine (lignocaine) and prilocaine to anaesthetize only certain structures so allowing other interventions. For this reason, they are used to anaesthetize the skin and the intercornual ligament before inserting an epidural needle, and for skin and tenoperiosteal anaesthesia before a tenotomy in type II tennis elbow. Because their local anaesthetic effect is stronger and faster acting than that of procaine, they are also used for diagnostic infiltrations around nerves and in tendons, ligaments and bursae.

In countries where procaine is not available, or there is patient allergy, bupivacaine 0.125% is an alternative. The maximal dose used is 60 mg, which corresponds to about 50 ml of a concentration of 0.125%. The immediate effect starts after 2–5 minutes and continues over 3–6 hours.

Side effects

Side effects of local anaesthetics are traditionally divided into three groups:

- Psychogenic reactions
- Toxic side effects
- Allergy.

Psychogenic side effects

These minor side effects are mainly caused by somatosympathetic reactions on pain and fear and are not related to the drug as such. Nevertheless the symptoms may be quite similar to those of real toxic reactions: pallor, cold sweating, dizziness, nausea, yawnings, palpitations and vasovagal collapse with syncope all may be present.[142] They should be taken seriously because if the patient is not placed supine quickly, cerebral hypoxia may follow, with unconsciousness, tremor and convulsions.

To avoid these effects, all patients who require an infiltration should at least sit or lie down and be given a full explanation of what is to happen. If symptoms do occur, the patient is immediately placed in Trendelenburg's position (head and thorax low, legs up) and oxygen given. The patient usually improves promptly after 1–2 minutes.

Toxic reactions

These are dose-dependent side effects related to the amount of product that reaches the blood circulation.[143] They may be the result of unintentional intravascular injection, absolute overdose, swift absorption or delayed elimination of the drug.[144]

If local anaesthetics are used at the indicated dose, which is usually less than half of the maximum dose allowed, and in a proper way – taking care during the administration that it is not directly intravascular – toxic reactions should never occur. However, if they do occur during an injection, administration must stop at once.

Types of reaction

Toxic side effects can be divided into two groups. They may be related to the central nervous system or to the cardiovascular system or to both.

Effects on the central nervous system

Although local anaesthetics may provoke stimulation or depression of both cortex and medulla, stimulation is the more frequent but is less severe than depression. Normally the depression period is preceded by a stimulation stage, but it may come on at once without a prior stage of excitement.[145]

Some *stimulation* of the cerebral cortex and the upper centres may sometimes occur even with a low dose. It is

characterized by anxiety, excitement, logorrhoea, hypertension, headache, dizziness, tinnitus, diminished hearing, disturbed vision, metallic taste, muscular fasciculations around the mouth and tremor. None of these symptoms is severe as such, but they are all signs of the presence of a toxic reaction that could lead to cardiovascular collapse. Further stimulation may be followed by convulsions, which indicate that severe cortical stimulation is present and may progress to postconvulsive depression.[145] Stimulation of the emetic centre causes nausea and vomiting. Stimulation of the cardiovascular centre in the medulla may cause tachycardia and hypertension; respiratory stimulation is characterized by an increased depth and frequency of breathing.

The first feature that draws attention to *depression* of the cortex is sleepiness, together with dysarthria and a feeling of coldness. If injection is not stopped at once and the necessary measures instituted, the outcome may be coma and death. Depression of the medulla may suppress vasomotor control resulting in pallor and hypotension, later followed by syncope and cardiac arrest. Respiratory depression is first characterized by irregular breathing with periods of apnoea and dyspnoea and often cyanosis. Finally, total respiratory arrest may result. A depressive effect is far more dangerous than is stimulation.

Effects on the cardiovascular system

A direct peripheral effect on the blood vessels causes vasodilatation, leading to hypotension. Local anaesthetics have a depressive effect on the myocardium, which can lead to bradycardia, arrhythmia and cardiac arrest. In patients with already weakened myocardium, heart failure may result.

Local anaesthetics can alter the blood pressure in different ways. Stimulation of the CNS leads to hypertension, depression to hypotension. Hypotension may be intensified via a direct vasodilatory effect on the blood vessels and by direct myocardial depression. Furthermore, in lumbar epidural injection, hypotension may be due to blockade of the sympathetic nerves.[146]

Clinical appearance

Toxic side effects may clinically appear in two ways:[147]

- *A delayed reaction* may occur within 5–30 minutes after the infiltration. This is the most frequent reaction and is due to slow absorption until a toxic level is reached. It usually first gives rise to stimulation of the cortex before respiratory symptoms and cardiovascular collapse occur. For this reason the patient should always remain under supervision during the first half hour following an injection.
- *An immediate reaction* may occur within seconds to minutes of the administration, with all toxic reactions coming on at once. It is usually the result of intravascular injection or of swift absorption. Collapse may occur very quickly and death may follow rapidly if resuscitation is not begun at once.

Treatment

The most important measures, even if only minor signs of CNS or cardiovascular involvement are present, are to stop further infiltration at once and to administer oxygen. These may be sufficient to stop further development towards more severe conditions. The rest of the treatment should be in relation to the degree of toxic reaction:

- *Fear or anxiety attacks* are best treated by intravenous diazepam (5–10 mg).
- *Cerebral signs* – tremor and convulsions – require immediate administration of 100% oxygen via a mask. Small intravenous doses (5–10 mg) of diazepam may be given. Barbiturates and short-acting muscular relaxants should only be used by the experienced and should always be preceded by the administration of oxygen.[144]
- *Hypotension:* the patient is put into the Trendelenburg position. If this is not sufficient, administration of vasoactive drugs such as dopamine or noradrenaline (norepinephrine) may be required.[143] In circulatory depression, intravenous fluid must also be given. Bradycardia can be treated by atropine.
- *Cardiac arrest:* oxygen and external cardiac massage are given.
- *Respiratory depression* is treated by oxygen and artificial respiration (intubation) (see Box 5.5).

Allergic (anaphylactic) reactions

Side effects not related to dose can occur even after the administration of small amounts of the agent. Previous exposure and sensitization to the active product or preservatives (methylparaben) or any other accessory material present is an essential precondition.

Two types of allergic reaction may occur: an anaphylactic reaction, which may be life threatening, and a local reaction

Box 5.5

Summary of treatment of side effects of local anaesthetics

Always:
- Stop further infiltration
- Give oxygen at once

Tremors and convulsions:
- 100% oxygen via mask
- Diazepam i.v. 5–10 mg

Vascular collapse:

Hypotension:
- Trendelenburg position
- Vasoactive drugs i.v. (dopamine, isuprenaline hydrochloride, adrenaline (epinephrine))
- Fluid i.v.

Bradycardia:
- Atropine

Cardiac arrest:
- External cardiac massage

Respiratory depression:
- Give oxygen
- Artificial respiration (intubation)

presenting as dermatitis from local contact with the skin. The latter is usually encountered only in professionals who use the product, rather than in patients.

Although allergic reactions are frequently mentioned in relation to local anaesthetics they are in fact rare.[147] According to Cyriax, anaphylactic reactions occur in 1/50 000 procaine infiltrations, though they are more frequently encountered with procaine than with the amides.[144,146,148] Since an anaphylactic reaction may be very dramatic, with a mortality rate of about 3.4%, one must always be aware that it is possible.[149] Before local anaesthetics are administered the patient must always be asked for evidence of an allergic constitution. If a patient claims to be allergic to local anaesthetics, a careful and detailed history must be taken because 99 out of 100 reactions are due to toxic or psychogenic side effects and not to an allergy as such.[147] An intradermal test with a small amount of agent can be useful but is not 100% reliable.[147]

An anaphylactic reaction may come on immediately after the injection or some time later, up to about 30 minutes. It is the immediate type which is often dramatic. The initial feature of an anaphylactic reaction is often *flushing* occurring within 20 minutes after administration. This may be quickly followed by dyspnoea due to *bronchiolar constriction* and localized *oedema of the larynx and glottis*. It may end in *respiratory obstruction* which is the main cause of death.

The respiratory symptoms are accompanied by vasodilatation which leads to *hypotension* and *shock*. Occasionally other anaphylactic reactions such as *urticaria* and *angioneurotic oedema* may also present immediately, but are far less dramatic.

Treatment

Treatment is different for immediate and delayed allergic reactions. The treatment is outlined in Tables 5.5 and 5.6.

Immediate reaction

Even when only minor signs of anaphylactic reaction are present 0.3–0.5 ml of *adrenaline (epinephrine)* 1/1000 (0.3–0.5 mg) is immediately administered by the subcutaneous route to provoke vasoconstriction, bronchiolar dilatation and resorption of oedema. Since adrenaline (epinephrine) is broken down quickly, it should be repeated every 20 minutes. Subcutaneous administration of adrenaline can only be done if the general circulation is intact. When blood pressure is too low it must be carefully administered intravenously. In this event 3–5 ml of adrenaline (epinephrine) 1/10 000 must be administered in repeated shots of 1 ml (0.1 mg) until effect has been attained.[150] Small repeated shots are necessary to avoid ventricular fibrillation. Some also advise inhalation of a 1/10 000 adrenaline (epinephrine) solution via aerosol in case of laryngeal oedema. *Steroids* inhibit allergic reactions but act too

Table 5.5 Classification of anaphylactic reactions of increasing severity and their treatment

Severity	Symptoms	Treatment
I	Urticaria Red conjunctivae Fever	Antihistamine
II	Hypotension Dyspnoea Tachycardia Nausea Diarrhoea	Trendelenburg position 100% oxygen Adrenaline (epinephrine) Antihistamine Corticosteroid Aminophylline
III	Shock: circulatory collapse and angioneurotic oedema Life-threatening spasms of the bronchi	Trendelenburg position 100% oxygen Intubation Infuse: Adrenaline (epinephrine) Antihistamine Corticosteroid Aminophylline
IV	Cardiac arrest Respiratory arrest	Heart massage Artificial breathing

Table 5.6 Medication used in anaphylactic reactions

Drug	Dose	Notes
Adrenaline (epinephrine)		
Adults		
Normal blood pressure	1/1000, 0.3–0.5 ml s.c.	To be repeated every 20 min
Severe hypotension	1/10 000, 3–5 ml i.v.	1 ml per shot
Children	1/1000, 0.01–0.03 ml/kg s.c.	
Antihistamine (clemastine)	2 mg i.m./i.v.	Every 6 h for up to 24 h
Corticosteroids (dexamethasone)	4–8 mg i.v.	Every 6 h for up to 24 h
Aminophylline		
Adults, initial dose	240 mg i.v.	
Children		
Initial dose	5 mg/kg i.v./i.m.	
Follow-up dose	0.4 mg/kg/h i.v.	

slowly in this situation. Oxygen should also be given but may be of little value if the airway is severely obstructed. In the latter case, *aminophylline* should also be injected.

The patient should remain under supervision during the first few hours after the anaphylactic reaction.

Delayed reaction

If the allergic reaction comes on only after 30 minutes, administration of an antihistamine drug is sufficient.

Corticosteroids

The adrenal corticosteroids are classified into two groups: mineralocorticoids such as aldosterone, with sodium-retaining activity, and glucocorticoids, which influence the intermediary metabolism (nitrogen catabolism, increased glucogenesis) and have a strong anti-inflammatory and anti-allergic effect. The ability to suppress inflammation has made the glucocorticoids very useful but also potentially harmful. Administered in high doses, they may cause Cushing's syndrome.[151]

All corticosteroids used in orthopaedic medicine are glucocorticoids. The first was hydrocortisone, extracted from the adrenal cortex by Kendall in 1936, and first intra-articularly injected by Thorn in 1950.[152] Since then many other steroids have been synthesized. Efforts to increase the anti-inflammatory effect and to diminish the influence on metabolism have remained largely unsuccessful so far. Thus, unnecessary use should be avoided.

The ideal steroid should meet the following criteria: little discomfort to the patient during and after injection, a low level of absorption into the systemic circulation (if absorption does occur, it should be slow), together with a prolonged local effect without general and local side effects.[153] Some preparations are formulated specifically for local use and are available as a crystalline suspension. The less water soluble they are, the less they are absorbed into the general circulation. As a consequence they have a more prolonged local effect and fewer general side effects. Intrasynovial administration has the advantage of a maximal local benefit with minimum systemic side effect.[154]

The agent we use most often is triamcinolone acetonide, in a concentration of 10 mg/ml. Throughout this book, this is the product and concentration intended, unless indicated otherwise in the text. It has a mean duration of activity of about 14 days, whereas triamcinolone hexacetonide has more prolonged activity.[155] Normal doses used are 5 mg for small joints, 20 mg for medium-sized joints and 50 mg for the hip and knee.

Therapists who prefer another type of corticosteroid should always administer the dose equivalent to the one indicated in the text (see Table 5.7).

Table 5.7 Corticosteroids

Product	Anti-inflammatory effect
Hydrocortisone	1
Cortisone	0.8
Prednisone	2.5
Prednisolone	4
Methylprednisolone	4
Triamcinolone	5
Betamethasone	28
Dexamethasone	28
Beclometasone	40

Effects of local corticosteroids

Corticosteroid injected locally has a local anti-inflammatory effect due to stabilization of the lysosomal membrane with decreased liberation of cytotoxic enzymes. Steroids also impair the proliferation of fibroblasts and decrease the rate of production of mature collagen. They decrease plasma fibrinogen as well and have an increased fibrinolytic activity.[156] Furthermore, corticosteroids reduce oedema formation and the escape of plasma protein across the capillary membrane, and diminish the number of leukocytes in exudate at an inflammatory site. All these effects lead to reduction of pain and fibrosis.[157–161]

When injected into a joint, steroid is partly broken down by enzymes from the synovial membrane and is partly resorbed into cells of the synovial fluid and cells of the synovium. A small amount enters the general circulation.

Indications for local corticosteroids

Joints

Beneficial effects occur in traumatic arthritis, monoarticular steroid-sensitive arthritis, rheumatoid arthritis, crystal-induced arthritis (gout and pseudogout), ankylosing spondylitis, lupus erythematosus and psoriasis.[153] Steroids are ineffective in Reiter's disease (Cyriax:[3] p. 52).

Monoarticular steroid-sensitive arthritis is of spontaneous onset without any other signs of rheumatological disorders and resolves equally spontaneously over months or years. The joints affected are the glenohumeral, the elbow, the knee, the hip, the ankle and the temporomandibular. The treatment of choice is intra-articular steroids. Usually, the joint must be kept under continuous anti-inflammatory influence for some time. Hence a specific sequence of injections must be observed.

Improvement is subjectively felt by the patient in that pain and stiffness diminishes, and objectively shown by a decrease of local heat and effusion together with improved function. Patients should be warned against overactivity at weight-bearing joints for the first days after injection to avoid further destruction of cartilage.[162] Moreover, the efficacy of an injection is greater with relative rest.

In arthrosis, lasting improvement is not to be expected.[163] Some authors even suggest, although this has never been scientifically proven, that it may accelerate the degenerative process.[162] If synovitis complicates arthrosis, intra-articular injection may well be beneficial.

Tendons

Steroids may be indicated in tendinitis, tenosynovitis and tenovaginitis. It is often used in tendinitis of the supra- and infraspinatus tendons and the subscapularis tendon at the shoulder.

The same applies for type II tennis elbow and for golfer's elbow at the tenoperiosteal insertion. In the lower limb, steroid injection is mainly used in supra- and infrapatellar tendinitis and for tendinitis of the peroneal tendon.

To avoid rupture, infiltration should be at the tenoperiosteal insertion or between tendon and tendon sheath, never into the body of the tendon.[162,164–167] Ruptures have been reported mainly after intratendinous infiltration with agents of high anti-inflammatory effect or at too high a concentration or when too frequently administered. When the rules are respected as set out in this chapter, there should be no danger of rupture.

Ligaments

In the acute stage – within 24 hours of the injury – of a ligamentous sprain at the ankle or tarsus or of the medial and lateral collateral ligaments at the knee, a steroid infiltration quickly helps but should only be done at the ligamentous insertions. Because the inflammatory reaction ceases shortly after administration, the ligamentous lesion can heal in the presence of movement. This leads to better functional results and to absence of adhesions, which are later often the reason for chronic pain.

In sprain of the cruciate ligaments of the knee, steroid infiltration is the only possible treatment, no matter what the stage of inflammation. Steroid infiltration is also an important part of the treatment in sprains of the radial and ulnar collateral ligaments of the wrist and in plantar fasciitis.[168]

Bursae

Depending on the type and location of bursitis, steroid is used at once or after an infiltration with procaine has been found to be unsuccessful. Pain, local tenderness and functional impairment are all reduced.[169]

Nerves

Compression of the median nerve in the carpal tunnel of the ulnar nerve at the ulnar sulcus or of any nerve root by an unreducible disc protrusion all usually benefit from an infiltration with triamcinolone around the nerve.[170]

Local side effects

Unwanted side effects of local corticosteroids are minimal compared with those of even low doses of oral steroids.[153] They are traditionally divided into local and general side effects.

Musculoskeletal side effects

There are a number of musculoskeletal side effects of local corticosteroid injection.

Iatrogenic infectious arthritis

This complication is the most feared although it is seldom encountered. The incidence varies from author to author: it follows between 1/1000 and 1/40 000 injections.[153,171] The usual organism is *Staphylococcus aureus*; less often, Gram-negative organisms are involved.[172] The condition should not be regarded as a real side effect caused by the steroid but is due rather to inadequacy of aseptic care or contamination, chiefly occurring during preparation of the syringe. Patients who suffer from diabetes, or who are receiving oral steroids or are immunosuppressed (leukaemia, AIDS, drug abuse) are more vulnerable.[173] Suppurative arthritis may often lead to therapeutic difficulties, and death may follow.[174]

Obviously this complication should be avoided by good antiseptic care, especially when the injection is made into a high-risk patient and when infiltrating in the neighbourhood of a joint or in the joint itself. Although skin lesions in psoriasis are highly colonized by bacteria, it has not been documented whether intra-articular injections given through such plaques increase the likelihood of an infectious arthritis.

Destruction of joint cartilage and evolution of steroid arthropathy

It has been suggested that intra-articular steroids may hasten the process of arthrosis by a deleterious effect on cartilage, leading to changes that closely resemble a Charcot-like neuroarthropathy. Steroid depresses the synthesis of collagen and proteoglycans, which may result in a loss of stiffness of the cartilage. In non-weight-bearing joints this has little or no effect. In weight-bearing joints it may result in fissure formation at the surface of the cartilage and cystic degeneration in the middle zone.[175–178] However, rapid progression to degeneration has not been proved with certainty.[171,179] Cases have been reported of multiple intra-articular injections in some joints not leading to any abnormalities on later radiography.[180,181] Often effects of local steroid cannot be differentiated from those caused by general administration of the product,[182] prompting the question whether it is a local or general effect. Because it is difficult to differentiate the possible destructive effects of the steroids from the natural progression of the osteoarthrosis, even though the risk may appear small, it is a good habit to avoid frequent injections. Moreover, injection into cartilage should never be done. When too much counter-pressure on the plunger is present, the tip of the needle must be replaced. It is also wise to rest weight-bearing joints for 24–48 hours after an injection.[139]

Flare up of crystal-induced arthritis

During the first 48 hours after an intra-articular injection of a crystalline suspension, a synovitis may flare up as response to the crystals. The mechanism is the same as in gouty arthritis. An equally painful inflammatory reaction is occasionally encountered after a local tenoperiosteal infiltration. Normally it disappears within 12–48 hours. If the reaction is prolonged, iatrogenic infection must be excluded.

Rupture of ligament or tendon

Tendon ruptures have been described after one or multiple infiltrations.[166,183,184] Infiltration of steroids into acutely injured ligaments in the rat significantly impaired the healing process relative to a non-injected ligament at 10 days and at 3 weeks after injury.[185] However, after 6 weeks the tensile strength (the ultimate stress) of the ligaments that had been injected with the steroids returned to a value that was equal to that of the controls that had not received an injection.[186] Although other studies have not confirmed these findings,[187,188,189] infiltration into the tendon body should never be done. In tenosynovitis, steroid can safely be infiltrated between tendon and tendon sheath and at the tenoperiosteal insertion, although multiple repetitive infiltrations must be avoided.

Calcification

Punctate calcifications of joint capsules and pericapsular calcifications are common after intra-articular and periarticular injections. Steroid paste can be found on the surface of infiltrated tendons. These observations are not clinically important.

Neurovascular complications

Direct intrafascicular injection of steroid in peripheral nerves may provoke permanent damage, whereas extrafascicular injection does not appear to be harmful.[190] The mechanism of injury is multifactorial and can be related to direct trauma with the needle, to ischaemia and to a neurotoxic effect of the steroid or of the buffer agents and additives such as polyethylene glycol and benzyl alcohol. The first features are severe radiating pain and numbness or paraesthesia in the sensory territory of the nerve, together with motor deficit. The pain usually responds poorly to narcotics and may persist for many years.[191] As to the steroid itself, triamcinolone hexacetonide and hydrocortisone are most hazardous and dexamethasone causes minimal damage, whereas triamcinolone acetonide is intermediate.[190,192]

Damage to the nerve should be treated conservatively for about 12 weeks. If the neurological deficit does not improve after this time, neurological consultation is necessary.

Dermatological side effects

Fat necrosis, atrophy of skin and subcutaneous tissue and depigmentation of the skin may be encountered. These are due to a faulty injection technique or to leakage of the product after an intra-articular injection. The latter occurs often in smaller joints if the volume injected is excessive. Consequently, if resistance during the injection increases markedly, the injection should be stopped.

General side effects

Although injected intra-articularly or into the soft tissues, corticosteroids do enter the circulation. The causes are leakage and absorption. Therefore general side effects depend on the administered dose, the frequency of injections, the number of joints injected and the aqueous solubility of the agent. The greater the aqueous solubility, the higher the absorption rate. Less soluble microcrystalline suspensions remain within the joint for longer. Administration of a given dose equally divided between two joints produces more general side effects than if the same amount was injected into a single joint – the result of a larger absorptive surface.[172]

The majority of the more severe systemic effects can be avoided if no more than two joints are treated at the same time, using a maximum of 40 mg triamcinolone and allowing an interval of 1 month between two injections.[193] If treatments are performed as recommended in this book general side effects are extremely rare.

Endocrinological side effects

There are five categories of potential endocrinological side effects.

Disturbance of hormonal equilibrium

This can result in either hyperglycaemia or suppression of the adrenal cortex via depression of plasma cortisol levels:

- *Hyperglycaemia*: glucocorticoids have an important influence on the intermediary metabolism. They increase circulatory glucose via stimulation of gluconeogenesis and decrease the intracellular use of glucose. Therefore it is wise to advise diabetic patients to check their blood sugar more closely for the first few days after the use of steroid.
- *Suppression of the adrenal cortex via depression of plasma cortisol levels*: small doses of steroid may provoke some suppression of the adrenal cortex.[194] This seems to occur not only when steroids are administered orally but also after intra-articular injections.[195] Prolonged administration renders the adrenals atrophic and provokes suprarenal insufficiency with symptoms such as hypotension, anorexia, fever and generalized joint or muscular pain.

Iatrogenic Cushing's syndrome

The full syndrome with weight gain, depression, insomnia, amenorrhoea, diminished libido, thinned skin, muscular weakness, polyuria and polydypsia is seldom encountered after local use of steroids.[180] Occasionally facial hirsutism and acne may be seen.

Flushing

In the first few days after an intra-articular injection, some patients suffer from erythema and warmth in face, neck and chest. This is a totally benign but rather frequent sensation which is more common after the use of triamcinolone.

Shaking and chills

Very rarely patients suffer from chills and shaking after the use of steroid, a reaction that normally abates within 24–48 hours.[154]

Interference with the menstrual cycle

In female patients repeated injections with steroid may lead to dysfunctional uterine bleeding. Steroids may also interfere with hormonal contraceptives. There is no evidence for a teratogenic effect.[196]

Musculoskeletal side effects

In addition to the local musculoskeletal side effects already mentioned, there can be systemic musculoskeletal effects.

Osteoporosis and increased risk of fractures

It is difficult to estimate the exact incidence of osteoporosis provoked by corticosteroids. Nevertheless, special care should be taken when administering them to post-menopausal females because of the increased likelihood of these side effects.[193,197]

Steroid myopathy, spontaneous tendon ruptures and aseptic necrosis

Any of these may occur, although they are all very rare.[198]

Immunological side effects

Suppression of the inflammatory mechanism sometimes leads to a disappearance of symptoms in non-injected joints. Chronic use of steroids may increase the liability to infections.

An allergic reaction to steroids is not expected because they all have immunosuppressive and anti-inflammatory activity.

However, a number of well-documented allergic anaphylactic (type I) reactions to corticosteroid medications have been reported.[199] Recent reports have warned of potential (though rare) anaphylactic reactions after intra-articular or intralesional injection of triamcinolone acetonide.[200–202]

One recent study indicates that the triamcinolone acetonide component responsible for the patient's reaction is the suspending agent carboxymethylcellulose.[203] It is therefore suggested that care be taken and component testing eventually considered when patients experience allergic-type reactions to drugs.

Miscellaneous side effects

Central nervous system, gastrointestinal and ophthalmological side effects have been reported:

- Prolonged use of steroids may provoke changes in personality and mood.
- In patients who have previously suffered from peptic ulcer and pancreatitis, steroids should he cautiously used.
- After long-term use of steroids some patients may complain of worsening of vision. This may be due to glaucoma or cataracts.[204]

Indications for and contraindications to local corticosteroids

The indications for corticosteroid injection are given in Box 5.6. Contraindications may be divided into absolute and relative (Box 5.7).

Viscosupplementation

Over the past 2 decades, the use of intra-articular viscosupplementation in the non-operative management of patients with osteoarthritis has become quite popular. Viscosupplementation refers to the concept of synovial fluid replacement with intra-articular injections of hyaluronic acid (HA) for the relief of pain associated with osteoarthritis.[205] HA is a high molecular weight polysaccharide and is an important component of synovial fluid and extracellular matrix of articular cartilage. It contributes to the elasticity and viscosity of synovial fluid. HA acts as a fluid shock absorber and it helps to maintain the structural and functional characteristics of the cartilage matrix.[206,207] It also inhibits the formation and release of prostaglandins, induces proteoglycan aggregation and synthesis, and modulates the inflammatory response.[208] Any degradation of HA is therefore associated with increased vulnerability to articular cartilage damage. Treatment with HA is indicated for patients who are functionally limited due to osteoarthritic pain and who have failed to respond adequately to standard treatment options and wish to postpone or avoid surgery. Viscosupplementation is currently accepted as a useful therapeutic modality in treating patients with osteoarthritis of the knee or hip,[209,210] with beneficial effects on pain, function and patient global assessment.[211] Recently, promising results for viscosupplementation in grade I and II ankle osteoarthritis have also been published.[212,213]

Box 5.6

Indications for corticosteroid injection

Tendons

- Tendinitis at a tenoperiosteal junction
- Tenosynovitis/tenovaginitis: injection between tendon and tendon sheath, never into tendon

Joints

- All non-supportive types of synovitis
- *Exception*: Reiter's disease

Bursae

- Acute subdeltoid bursitis
- Retrocalcaneal bursitis
- Ischial bursitis
- Bursitis intractable to local anaesthetics

Ligaments

- Acute stage of a sprained ligament
- Plantar fasciitis
- Sprained cruciate ligaments at the knee
- Sprain of radial and ulnar collateral ligament at the wrist

Spinal disc lesions

- Epidural injection: in patients intractable to local anaesthesia
- Sinuvertebral block

Box 5.7

Contraindications to corticosteroid injection

Absolute contraindications

- Infection of a joint
- Severe infection of neighbouring skin
- Osteomyelitis in neighbouring bones
- Bacteraemia
- Bacterial endocarditis
- Active tuberculosis and herpes corneae
- Immune deficiency (leukaemia, AIDS)
- Allergy to steroid or its vehicle
- Osteochondral fracture
- Joint prosthesis
- Uncontrolled clotting disorder

Relative contraindications

- Anticoagulant treatment: the risk of bleeding from the needle puncture is small, but clotting should not be excessively delayed[171]
- Haemarthrosis
- Reiter's disease
- Markedly unstable joint
- Poorly controlled diabetes
- Adjacent abraded skin: chance of infection is real

Table 5.8 Phenol preparation for injection (P2G)

Sclerosing agents

Introduction

Chemical agents such as phenol and dextrose are infiltrated into weakened ligaments and tendons in order to create the formation of strong, thickened fibrous tissue. Because of its proliferative effect on connective tissue, the technique is called *prolotherapy* or *sclerotherapy*.

Product

The original solution, used by Hackett and consisting of zinc sulfate and carbolic acid, provoked painful reactions and was not totally risk free.[214] The mixture used nowadays is the one chosen by Ongley which has a safe reputation as it was regularly used to sclerose varicose veins. It is formulated as described in Table 5.8 and is mentioned under the name P2G.[215]

Mode of action

The mechanism of action for prolotherapy has not been clearly established. The main hypothesis is that the infiltration produces a local inflammatory reaction which is followed by an increased proliferation of fibroblasts and production of new collagen fibres. The final outcome is tightening, reinforcement and loss of normal elasticity of the ligaments.

Liu *et al*[216] and Maynard *et al*[217] studied the histologic effect of injections with a sclerosant. Biopsies of infiltrated medial collateral ligaments of the knee of the rabbit showed not only increase in ligamentous mass and strength but also a normal alignment of the fibres. In other words, the newly produced connective tissue did not have the chaotic appearance of scar but appeared much the same as normal tissues, except that they were thicker, stronger, and contained fibres of varying thickness.

Klein *et al*[218] performed biopsies of posterior sacroiliac ligaments in three patients with chronic low back pain both before and after prolotherapy injections. After six injections at intervals of a week they found an increase in the average ligament diameter measured by electron microscopy from 0.055 micrometres to 0.087 micrometres. Light microscopy showed an increase in collagen-producing fibroblasts. The ligament orientation was organized and linear, as in normal ligaments.

In addition to the effects on fibrous tissue, phenol also has a neurolytic effect. When injected in or around the medial branches of the posterior ramus, it provokes a chemical denervation. This may explain the quick relief (sometimes from the day after the injection) obtained by a number of low back pain patients, treated with sclerosant injection.[219]

Another possible mode of action is through the sclerosing of pathologic neovessels that are frequently associated with painful tendinopathy.[220,221] Finally, the potential of prolotherapy to stimulate release of growth factors favouring soft tissue healing has also been suggested as a possible mechanism.[222]

Table 5.9 Prolotherapy: Indications

Ligaments	Lumbar spine	Lumbar instability
		Chronic postural backache
		Intractable backache
	Sacroiliac joints	Sacroiliac dysfunction (ligamentous pain)
	Peripheral joints	Carpal instability
		Tibiofibular ligaments
		Acromioclavicular ligaments
Tendons		Achilles tendinitis (midportion)
		Infrapatellar tendinitis
		Tennis elbow type II
		Recurrent supra- and infraspinatus tendinitis

Indications (Table 5.9)

Ligaments

1. The main indication for sclerosant therapy is at the lumbar spine. In recurrent disc protrusions or in chronic backache from postural ligamentous pain (see p. 459), a series of infiltrations is made in all the dorsal ligaments of L4–L5–S1 motion segments.

   Prolotherapy is also used for pain relief in 'intractable backache' of the lumbar spine (see p. 582). The positive effect after the injections is thought to be caused by the neurolytic effect of the phenol. The agent is infiltrated around the lateral or medial branch of the posterior ramus and may cause pain relief of months' or years' duration.
2. Sclerosing injections are also used in treating sacroiliac strains. Infiltration is always at the ligamentoperiosteal junction (see p. 608).
3. Recurring carpal subluxations or in the inferior tibiofibular ligament. Infiltration is into the remains of the ligament at the ligamentoperiosteal attachment. The injections can also be used in the treatment of recurrent subluxations and strain of the *acromioclavicular joint*.

Tendons

During the last decade some reports of good results with prolotherapy in the treatment of painful chronic mid-portion Achilles tendinosis were published.[223,224] It is suggested that neovessels play a key part in causing chronic tendon pain, hence the curative effect of their sclerosis.[225,226] Prolotherapy has also been used in the treatment of chronic infrapatellar tendinitis,[220] hip adductor tendinopathy[227] and chronic plantar fasciitis refractory to conservative care[228]. Also type II tennis elbow (tendinopathy of the origin of the extensor carpi radialis

brevis) in which previous infiltrations with steroid have given poor or only temporary relief is a good indication for sclerosing injections.[229,230]

Finally, proliferant infiltrations may also be required in recurrent supra- or infraspinatus tendinitis. Again the injections should be given tenoperiosteally.

Side effects and complications

Infiltration of a sclerosant is quite painful. Therefore 25% of a strong local anaesthetic should always be added to the sclerosant solution. After an hour and up to 2 days thereafter there is considerable after-pain, sometimes to such an extent that the patient needs strong analgesics. Apart from the after-pain there are very few reported side effects.

In 1993 Dorman published a survey of prolotherapy injections performed on a total of 494 845 patients.[231] Of these, 343 897 were treated for low back pain. Only 66 minor complications were reported. These included 24 reports of allergic reactions and 29 instances of pneumothorax. All of these resolved without serious problems. There were also 14 reports of major complications, defined as the patient needing hospitalization or having transient or permanent nerve damage.

Results

A double-blind controlled study of prolotherapy was published in *The Lancet* in 1987.[215] The investigators used a strict set of criteria (such as no litigation, long-standing pain, no severe medical illnesses and a diagnosis of ligamentous back pain). One half of a group of 81 patients received prolotherapy injections with a solution of dextrose, phenol, lidocaine (lignocaine) and glycerin, while the others were injected with saline. The average length of time of symptoms was 8.98 years in the treatment group and 10.72 years in the placebo group. The results showed a statistically significant difference in the two groups, with the prolotherapy group showing a marked decrease in subjective pain as compared to the saline groups ($p < 0.00l$ at 6 months). A later double-blind study in 1993 showed similar results.[232]

History

History taking in patients with problems in the neck, trapezius or shoulder region should be as detailed as possible and great care should be taken to define every symptom precisely. Especially when a controversial treatment, such as manipulation, is to be considered, it is vital that nothing has been forgotten that could constitute a contraindication.

Age may be important, because some disorders do not occur before or do typically occur at a certain period of life. For instance, torticollis in a baby is probably congenital. The same clinical picture in a 5-year-old child is more likely to be caused by contracture of the sternocleidomastoid muscle after, for example, glandular swelling or abscess formation. During and after adolescence it is more probably the result of a disc protrusion.

The same argument applies to root pain. Under the age of 35 it is scarcely ever caused by a disc except after trauma, in which it may occur from 30 years upward. Radicular pain in a young person is usually the result of a neurofibroma, while in the elderly it is commonly the result of compression by an osteophyte or invasion from secondary deposits in the spine, rather than a disc protrusion.

Early morning headache is typical in the elderly and is often the result of contracture in upper cervical ligaments. Headache from temporal arteritis also occurs late in life.

Whenever symptoms appear in a patient of the 'wrong' age group, further investigation should be requested in order to exclude more serious disorders.

The patient's *work*, *hobbies* or preferred *sport* may give an idea of postures, movements or strains that may be causative or provocative.

Cervical spine lesions may lead to the following symptoms: pain, paraesthesia, vertigo or symptoms related to the vertebral artery, and incoordination and spasticity.

Pain

Pain is the most common symptom. Its localization may give an idea of the position of the lesion. Details about its evolution and behaviour help to determine the nature of the disorder.

If this is the patient's first presentation with a problem in the cervical spine, questions are asked about the current complaints (see below). In a recurrence, a detailed and chronological reconstruction of the past history should be made.

The patient may present with acute, subacute, chronic or recurrent pain. Acute and subacute episodes are characterized by difficulty in moving the head without exacerbation of the pain. Except in young people with torticollis or after injury, acute lesions are not as common as more chronic complaints. Chronic lesions come and go for months or years without any tendency towards spontaneous recovery. Most problems in the cervical spine, however, are recurrent, which implies that the course is characterized by definite attacks of short duration. The examiner should then find out whether the patient

© Copyright 2013 Elsevier, Ltd. All rights reserved.

is totally free from pain in between the attacks, for how long the symptoms last and whether the pain is always felt on the same side.

Onset

Next, the following questions are asked about the onset of the pain.

- Where did it start?
  - Pain of cervical origin very often starts at the cervical spine but frequently spreads or shifts to another region quite quickly, so that the cervical source may pass unnoticed.
  - Interscapular onset of pain is typical of a lower cervical disc lesion that compresses the dura. In contrast, it is very unusual for pain to begin in the arm. Should this occur, the possibility of a neurofibroma, compressing a nerve root, has to be considered in young people. In the elderly, an osteophyte or even a malignant process is more probable.
- When did it start?
  - Pain of cervical origin may occur in discrete attacks, especially when a disc lesion is responsible. It is important to encourage the patient to recall the first episode and to ask for a chronological account. In discal root pain, a normal period of spontaneous relief should be recognizable.
- How did it start?
  - The origin may be spontaneous, either acute or chronic, but may also be the consequence of injury. In the latter case, more details should be sought about the type of injury (e.g. a fall or whiplash). It is then necessary to seek further investigations to exclude fractures or luxations.

Evolution

More detailed information is then obtained about the development of the complaints in relation to localization, duration and intensity.

The *localization* may change, either because the pain shifts to another place or because it spreads. Pain that spreads and gradually expands over a larger area is typical of an expanding lesion and should always arouse suspicion. On the other hand, pain that shifts from the scapular area to the upper limb is highly indicative of a shifting lesion (or disc lesion). The fragment of disc substance first displaces posterocentrally and compresses the dura mater, which results in central, bilateral or unilateral scapular pain; it then moves laterally and impinges on the dural investment of a nerve root. The scapular pain disappears and is replaced by a radicular pain down the upper limb. In order to interpret the distribution and evolution of the pain correctly, the mechanism of dural pain should be understood. Because the anterior aspect of the dura mater is innervated by a dense network of branches of sinuvertebral nerves originating at several levels, extrinsic compression and subsequent irritation of the dura may give rise to pain felt in several dermatomes. This phenomenon is called 'multisegmental pain' and is described in Chapter 1. Because the dural investment of the nerve root is only innervated from its own recurrent nerve, irritation here results in pain strictly felt in the corresponding dermatome, thus strict segmental pain.

Also *the duration of the pain* is informative. Most benign cervical disorders are intermittent. If pain progressively worsens, then the presence of an irreversible lesion such as metastases must be borne in mind, particularly in the elderly. Root pain as the result of a disc protrusion lasts for a variable but limited period and then ceases as spontaneous remission takes place (see Ch. 8). Hence, root pain that lasts longer than 6 months should arouse suspicion of another, possibly progressive cause.

As cervical disorders are frequently episodic, the patient should be asked to describe *previous episodes* in as detailed a way as possible. Often a recurrence can be ascribed to instability of the affected structure. Once an intervertebral disc fragment has displaced, it may do so again, because the cartilage remains unhealed. Further displacement may be in a different direction and it is thus possible for the pain to be variable and not on the same side. Therefore, pain that changes sides from one attack to another very strongly suggests the presence of a disc lesion. Also the duration of the previous bouts may have some prognostic value, as it can give an idea of how long the current symptoms may be expected to last. The patient should be questioned about previous successful treatment because, if the present episode is a recurrence, it is very likely that it will respond to the same treatment. Has the patient been totally free of pain between attacks? Freedom from symptoms indicates that the patient went into complete remission and this result could be obtained again. Failure of complete remission requires a search for the reason: possibly previous treatments have not been completed. Alternatively, age may be a factor in that some conditions have a tendency to become more persistent with advancing years.

Current pain

After the patient has given a thorough description of the onset and evolution, the moment has come to ask for details about the pain experienced at present: its localization, the influence of posture and movements, and how it is affected by cough.

Localization

The localization may vary: headache, pain in the face, neck, scapular area, pectoral area or down the upper limb are all possible.

Headache

If headache is referred from the cervical spine, the patient will usually mention an association between the symptoms and certain postures and/or movements. The pain may be bilateral or unilateral, and can be either segmental or multisegmental. Segmental pain originates from the upper cervical segments (C1 and C2). Disorders at the joints between occiput and atlas, or between atlas and axis, may give rise to pain felt at the centre of the upper neck and spreading to the occiput, the vertex (C1) and/or the temples and forehead. As the pain is

not always felt in the neck, localization to the head only can divert attention from the cervical spine. Multisegmental headache results from irritation of the dura at any cervical level. The pain often radiates from the mid-neck up to the temple, the forehead and behind one or both eyes, but rarely to the bridge of the nose. If, apart from this distribution, there is also downward reference of pain to the scapular area, the dural origin is clear.

Some types of headache can be recognized by paying attention to the history.

Early morning headache in elderly patients is a typical example. The patient wakes every morning with headache and/or occipital pain. After some hours the symptoms ease and have completely disappeared by midday. Symptoms do not recur until the next morning. The sequence is repeated daily without fail and, as the years go by, pain tends to last longer into the day. This type of headache responds spectacularly to manipulative treatment (see p. 201).

Migraine is another typical history. Symptoms usually start during adolescence and may persist for many years. The vascular origin of this disorder has been widely accepted and the following features are well known: an 'aura' which frequently includes visual hallucinations, photophobia, nausea, vomiting and other bizarre experiences, often precedes an attack; pain is severe, unilateral and well localized, though may change sides for each attack and is usually described as throbbing or bursting.

C*luster headache* is very severe, is more common in men, and occurs on a regular basis. The pain is always felt on the same side, mainly above the eye, and may be accompanied by a partial Horner's syndrome.

Pain in the face

This may either have a local origin or be referred. Local causes include sinusitis, dental problems, temporomandibular lesions, lesions of the facial bones, neuralgia and arteritis. Referred pain may be a segmental C2 pain or a multisegmental dural pain. The latter should always be borne in mind because, if a local cause is not found, treatment to the cervical spine may be curative.

Pain in the neck

Local pain in the upper neck is usually the outcome of a local lesion: one of the ligaments of the upper cervical segments or one of the upper facet joints. Rarely, the muscular insertions on the occiput are responsible. However, upper cervical pain may also have a multisegmental dural origin. Mid- or lower cervical pain is most often caused by a mid- or lower cervical discodural conflict, especially if the pain is felt centrally or bilaterally. Unilateral and lower cervical pain that is well localized often originates from a facet joint.

Pain in the trapezioscapular area

This is the most common pain reference for cervical lesions. The majority of pain in the trapezius or scapular area has a cervical origin, and must usually be considered as the multisegmental reference of a discodural conflict (Fig. 6.1). The pain may be unilateral, bilateral or interscapular. Depending on the patient's age, it may be intermittent or constant; the older the patient, the more likely the pain will last over longer periods. Upper scapular pain or pain in the trapezius area may also have a C4 segmental origin. Other sources of trapezioscapular pain are a thoracic lesion, a local scapular lesion or a shoulder girdle problem.

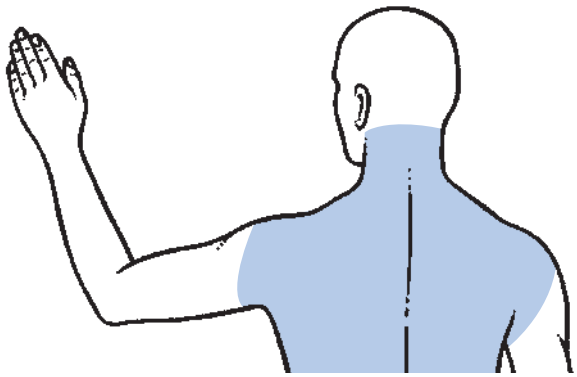

Fig 6.1 • Multisegmental scapular pain.

Pain in the pectoral area

Another rare manifestation of multisegmental dural reference is pain in the pectoral area. Because the pain is usually felt deeply and there is a strong popular association between pectoral (retrosternal) pain and cardiac disease, the pectoral discomfort can be initially misjudged as angina.

Pain down the upper limb

Dural pain never presents down the arms. Therefore, upper limb pain is always segmental in origin and is referred within its dermatomal borders. If the lesion is discoradicular, the normal time sequence of the symptoms must be appreciated: neck pain first, followed by unilateral scapular pain and then finally segmental pain. It is therefore important to ask whether or not the arm pain has been preceded by neck and/or scapular pain. If not, a non-discogenic origin of the pain is to be considered.

Exacerbation of pain by cough

This is uncommon in cervical lesions but may occur in a disc prolapse, when the pain is usually felt in the scapular region. Pain in the arm on coughing is one of the symptoms that draws attention to a neuroma (see Ch. 9).

Paraesthesia

Paraesthesia is a very common symptom which may originate from any nerve fibre in the cervicoscapular area or in the arm (Table 6.1). Paraesthesia is often experienced as a 'pins and needles' sensation. In other instances, the patient may describe the feeling as 'numbness'. The moment the patient mentions the presence of such symptoms, the examiner should carefully determine how proximal they are because, as has been explained in Chapter 2, the point of compression always lies proximal to that of the paraesthesia. The lesion may lie at any one of a number of different levels but the vaguer the distribution of the pins and needles, the more proximally the lesion needs to be sought.

Table 6.1 Paraesthesia

Level	Cause/site of cause	Symptoms
Cervical	Myelopathy:	No pain
	Intrinsic	Multisegmental paraesthesia on neck flexion
	Extrinsic	Lhermitte's sign
	Nerve root	Pain Segmental paraesthesia Compression phenomenon
Shoulder girdle	Brachial plexus	Vague paraesthesia Release phenomenon
Arm	Nerve trunk	Defined area of paraesthesia Specific tests
	Nerve ending	Cutaneous analgesia (Paraesthesia)

At the cervical spine

Spinal cord

External pressure on the spinal cord is characterized by painless paraesthesia in the upper and/or lower limbs felt distally and in a multisegmental distribution. The paraesthesia comes and goes in a wholly irregular way, most marked by day. Neck flexion usually increases the symptoms, or Lhermitte's sign may be present: an electric shock sensation in the trunk and/or upper limbs following forceful passive flexion of the cervical spine. Differential diagnosis has to be made from pernicious anaemia, diabetes and peripheral neuritis.

Nerve root

When a nerve root is affected, paraesthesia appears distally in the corresponding dermatome. The pins and needles come and go in an erratic fashion and do not last for more than an hour at a time. Pain resulting from external pressure on the dural sleeve may precede or accompany the paraesthesia.

At the shoulder girdle

Lesions of the brachial plexus at the thoracic outlet give rise to paraesthesia in one or both hands and affect all digits. When there is external pressure and because of the release phenomenon, pins and needles are only felt after the compression has ceased (see Ch. 2). They are often nocturnal, waking the patient after some hours' sleep.

In the arm

When one of the peripheral nerves in the upper limb is involved, paraesthesia (and sometimes pain) is felt in the territory of that nerve (radial, median or ulnar). The well-known distribution of paraesthesia (three and a half radial, or one and a half ulnar fingers) often gives a clue. Differentiation from radicular paraesthesia is generally not difficult. In case of doubt, specific tests to elicit the pins and needles can be performed (e.g. Tinel's test). The pins and needles are often accompanied by cutaneous analgesia, which may be marked, especially in distal lesions.

Vertigo or symptoms related to the vertebral artery

It is well known that vertigo may be the consequence of vertebrobasilar vascular insufficiency. However, cervical disorders without any impairment of the vertebral artery can also give rise to vertigo. The explanation is that the cervical spine, together with the eyes and the labyrinths of the ear, is an important source of proprioceptive information that influences the sense of balance. When vertigo is a dominant symptom, the examiner must carefully look for its origin, especially if a manipulative treatment is considered (see Ch. 11).

Incoordination and spasticity

These complaints are indications that something is amiss with either deep (proprioceptive) sensibility, or the vestibular system or the cerebellum.

Medication

Current medication may have a bearing on both diagnosis and management, and should be carefully ascertained, especially because anticoagulants are contraindications to manipulative therapy (see Ch. 5).

A summary of history taking is given in Box 6.1.

Inspection

Inspection and examination are performed on the standing patient. The examiner stands behind the patient and looks at the neck and scapular region. First the posture of neck and head is observed. The head should be in the midline, with the chin above the manubrium. A normal neck shows a slight lordotic curve. Loss of the lordotic curve, with the head fixed in flexion, suggests a block at the back of an intervertebral joint and is most common after whiplash injuries. Next, neck length is ascertained. A short neck is present in Klippel–Feil syndrome (due to fusion of several vertebrae)[1] and a webbed neck in a girl is typical of Turner's syndrome.[2] Then the examiner notices if the head is tilted or rotated in one direction, which indicates torticollis. A careful analysis of the torticollis is then made. The neck may be held in lateral deviation or in a combined position of lateral deviation and rotation. The lateral tilt as well as the rotation can be towards or away from the painful side. In acute discodural torticollis, the head is usually deviated in lateral flexion away from the painful side. There is usually no fixation in rotation. Shortening of the sternocleidomastoid muscle (congenital or acquired) leads to a deviation of the head in lateral flexion towards the pain combined with rotation to the other side (see Ch. 8).

2 Nerve root

Lesion at the shoulder girdle (brachial plexus)

Lesion in the arm (peripheral nerve)

Vertigo or symptoms related to vertebral artery

Incoordination and spasticity

Medication

The scapular and deltoid areas are surveyed. Deviations are noted in the position of the scapulae and in the muscular contours of neck, trapezius and shoulder muscles.

Functional examination

A complete examination of the cervical spine is comprised not only of neck movements but also of shoulder and upper limb tests. Many of the symptoms that occur in the upper limb originate from the neck. Hence an upper limb scanning examination must always be performed to distinguish them from local lesions. The examination includes articular tests, root tests, cord tests and tests for the peripheral joints. Before the examination starts, the examiner asks the patient if anything can be felt at that moment. If the answer is affirmative, the next questions will be: what is felt, and where? During the subsequent test session the examiner will find out if the movements have any influence on these symptoms or evoke other symptoms.

Neck movements

The movements are first performed actively and then repeated passively; after this, resisted movements are tested.

Active movements

The patient is asked to flex and extend the head and to rotate and tilt it in both directions (Fig. 6.2). The amplitude of each movement is noted and the patient indicates whether it is painful and, if so, where. Neck flexion must be considered not only as an articular test for the cervical spine but also as a dural test for the thoracic spine in that it stretches both the cervical and the thoracic dura. Hence, if pain is elicited in the upper thoracic region, it may be the consequence of a dural impingement at either a cervical or a thoracic level. The relation of the movements shows either a symmetrical (full articular) pattern (Fig. 6.3) or an asymmetrical (partial articular) pattern (Fig. 6.4). The full articular pattern of the cervical spine is: some or great limitation of extension, equal degree of limitation of both rotations and both lateral flexions and no limitation of flexion. All other combinations of pain (and limitation) are classified as partial articular patterns.

Passive movements

Next, the same movements are performed passively. However, it is not always necessary to carry these out. Flexion and both lateral flexions are done in doubtful cases only, but passive extension and both passive rotations are always executed with great care. Pain, limitation and the end-feel are assessed. The normal end-feel is capsular. Abnormal end-feels are muscle spasm, bone-to-bone, crisp, empty, soggy and elastic rebound. They point towards particular pathological entities (see Ch. 4).

Passive extension

The examiner asks the patient to extend the neck. Both forearms are then placed against the patient's scapulae with the fingers on the patient's forehead. Simultaneous radial deviation of both hands tests the end-feel in extension. By executing the test very gently, hard axial pressure is avoided.

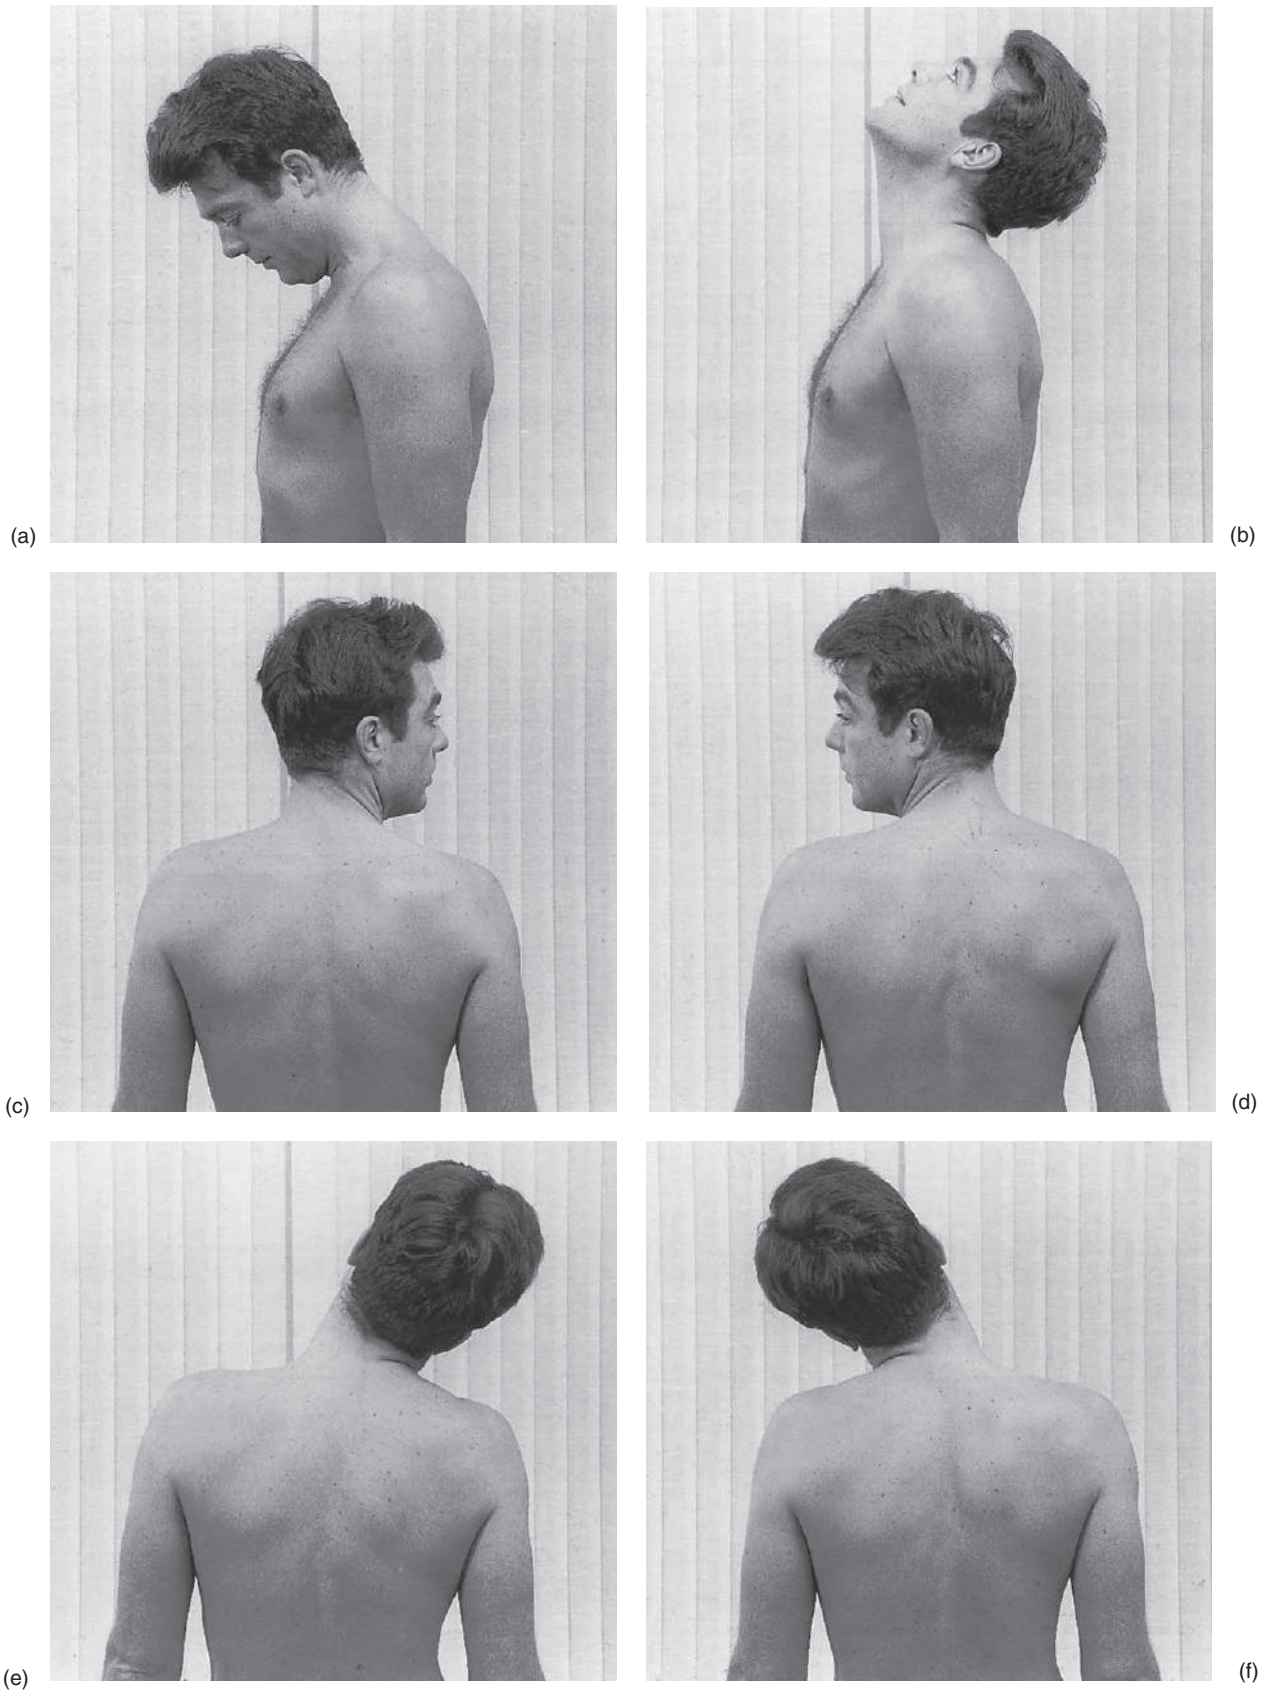

Fig 6.2 • Active movements: flexion (a), extension (b), rotation (c, d) and lateral flexion (e, f) of the head.

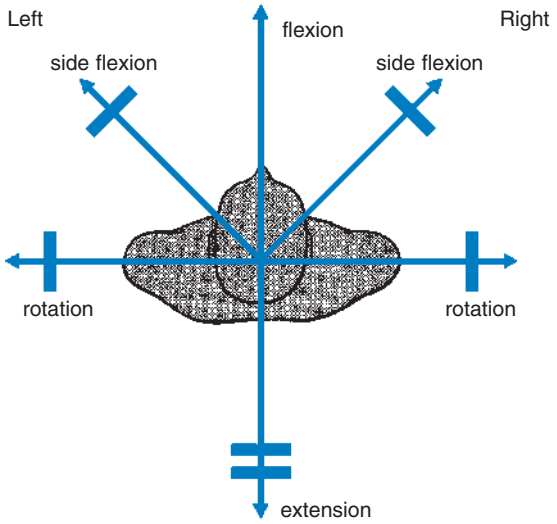

Fig 6.3 • The full articular pattern.

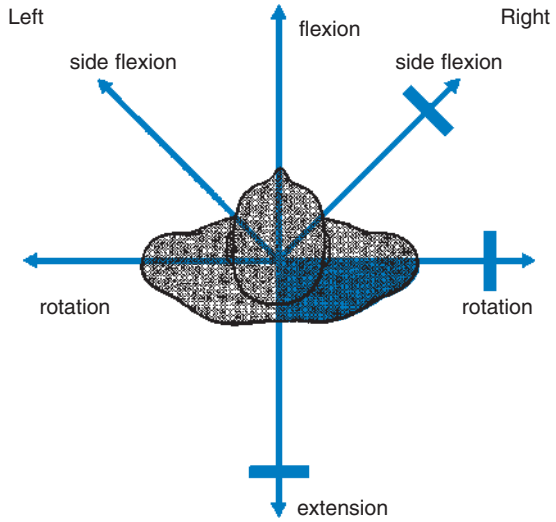

Fig 6.4 • Example of a partial articular pattern (colour indicates pain).

Rotation

The patient turns the head in rotation, first to one side, then the other. To avoid trunk movements, the examiner stabilizes the patient's body using the forearms. One is placed against the patient's scapula at the side towards which the patient turns the head and the other at the anterior aspect of the other shoulder. The hand of the arm that overlies the scapula moves into ulnar deviation and grasps the patient's forehead on the contralateral side. The other hand moves into radial deviation and grasps the patient's occiput on the side facing the examiner. Movement is performed by a simultaneous action of both hands. As the head turns, end-feel is again noted.

Lateral flexion

The examiner places the ipsilateral hand laterally against the patient's shoulder. With the other hand placed above the ear at the opposite side, gentle side flexion is undertaken.

Flexion

The patient bends the head and the examiner gently assists it into greater flexion. Excessive pressure should be avoided.

Resisted movements

After active and passive tests, resisted movements are performed. Conduction of both rotations suffices. The other movements are only carried out in case of doubt and for the purpose of differential diagnosis. Pain and/or weakness are ascertained. Interpretation of positive resisted movements must be done in the light of the overall clinical picture. The response can be obscured in acute lesions, where the slightest effort augments the pain as the result of transmitted stress. Muscular and tendinous lesions are extremely uncommon at the cervical spine. The movement also gives information on motor conduction of the first cervical nerve root.

Primary test: rotation

The patient holds the head in the neutral position. The examiner places the forearms against both scapulae with the fingers just above the patient's ears and the fingertips pointing forwards so that they lie on the temples (Fig. 6.5). The patient is asked to rotate the head and the movement is resisted with the fingertips.

Secondary tests: extension, flexion and lateral flexion

These are illustrated in Figure 6.6.

Flexion

The examiner stands beside the patient and places one hand on the upper interscapular area and the other hand on the forehead. The patient is asked to push the head forwards and resistance is provided.

Extension

The examiner stands beside the patient. One hand is placed laterally on the sternum and the other on the occiput. The patient is asked to pull the head backwards and resistance is provided.

Lateral flexion

The examiner stands behind the patient. One hand is placed laterally on the opposite shoulder and the other above the ear. The patient is asked to push the head against the hand. Resistance is exerted.

Scapular movements

Scapular movements are performed to establish the mobility of the scapula in relation to the thorax. They also test the shoulder girdle and the thoracic part of the dura mater.

Active movement

The patient is asked to elevate the shoulders (Fig. 6.7). Pain and/or limitation are checked.

The mobility of the scapula on the thoracic cage, together with the integrity of the acromioclavicular joints, the sternoclavicular joints and the joints between the first ribs and the vertebral column, is assessed. Any pain and/or limitation

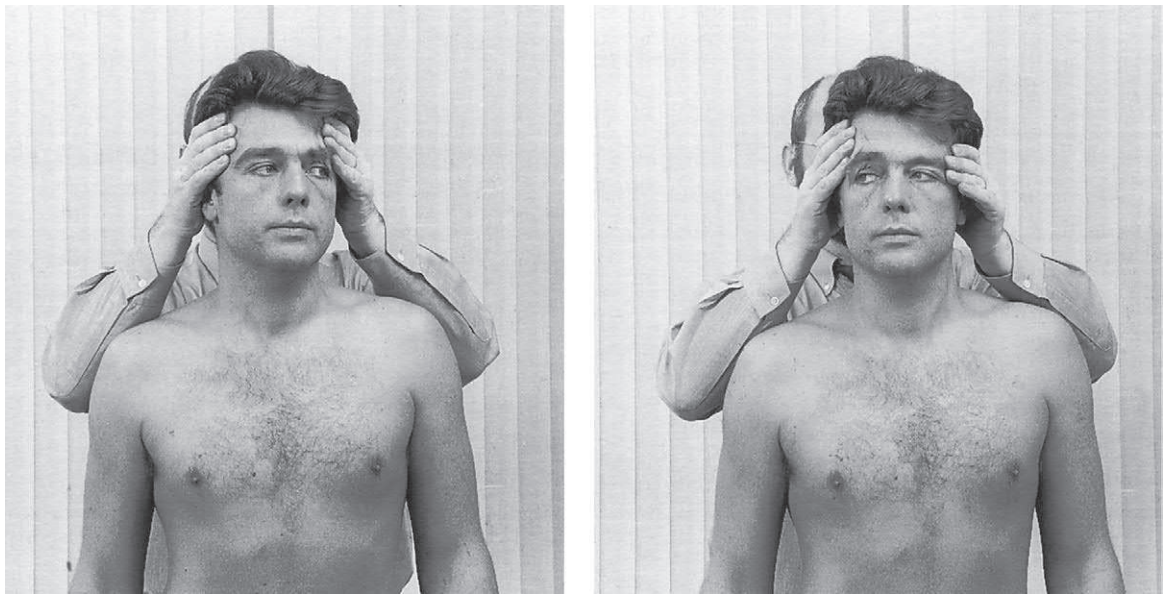

Fig 6.5 • Primary resisted movement: rotation.

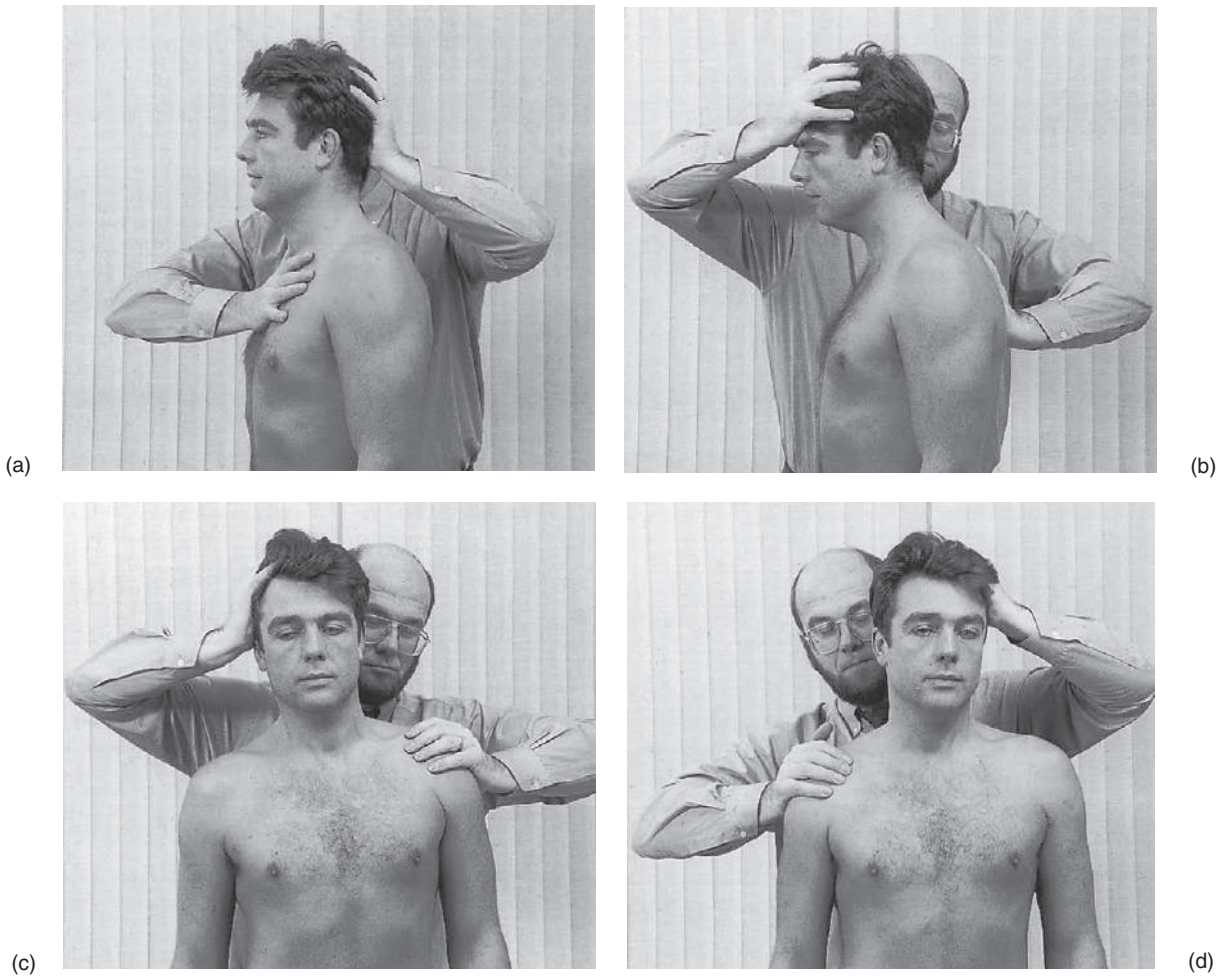

Fig 6.6 • Secondary resisted movements: extension (a), flexion (b) and lateral flexion (c, d).

Fig 6.7 • Active elevation of the shoulders.

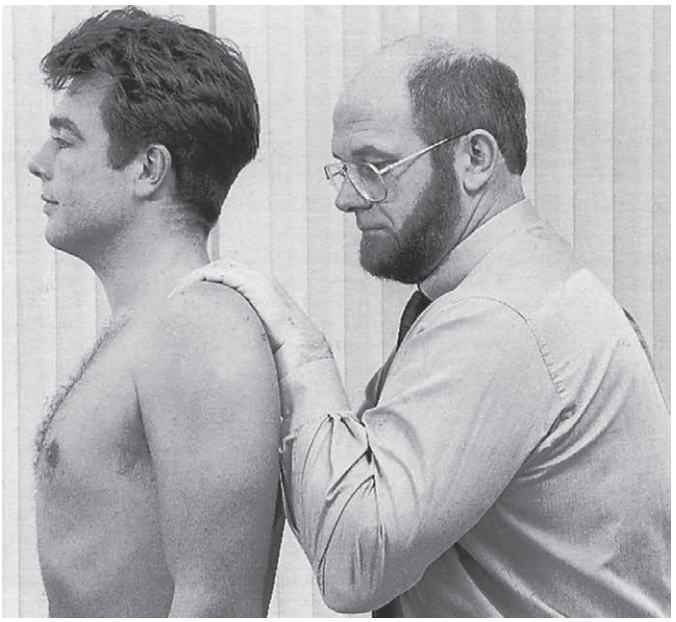

Fig 6.8 • Resisted elevation of the shoulders.

suggest the need for a full shoulder girdle examination (see p. 210).

Resisted movement

The patient is asked to keep the shoulders elevated while the examiner applies a downward force on them (Fig. 6.8). This tests the trapezii muscles and the motor conduction in C2–C4. Normally the trapezii are stronger than the downward pressure.

Arm tests

Arm movements test the integrity of the muscular system.

If pain is elicited, alternative causes of pain down the upper limb should be sought. When one or more movements are weak a neurological problem is responsible. The pattern presented will indicate the possible level.

Active elevation

The patient is asked to elevate both arms sideways, as high as possible (Fig. 6.9). This is a swift scan for shoulder and shoulder girdle problems. If there is pain and/or limitation, a complete shoulder examination should follow (see Ch. 12).

Resisted movements

Isometric resisted tests are done bilaterally, so that strength may be compared. These are mainly tests for motor conduction and so strength is noted, but, if the test elicits pain, the possibility of a local lesion should be considered.

The tests are illustrated in Figures 6.10–6.13. Detailed execution of the different tests is discussed in the relevant chapters on the shoulders, elbow and wrist.

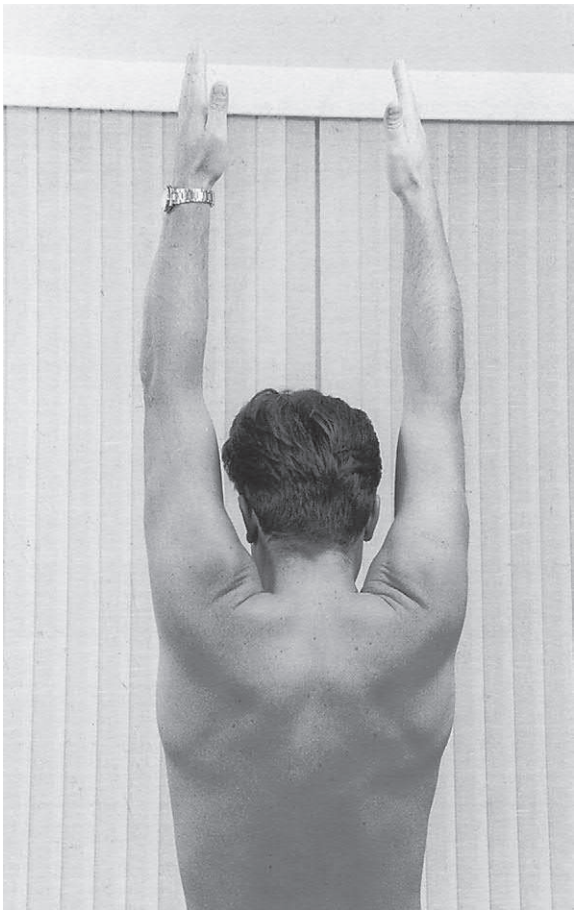

Fig 6.9 • Active elevation of the arms.

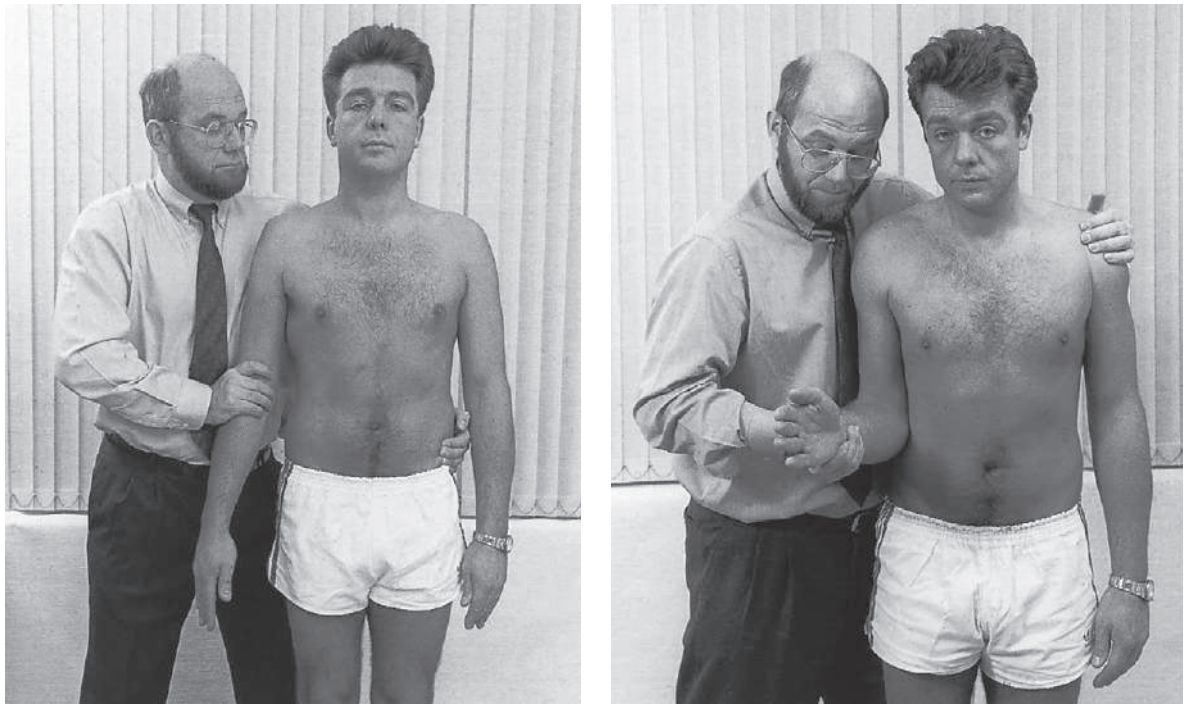

(a) (b)

Fig 6.10 • (a) Resisted abduction of the shoulder tests the C5 nerve root and the abductor muscles. (b) Resisted external (or lateral) rotation of the shoulder tests the C5 nerve root and the external (or lateral) rotators.

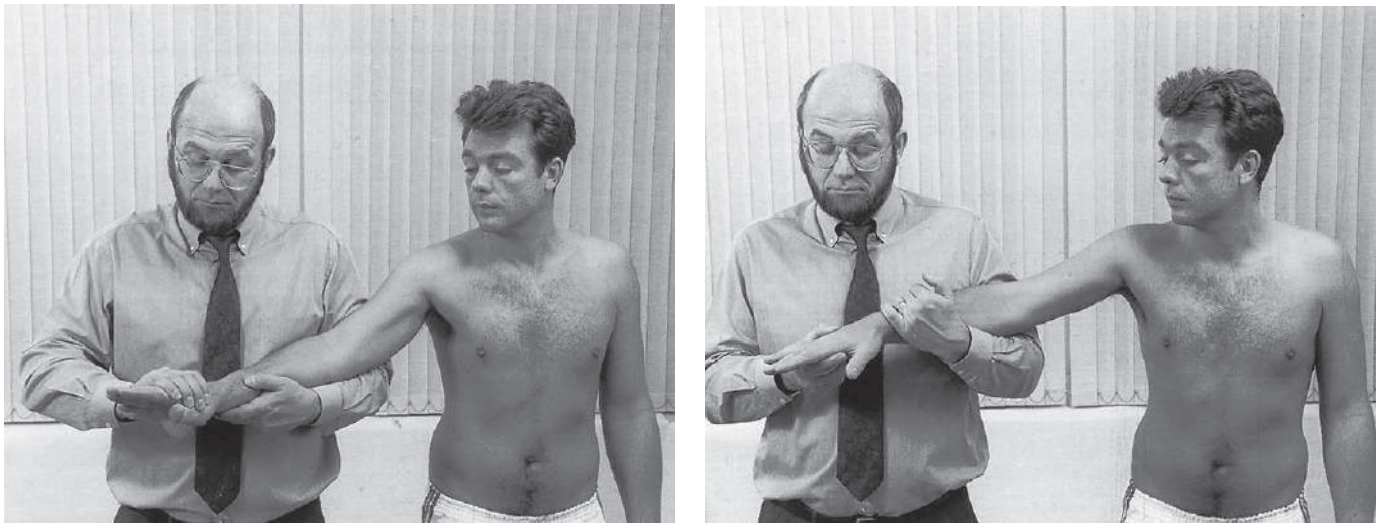
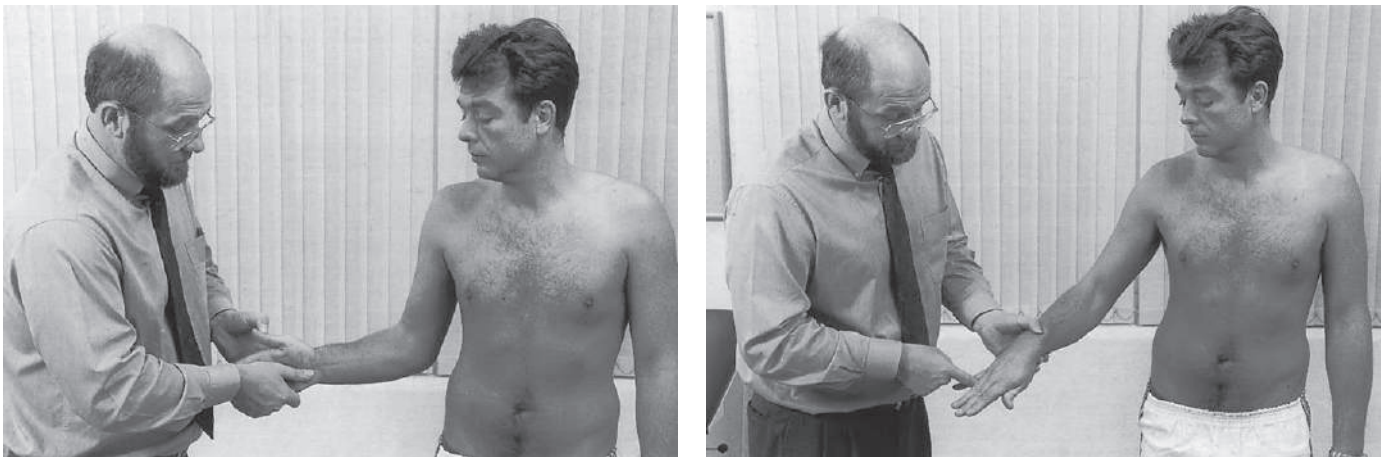
Fig 6.11 • (a) Resisted flexion of the elbow tests the C5 and C6 nerve roots and the elbow flexors. (b) Resisted extension of the elbow tests the C7 nerve root and the elbow extensors.



(a) (b)

Fig 6.12 • (a) Resisted extension of the wrist tests the C6 nerve root and the wrist and finger extensors. (b) Resisted flexion of the wrist tests the C7 nerve root and the wrist and finger flexors.



(a) (b)

Fig 6.13 • (a) Resisted extension of the thumb tests the C8 nerve root and the thumb extensors. (b) Resisted adduction of the fifth finger tests the T1 nerve root and the intrinsic muscles of the hand.

Resisted abduction of the shoulder

This tests the C5 nerve root and the abductor muscles of the shoulder (deltoid and supraspinatus). The test is performed with the arm hanging down, a few degrees of abduction being permitted. The patient is asked to resist the examiner's attempt to push the arm inwards.

Resisted external rotation of the shoulder

The C5 nerve root is tested as well as the external rotators of the shoulder (infraspinatus and teres minor). The patient is asked to bend the elbow to a right angle and to hold it firmly into the side. The examiner's attempt to push the forearm medially should be resisted.

Resisted flexion of the elbow

This test examines nerve roots C5 and C6 and, at the same time, the flexors of the elbow (biceps, brachialis and brachioradialis). The patient holds the elbow in 90° flexion and supination, and resists the examiner's attempt to extend the elbow.

Resisted extension of the elbow

This tests nerve root C7 and the extensor of the elbow (triceps). The elbow is again held at a right angle and the examiner's attempt to bend the patient's elbow is resisted.

Resisted extension of the wrist

The C6 nerve root is tested, as well as the extensors of the wrist (extensores carpi) and fingers (extensor digitorum

communis). The elbow is held in extension. The patient resists the examiner's attempt to flex the wrist.

Resisted flexion of the wrist

This test examines nerve root C7 and the flexors of the wrist (flexores carpi) and fingers (flexores digitorum). The elbow is held in extension. The examiner's attempt to extend the wrist is resisted.

Resisted extension of the thumb

The C8 nerve root is tested, as well as the extensors of the thumb (extensores pollicis). The examiner's attempt to flex the thumb is resisted.

Resisted adduction of the fifth finger

This tests the T1 nerve root and the intrinsic muscles of the hand, i.e. the adductors of the little finger. The patient squeezes the examiner's finger between the fourth and fifth fingers. The examiner assesses the strength.

Sensory conduction

The examiner passes his fingers over the patient's skin in the different dermatomes (Fig. 6.14). The patient is asked if the sensation is the same over all areas.

One arm is compared with the other, and each dermatome is compared with the others in the same limb.

Testing reflexes

The main reflexes are tested and note is taken of whether they are normal, diminished, absent or inverted. Each side is always compared with the other.

Biceps reflex

The patient's elbow is held at a right angle and is well relaxed. The tendon is stretched by the pressure of the examiner's thumb on which the hammer is tapped. The C5 and C6 nerve roots are tested. The reaction is elbow flexion (Fig. 6.15).

Fig 6.14 • Testing sensory conduction.

Brachioradialis reflex

The patient's elbow is held at a right angle and is well relaxed. The hammer taps on the distal end of the radius. This tests the C5 nerve root. The reaction is elbow flexion (Fig. 6.16).

Triceps reflex

The patient's elbow is 90° flexed and well relaxed. The hammer strikes the triceps tendon, just proximal to the olecranon. The C7 nerve root is tested. The reaction is elbow extension (Fig. 6.17).

Plantar reflex

To test the plantar reflex, the examiner uses the sharp end of the reflex hammer to stroke the sole of the patient's foot, starting at the lateral aspect of the heel and moving along the

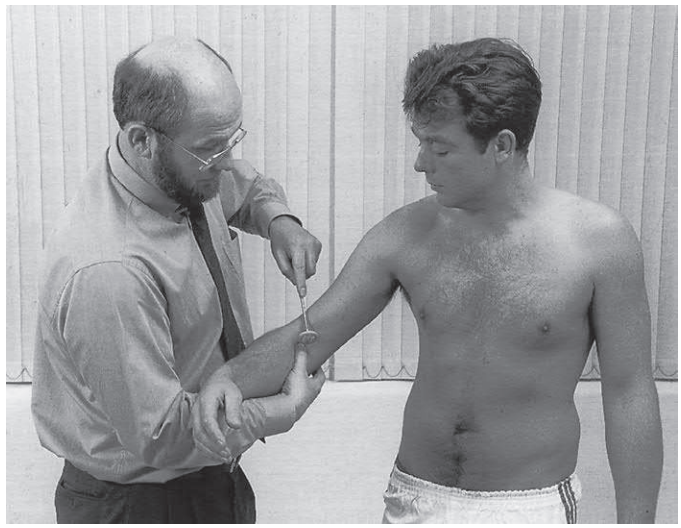


Fig 6.15 • Testing the biceps reflex: C5 and C6 nerve roots. The reaction is elbow flexion.

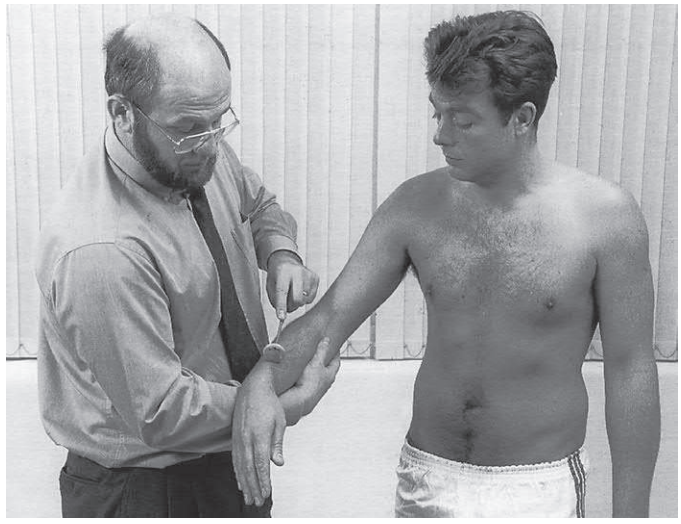

Fig 6.16 • Testing the brachioradialis reflex: C5 nerve root. The reaction is elbow flexion.

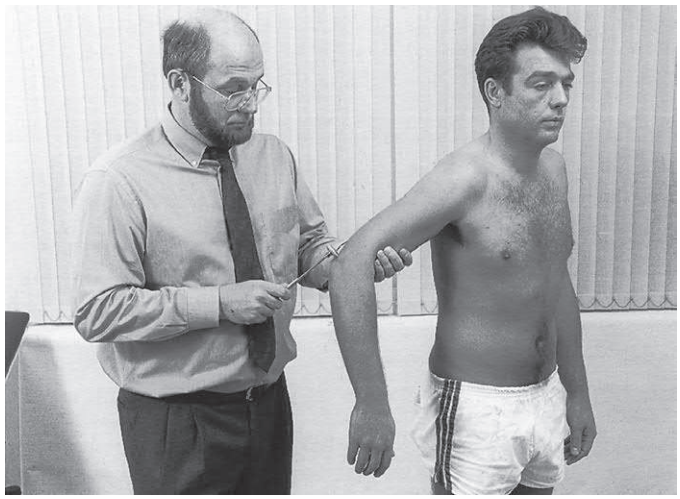

Fig 6.17 • Testing the triceps reflex: C7 nerve root. The reaction is elbow extension.

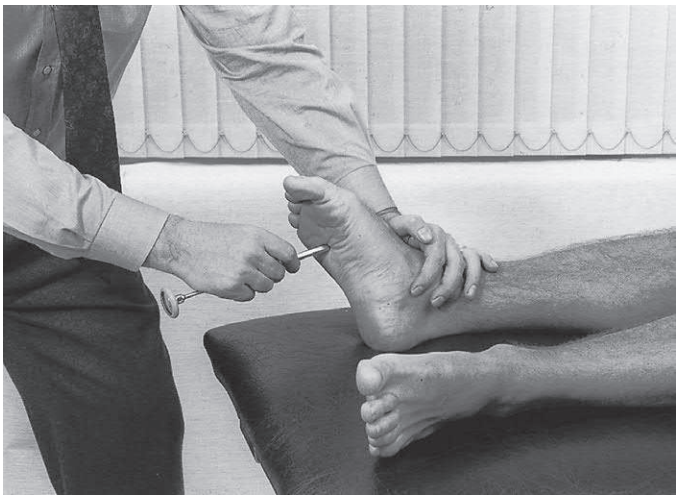

Fig 6.18 • Testing the plantar reflex: central nervous system. The reaction is flexion of the toes.

lateral border of the foot to the base of the fifth metatarsal bone and then onwards to the base of the big toe at the medial aspect of the foot. The normal reaction, as described by Strümpell, is flexion of the toes and withdrawal of the foot (Fig. 6.18). The pathological reflex – Babinski's sign – is a slow extension of the big toe, combined with spreading of the other toes and flexion of knee and hip. The presence of Babinski's sign indicates a (severe) central disorder.

Hoffmann's sign

The hand is supported and pronated so that wrist and fingers fall into slight flexion. The middle finger is firmly grasped and partially extended. The nail is then flicked by the examiner's thumbnail. This flicking should be done with considerable force. The sign is considered to be positive when quick flexion of both the thumb and the index finger results.[3] A positive sign is indicative of possible pyramidal tract pathology (Fig. 6.19).[4]

A summary of the neurological deficit at each level is given in Table 6.2.

A summary of the functional examination is given in Box 6.2.

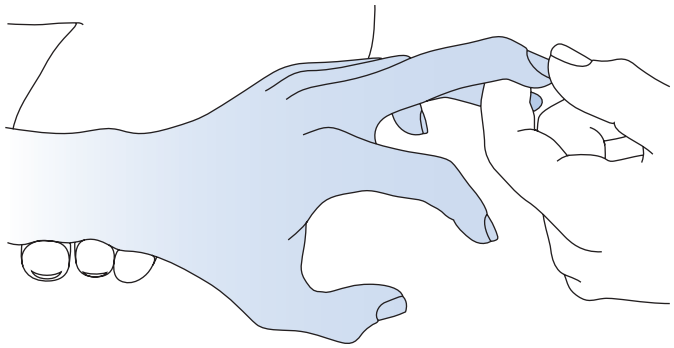

Fig 6.19 • Hoffmann's sign is elicited by flicking the distal phalanx of the long finger. Flexion of the thumb at the interphalangeal joint is a positive response.

Technical investigations

Technical investigations have become a routine measure in the evaluation of patients with neck pain for several reasons: to assist diagnosis, to complement the clinical diagnosis, to meet the patient's request for 'radiography', or for medicolegal reasons.

During recent decades there has been a tendency to reduce the time spent on history taking and clinical examination and to proceed immediately with technical investigations in order to detect the anatomical changes that are held to be responsible for a patient's condition. This trend not only has serious financial consequences but also leads to diagnostic errors. It is important to realize that imaging, whether it is X-ray, computed tomography (CT) or magnetic resonance imaging (MRI), does not reveal the source of the pain but only shows anatomical changes that may or may not be consistent with the patient's description of the pain. Most of these anatomical alterations reflect painless degenerative changes that are normal at certain ages and which may also be present in asymptomatic individuals. The examiner should constantly keep in mind the fact that the presence of anatomical and morphological changes does not automatically imply causality. For example: CT and MRI are widely used to demonstrate the existence of discal disorders, which also exist in a large number of asymptomatic people. Boden[5] cites a figure between 14 and 28% and Teresi[6] a figure of 23%. According to Matsumoto *et al*, degeneration is present in 86% of the discs of asymptomatic individuals of over 60 years of age. Posterior disc protrusion is observed in 7.6% of asymptomatic subjects.[7]

However, technical procedures may be of great help in complementing the clinical findings, i.e. to confirm a tentative diagnosis or to exclude serious disorders. The examiner should always remember, however, that a clinical diagnosis is a basic requirement and that imaging techniques should never be used

Table 6.2 Neurological deficit at each level

Level	Deficit
C1–C2	Tingling in the occipitoparietal region. Muscular weakness is rare
C3	Paraesthesia or numbness at the lower pinna, the posterior part of the cheek, the temporal area and the lateral aspect of the neck. Weakness is clinically not detectable. Cutaneous analgesia is uncommon (the lateral aspect of the neck)
C4	A horizontal band of cutaneous analgesia along the spine of the scapula, the mid-deltoid area and the clavicle. Slight weakness of the trapezii. Paraesthesia does not occur
C5	Weakness of the supraspinatus, infraspinatus, deltoid and brachial biceps muscles. The biceps and brachioradialis jerks are sluggish or absent. Paraesthesia and sensory deficit do not occur
C6	Paraesthesia in thumb and index fingers. Analgesia at the tips of thumb and index fingers. Weakness of the biceps, brachialis, supinator brevis and the extensores carpi radiales muscles. The biceps jerk is sluggish or absent
C7	Paraesthesia in index, middle and ring fingers. Cutaneous analgesia at the dorsal aspect of the index and middle fingers. The weak muscles are the triceps and the flexor carpi radialis. The triceps jerk may be affected
C8	Paraesthesia in the middle, ring and little fingers. Cutaneous analgesia at the little finger. The weak muscles are both extensors of the thumb, the extensor and flexor carpi ulnaris, the adductor pollicis, the common extensor of the fingers and the abductor indicis
T1	Paraesthesia and cutaneous analgesia at the ulnar aspect of the hand, and weakness of the intrinsic muscles of the hand
T2	Paraesthesia and motor and sensory deficit are very uncommon

Box 6.2

Summary of the functional examination

Neck movements

6 active movements:
pain/limitation

3 (or 6) passive movements:
pain/limitation/end-feel

2 (or 6) resisted movements:
pain/weakness – C1

Scapular movements

Active elevation
pain/limitation → Shoulder girdle examination?

Resisted elevation
C2–C3–C4

Arm tests

Tests for neurogenic integrity and alternative causes of arm pain

Active elevation:
pain/limitation → Shoulder examination?

Resisted movements?
(tests for motor conduction):

shoulder:
- abduction – C5
- external rotation – C5

elbow:
- flexion – C5/C6
- extension – C7

wrist:
- flexion – C7
- extension – C6

thumb extension – C8
little finger adduction – T1

Sensory conduction

Reflexes:
Biceps – C5/C6
Brachioradialis – C5
Triceps – C7
Plantar – CNS
Hoffmann's – CNS

as screening tests. Also, decisions about treatment procedures should be made on clinical grounds but may be influenced by specific findings on imaging.

Radiography may show congenital anomalies but quite often these are not clinically significant. Another reason for obtaining plain films is to exclude fractures and luxations.[8] Plain radiography has a specificity of 100% in low-risk patients.[9,10] However, in high-risk patients, helical CT scan seems to be the preferred initial screening test for detection of cervical spine fractures.[11,12] The most important consideration with cervical X-rays is perhaps the risk of missing tumours and infections. It is important to remember, however, that bony disorders are not always visible on plain X-rays in their initial stages, and a negative examination may give a false feeling of security.

Computed tomography is a good diagnostic tool for bony disorders, such as fractures and luxations, where it is often more effective than plain radiography and MRI.[13] It is useful to demonstrate osseous neural foraminal stenosis, bone destruction or bone proliferation and ossification of the posterior longitudinal ligament. It is also effective for detecting cranial migration of the odontoid process in rheumatoid arthritis patients.[14]

Magnetic resonance imaging – because of its superior depiction of soft tissue anatomy – is a preferred tool for the diagnosis of soft tissue disorders such as pre- or paravertebral haemorrhage or oedema, ligamentous lesions and disc herniations.[15] It is also excellent for demonstrating cord compression and nerve root injuries.[16] It appears to be the most reliable imaging study for diagnosing spinal infections[17] and tumours.[18] Dynamic functional MRI may provide additional information in patients with rheumatoid arthritis.[19]

Scintigraphy is most useful for the detection of quantitative changes in the skeleton in bone metastases and inflammatory and metabolic bone diseases.

Electromyography has a low sensitivity and specificity, and is therefore only secondary in the diagnosis of cervical nerve

root palsies, which can easily be detected by clinical testing. It can have a certain importance in cases with medicolegal implications.

Conclusions

- Technical investigation should not replace clinical examination.
- It may be used to clarify the clinical picture or to exclude a serious disorder.
- The results must be evaluated with great care and only in the light of the clinical picture.
- In doubtful cases, clinical evaluation will be more important than technical investigations.
- Treatment decisions should never be taken on the outcome of imaging studies alone.

Interpretation of the clinical examination of the cervical spine

CHAPTER CONTENTS

Interpretation of the history 135
Pain 135
Paraesthesia 137
Interpretation of the functional examination 138
Interpretation of neck movements 138
Interpretation of shoulder girdle movements 140
Interpretation of arm movements 141

A standardized clinical examination enables the examiner to recognize clinical patterns. He/she will easily distinguish common patterns from uncommon ones and recognize so-called 'warning signs' (see Ch. 9). Neck, shoulder girdle and shoulder problems are differentiated and a distinction is made between 'mechanical' conditions, such as disc lesions or capsuloligamentous lesions, and 'non-mechanical' conditions, such as rheumatological, neurological or infectious disorders.

Interpretation of the history

Most symptoms (elements taken from the history) are purely subjective. They are: pain, paraesthesia, numbness and dizziness. Others, such as diminished mobility and weakness, are more objective and can be checked during the functional examination.

Pain

Pain is usually the leading symptom. Pain behaviour is extremely important and is defined by the following elements: localization, onset, evolution, influencing factors, duration and accompanying symptoms.

Localization

The actual site of the pain is a first rough pointer. Pain may be localized or vague, and is felt either in the neighbourhood of the lesion or at a distance (see Referred pain, Ch. 1).

Very localized pain, accurately indicated by the patient, is often a ligamentous or facet joint problem. Bony lesions also give rise to localized pain. Pain that is vaguely defined and spreads over a larger area is usually referred. It is then distal to the lesion (see Rules of referred pain, Ch. 1). Referred pain that is felt in a particular dermatome (segmentally referred) is often radicular in origin but may also result from any soft tissue lesion in the region of the neck. The source is usually an inflammation and/or compression of a mid- or lower cervical nerve root, giving rise to pain in the shoulder area (C4) or in the upper limb (C5–T2). It often indicates a discoradicular interaction, but other causes of root pain should also be considered, such as degenerative conditions or a space-occupying lesion in the radicular canal.

Pain that is felt in several adjacent dermatomes at the same time is quite common and indicates a multisegmental type of reference (see Fig. 7.1). Multisegmental pain reference may be either the result of multiradicular involvement – which is extremely uncommon in the cervical spine and should immediately arouse suspicion (see Warning signs, Ch. 9) – or the result of a discodural interaction. In the latter case other dural symptoms may also be found and the functional examination shows a clinical picture of internal derangement (see Ch. 8). It should be stressed that dural symptoms are mostly discogenic in origin but may also occur in any space-occupying lesion in the spinal canal interfering with the sensitivity or the mobility of the dura mater. Dural pain is usually felt at the lower neck, in the trapezius area and the upper scapular and interscapular region, either centrally or unilaterally. The pain may spread further, upwards to the head, face and upper neck or the mid-scapular, pectoral and axillary regions.

© Copyright 2013 Elsevier, Ltd. All rights reserved.

Onset (Fig. 7.2)

Pain may come on suddenly, gradually or as the result of an injury. Pain that starts suddenly is activity-related. It is a manifestation of sudden internal derangement of an intervertebral joint, mostly the result of the displacement of a discal fragment. It is then usually accompanied by sudden twinges when moving. It comes and goes in an irregular way and tends to recur. Functional examination shows the articular involvement. Pain that comes on gradually is not very informative because many different conditions begin in that way. If the pain is related to specific activities, a mechanical condition (see Ch. 8) is probable; if such a relation between symptoms and movements or postures is not found, a non-mechanical condition should be considered (see Ch. 9). If an injury is responsible for the development of the patient's symptoms, further technical investigation will be necessary to exclude serious disorders such as fractures and luxations.

Evolution (Fig. 7.3)

Pain may shift from one place to another, mostly from the centre of the neck to one side or from the cervicotrapezioscapular area to the upper limb. The meaning of pain that moves is important: the pain shifts because the lesion shifts. There are not that many lesions that may change their position; a loose fragment of disc is one of the few possibilities. Since discodural or discoradicular interactions occur in episodes, pain may switch sides from one attack to another. Pain may also expand, which means that it increases in extent and in intensity. Expanding pain is always a serious warning sign in that it indicates an expanding lesion: for example, a tumour. In most cases of discoradicular interactions, pain has started proximally in the neck, trapezius and/or scapular area before it shifts to the upper limb. However, in younger patients, discoradicular pain may be felt in the arm from the very beginning. The lesion is then called a primary posterolateral disc protrusion. Other instances that start with pain in the arm without previous neck or cervical pain are neurofibromas and root compressions by osteophytic outcrops or metastases.

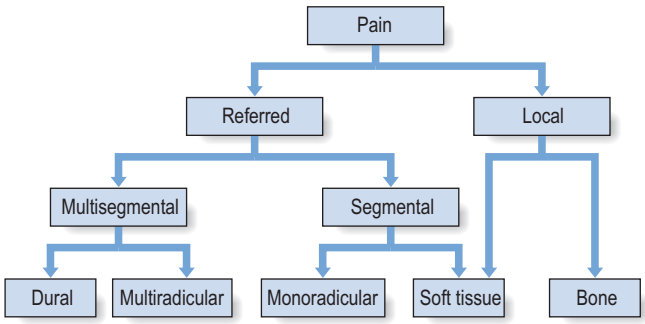

Fig 7.1 • Reference of pain.

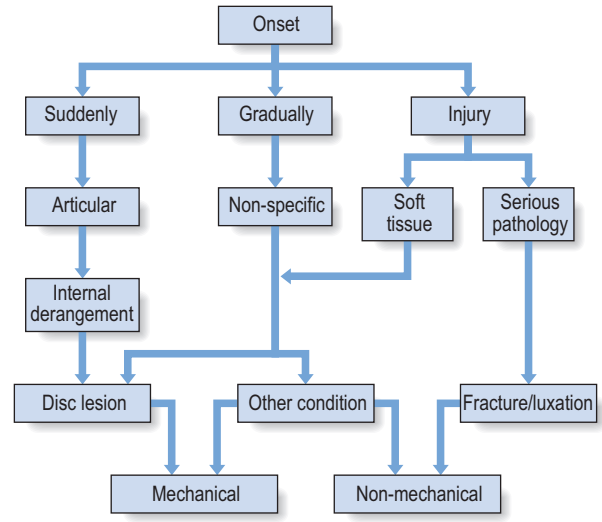

Fig 7.2 • Onset of pain.

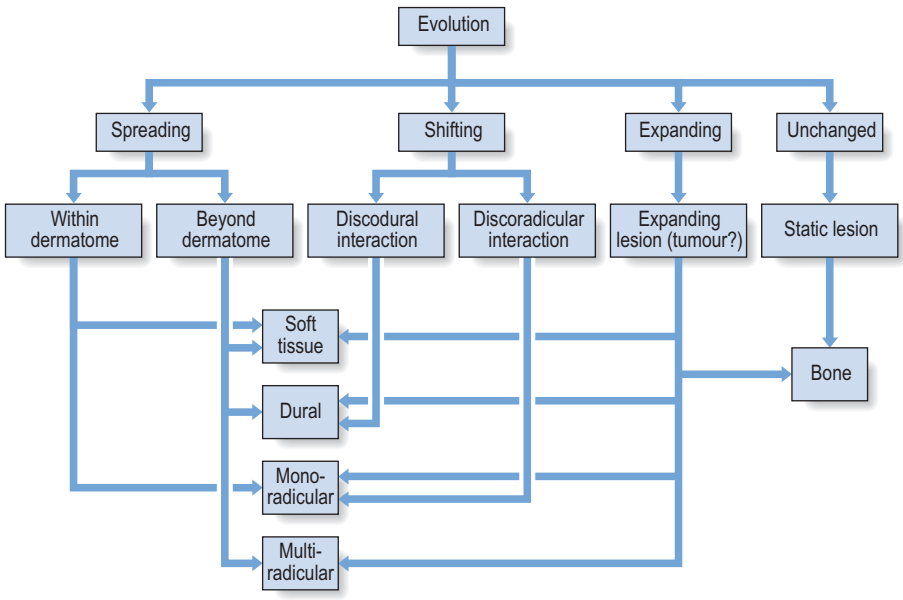

Fig 7.3 • Evolution of pain.

Factors influencing pain

The questions: What brings the pain on? and What makes the pain disappear? are necessary to find out whether or not the condition is related to activity or posture. Most disorders are activity-related: discodural or discoradicular interactions, degenerative conditions, muscular and capsuloligamentous lesions. The type of activity that has an influence on symptoms may help in determining the possible type of lesion. Disc lesions are affected by certain movements, especially towards kyphosis, as well as by certain postures, whereas ligamentous conditions are mostly purely postural. In the latter case, maintenance of positions will aggravate pain and altering the position relieves the pain. When the condition is non-activity-related it is of the non-mechanical type and suggests bony lesions, rheumatoid-type conditions, infections, intraspinal or neurological disorders, or visceral pathologies.

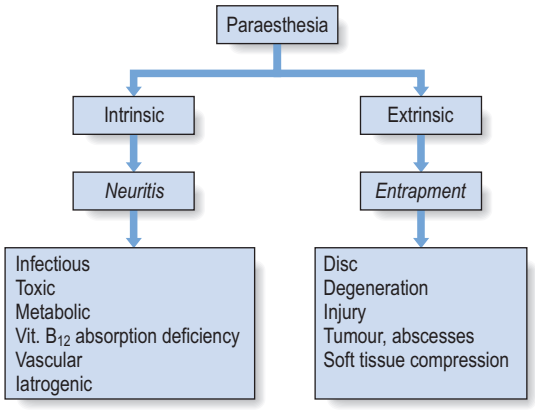

Fig 7.4 • Paraesthesia.

Accompanying symptoms

Coughing or sneezing that causes pain in the trapezius or scapular region is a common symptom in discodural or discoradicular interactions, although any space-occupying lesion in the spinal canal may elicit such symptoms. Pain in the arm on coughing is considered unusual and mandates a closer look: the patient could be suffering from a neurofibroma. Twinges – sudden bouts of pain resulting from movement of the head – are a typical articular symptom. They very much suggest internal derangement in the intervertebral joint – a disc protrusion. Morning pain is typical of arthritic and rheumatoid-type conditions such as ankylosing spondylitis. It also occurs in capsuloligamentous contracture following degeneration ('the elderly man's morning headache' – see Ch. 8). Nocturnal pain is generally accepted as being of the inflammatory type, although mechanical pain may occur when the patient has a poor sleeping posture in which the head is put into a painful position.

Duration of pain

Except in acute torticollis, which recovers spontaneously within a maximum of 10 days, neck pain has no tendency to spontaneous recovery. It may improve after some time but it may also persist. If the cause is internal derangement it usually does improve but tends to recur, certainly in young people. In the elderly the tendency to spontaneous remission is inclined to diminish. Neck pain that not only continues but also increases in intensity is very suggestive of malignancy. Root pain that is the result of a discoradicular interaction has a spontaneous remission over a period of 3–4 months reckoned from the moment of the 'shift': the pain appears in the arm and the scapular pain disappears. Root pain that has not diminished after several weeks is probably the result of another condition, either degenerative or malignant.

Paraesthesia

Paraesthesia is the major differential diagnostic feature distinguishing lesions in nervous tissue and other structures. This may vary from real 'pins and needles' to 'numbness' and may evolve towards a sensory deficit. If paraesthesia is mentioned and is clearly related to the lesion, a nervous disorder or a lesion affecting a nervous structure is present. The problem may be intrinsic ('neuritis') or extrinsic ('entrapment') (see Fig. 7.4).

Intrinsic neuritis may result from infectious (mononucleosis), toxic (ethyl alcohol or lead poisoning), metabolic (diabetes mellitus) or vascular conditions (arteriosclerosis), may have an iatrogenic cause (injection) or may follow vitamin B_{12} absorption deficiency.

When the lesion is the result of *external pressure on the nerve*, the cause must be sought in the intervertebral disc (discoradicular interaction), degenerative conditions (lateral recess stenosis), injury (fractures or luxations), space-occupying disorders (tumour, abscess, haematoma, aneurysm) or other soft tissue compression (fibrous bands, scars).

In nerve tissue compression three major features have to be interpreted: proximal extent, localization and behaviour. The patient has to understand clearly the difference between pain and paraesthesia because both behave differently. The lesion responsible for the development of pins and needles always lies proximal to their *proximal extent*; in other words, the area of paraesthesia is always felt distally to the site of compression. The *localization* of the paraesthesia is defined to a multisegmental area (spinal cord), a segmental area (nerve root) – dermatome – or the territory of a peripheral plexus or nerve. The *behaviour* of the symptoms depends on which part of the nervous system is involved and subsequently on which mechanism is active: spinal cord, nerve root, nerve trunk or nerve ending (see Complete information on pressure on nerves in Ch. 2).

Interpretation of the functional examination

The functional examination of the cervical spine does not cause technical problems. Active, passive and resisted movements

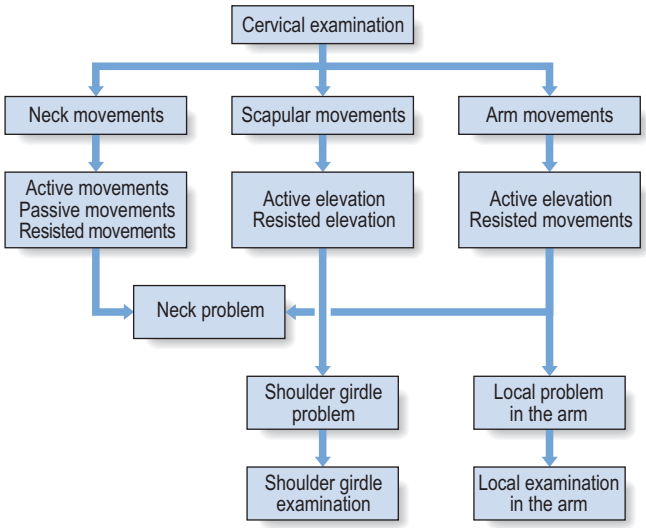

Fig 7.5 • Cervical examination.

are easy to perform and easy to assess; the patient reports pain and the examiner detects limitation, changes in the end-feel and weakness. Interpretation rests on these physical findings and clinical patterns will emerge. Because the examination comprises tests at three different levels – neck, shoulder girdle and arm – it is possible to establish the level at which the lesion should be sought (Fig. 7.5). If signs are found at all three levels, it is logical to look for the lesion 'half-way', i.e. in the shoulder girdle.

If *neck movements* – active, passive and/or resisted – are clearly disturbed, the problem must lie in the neck. When, on the contrary, they are totally negative, a lesion in the neck is very unlikely. A neck that moves perfectly well in all directions, actively as well as passively, with a normal end-feel, cannot have a serious articular problem. Passive movements that cover the full range and are painless indicate that the inert structures are neither painfully stretched nor compressed. Negative isometric tests show that the contractile tissues are also functioning well and that there is nothing wrong with the bone to which they are attached. Pain in the absence of any positive test must therefore be referred or at least of the non-mechanical type: for example, inflammatory.

Positive scapular movements usually point towards a lesion in the shoulder girdle, although it is possible to find slight positive signs in a disorder of the cervical spine; elevation and/or approximation of the scapulae also act as a dural sign. If a shoulder girdle problem is suspected, a complete shoulder girdle examination should follow (see online chapter *Clinical examination of the shoulder girdle*).

Positive arm tests may occur in cervical disorders such as spinal cord or nerve root palsy, but if they provoke pain felt in the arm, they usually indicate a local lesion in the upper limb – shoulder arthritis, subdeltoid bursitis or tendinitis. Elevation of the arm is thus also used to detect alternative causes of pain down the upper limb. Peripheral nervous lesions will also be detected during routine arm tests. In all these instances, an appropriate and full examination of shoulder, elbow or wrist must follow.

Interpretation of neck movements

(Fig. 7.6)

Neck movements are usually disturbed in two ways: either both active and passive movements, or active and resisted movements are positive. If all three sets of tests are positive, the examiner should be careful: a serious condition could be present.

Active and passive movements are positive

Painless active limitation is not usually a reason for consultation unless it interferes with certain activities: for example, reversing a car. Painful limitation will disclose a certain pattern, which can be confirmed by passive testing; the same limitation will be found but the end-feel will add some information about the structure that causes the restriction. Two main 'patterns of limitation' may be recognized: the full articular pattern or any other pattern that deviates from the full pattern.

Limited movement: the full articular pattern

The full articular pattern at the cervical spine is no limitation of flexion, equal degree of limitation of side flexion and rotation, and some or serious limitation of extension (see Fig. 7.7).

Painless limitation with a hard end-feel in an elderly person indicates that the patient has arthrosis of the cervical spine. Apart from some stiffness and a vague ache, this condition does not really cause serious problems.

Painful limitation in a full articular pattern, however, points towards a more serious condition, such as ankylosing spondylitis, rheumatoid arthritis, recent fracture or luxation, postconcussional syndrome, bone disease or a lesion of the upper cervical complex. The history and the end-feel can add more information about the aetiology, but usually further paraclinical investigations are required.

Limited movement: partial articular patterns

A partial articular pattern is a clear asymmetrical presentation of pain and/or limitation. This common finding usually indicates internal derangement (displacement of a disc fragment with discodural or discoradicular interaction). The complete clinical picture must, of course, be compatible with history and end-feel – see Chapter 8.

Specific types of partial articular pattern – the convergent type and the divergent type – may indicate a lesion of a facet joint (see Ch. 7), although it is not impossible for the same pattern to arise in an ordinary disc lesion too.

Full range: partial articular patterns

The same asymmetric pain patterns may occur in the absence of any clinically detectable limitation. This usually has the same significance, although the examiner has to be even more careful because a non-activity-related condition could easily be responsible.

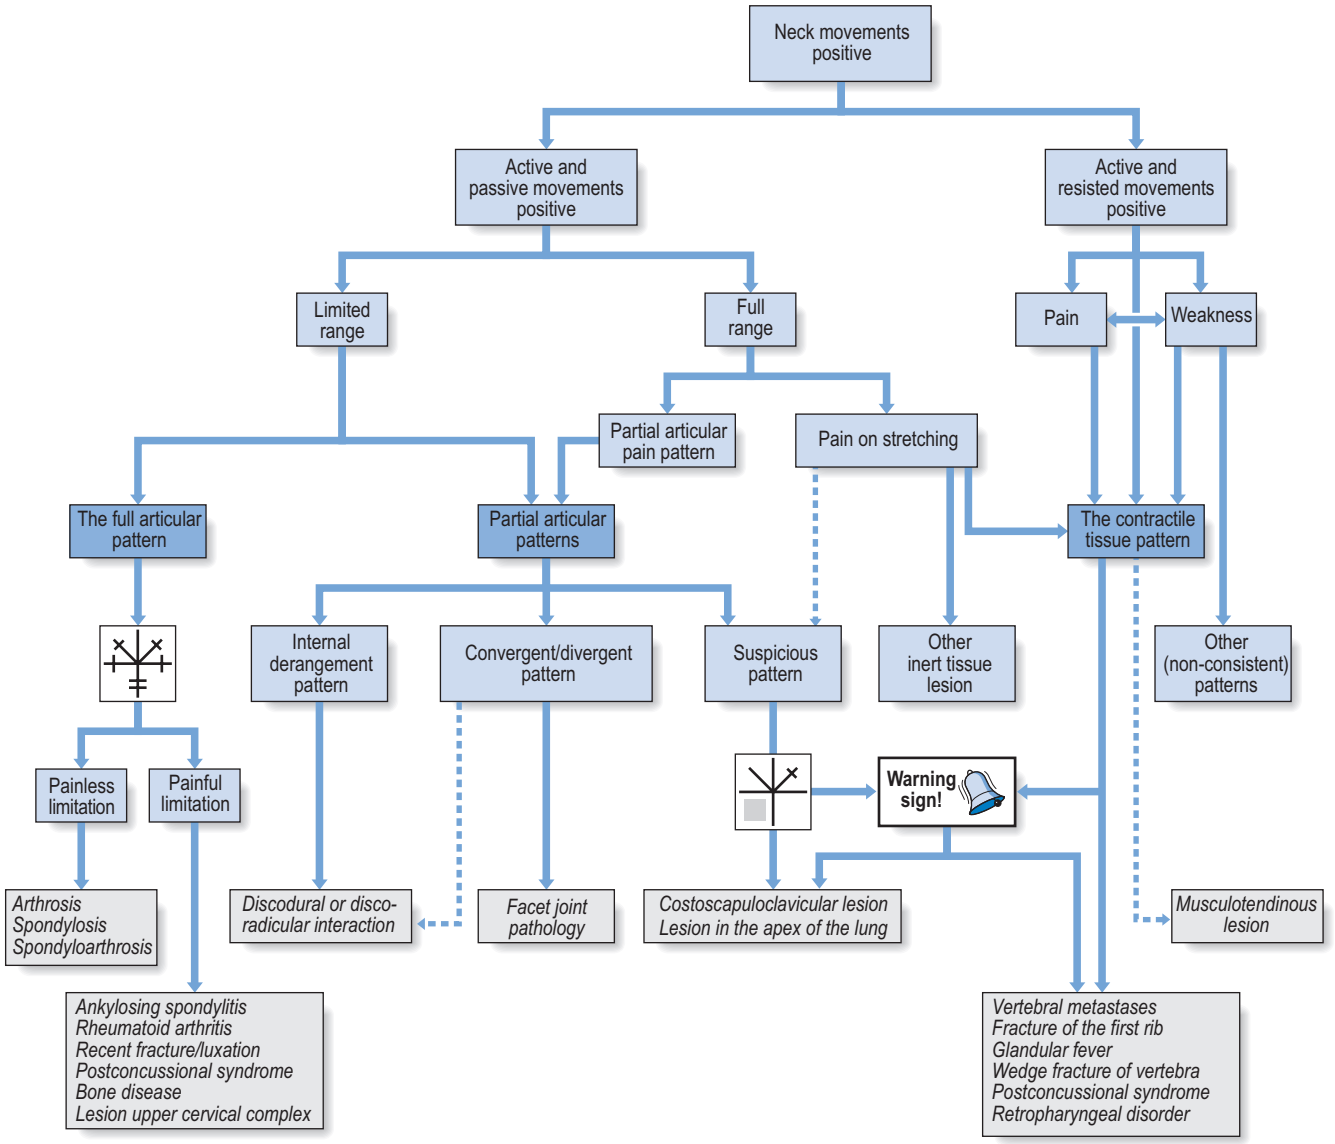

Fig 7.6 • Interpretation of neck movements.

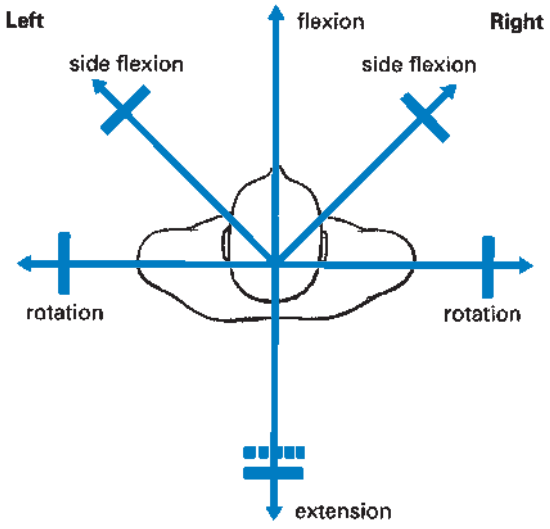

Fig 7.7 • The full articular pattern.

Limited movement: a suspicious partial articular pattern

Warning

The partial articular pattern in which side flexion away from the painful side is the only painful movement is an important warning sign (Fig. 7.8).

A displaced fragment of disc is very unlikely to disturb side flexion while leaving all other movements free. Often, the reason for this particular limitation of movement lies outside the cervical column (neck, mediastinum or apex of the lung).

Active and resisted movements are positive

Isometric testing – movements performed against maximal resistance – may cause pain, weakness or a combination of both. The muscular contraction augments the pressure in the intervertebral joints. It is therefore not totally impossible to find positive resisted movements in an articular lesion, especially when the condition is in an acute or subacute stage – for example, acute torticollis – or when there is a high degree of inflammation. The passive tests, however, should still dominate.

When a clear *contractile tissue pattern* is found – pain on isometric testing in one direction, but also on active and passive stretching in the opposite direction – the possibility of a lesion of a musculotendinous structure, although not so common, should be considered. When resisted movements are clearly more positive than active and passive ones, or when the pattern includes weak movement(s), this has to be considered as a warning sign. Vertebral metastases, fracture of the first rib, glandular fever, wedge fracture of a vertebral body, postconcussional syndrome and retropharyngeal tendinitis or abscess should be excluded.

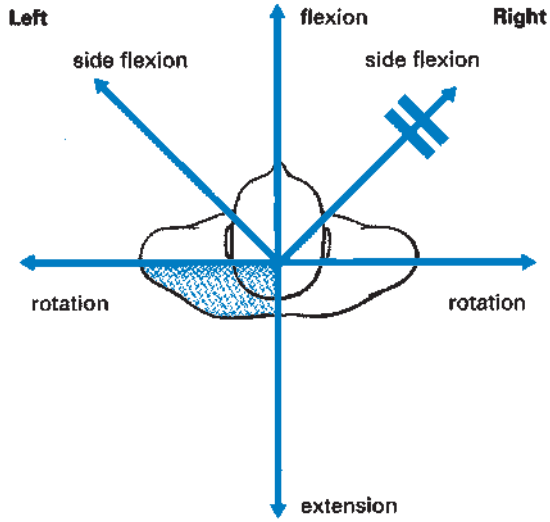

Fig 7.8 • A suspicious partial articular pattern (colour indicates pain).

Warning

- Isometric contraction that is more painful than active or passive movements warrants a closer look.
- Weakness of one or more neck movements indicates a serious disorder. Further investigations are required.

When no clear pattern of pain and/or weakness is detected or when the pattern is inconsistent, diagnosis on clinical grounds is extremely difficult, and the patient should be sent for further investigations.

Interpretation of shoulder girdle movements (Fig. 7.9)

Shrugging the shoulders involves quite a number of different structures: acromioclavicular joint, sternoclavicular joint, upper rib joints, costo- and coracoclavicular ligaments, costocoracoid fascia, upper lung, brachial plexus and muscular structures – elevators are at work, while depressors become stretched.

Pain when the shoulders are shrugged may occur in a lesion of the shoulder girdle that becomes painfully stretched: for example, sternoclavicular arthritis, healed apical tuberculosis, and lesions of the first or second thoracic nerve root, subclavius, costocoracoid fascia or first costotransverse joint. It is important to remember that this test also stretches the thoracic dura mater and thus provokes pain in a thoracic discodural interaction.

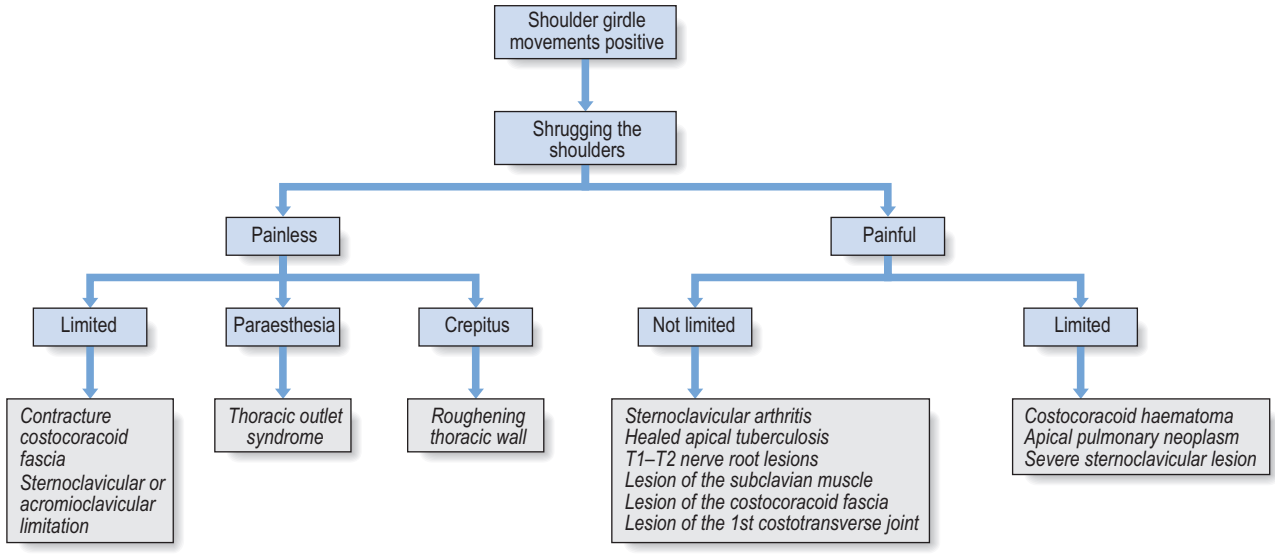

Fig 7.9 • Shoulder girdle movements.

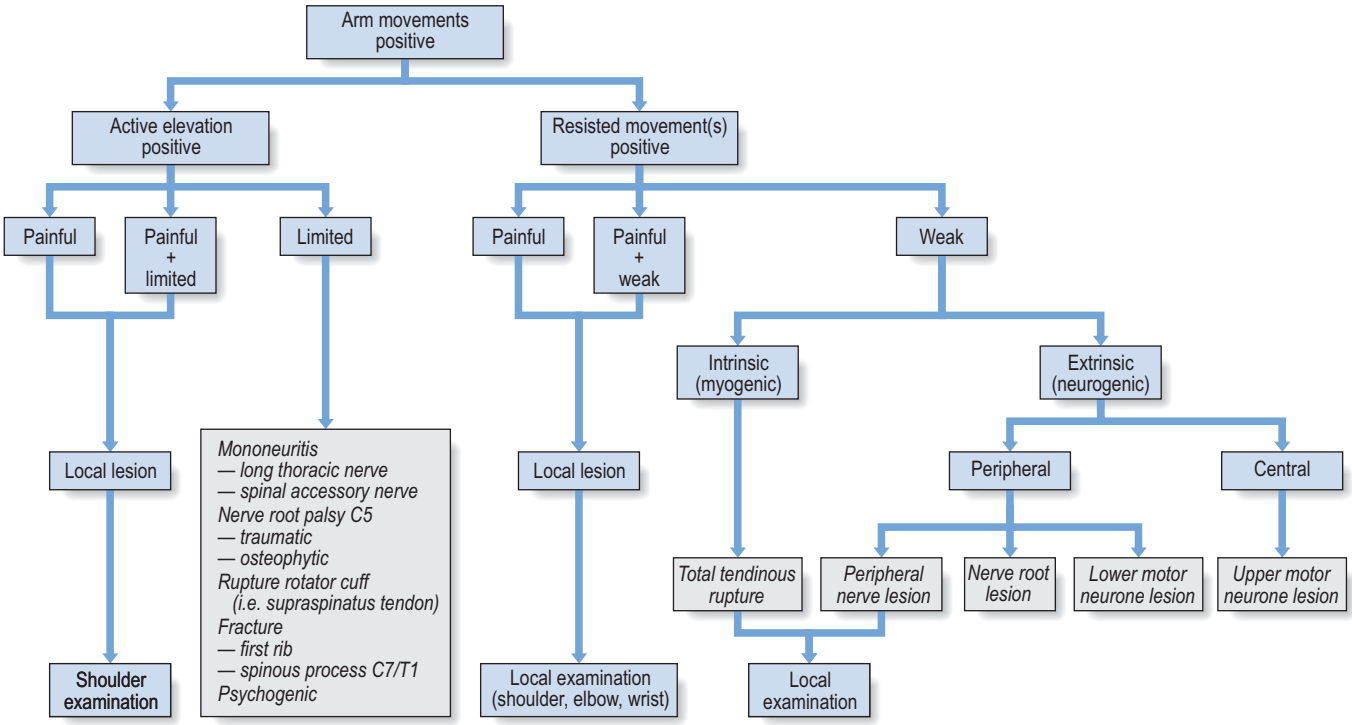

Fig 7.10 • Arm movements.

Painless limitation shows that the mobility of the scapula in relation to the thorax is impaired, either by contracture of soft tissue at the shoulder girdle or by gross lesions at the sternoclavicular or acromioclavicular joint.

Painful limitation is rare and is indicative of a lesion, such as a haematoma in contact with the costocoracoid fascia, an apical pulmonary neoplasm or a severe sternoclavicular lesion.

Pins and needles in one or both hands on sustained movement suggests the thoracic outlet syndrome. Crepitus indicates roughening of the posterior thoracic wall (see online chapter *Disorders of the inert structures*).

Interpretation of arm movements (Fig. 7.10)

Active elevation of the arm is positive

When active elevation is *painful* but not limited, the examiner should ascertain where the pain is felt. If positive neck signs have been found and the shoulder movement hurts in the neck region, this is probably the result of 'transmitted stress' and thus irrelevant. If the movement hurts in the shoulder and/or down the arm, the problem is local and full examination of shoulder, elbow or wrist should follow.

Active elevation that is *painful and limited* is probably the result of a local condition in the shoulder girdle or in the shoulder. A proper examination of shoulder girdle and arm should follow and disclose the lesion.

A number of conditions *limit* active but not passive elevation of the arm. Apart from more generalized disorders, the following neurological lesions can be responsible: mononeuritis of the long thoracic or spinal accessory nerves, osteophytic or traumatic root palsy of C5. Tendinous ruptures, especially of the supraspinatus tendon, may also limit arm elevation, as does fracture of the first rib or of the spinous process of C7 or Tl. Psychogenic pain is another possibility.

Resisted arm movements are positive

When one or more isometric tests of the arm are painful and/or weak, the lesion must be sought in shoulder, elbow or wrist. The appropriate local examination then leads to a diagnosis.

Painless weakness is sometimes difficult to detect. The patient is asked to perform a maximal contraction and the examiner assesses the strength. Weakness may vary from a subtle paresis, typical of nerve root compression by a fragment of disc, to complete paralysis, as found in more serious neurological disorders or in complete tendinous rupture.

The examiner should be able to establish whether the condition is myogenic or neurogenic. Neurological weakness either has a central cause – upper motor neurone lesion – or is the result of a peripheral nerve lesion – lower motor neurone, nerve root, plexus or local peripheral nerve. When the weakness is segmentally distributed, the problem must lie in the cervical spine. In more generalized neurological conditions (e.g. diseases of the central nervous system and cerebrovascular accidents), the weakness is more extensive. Painless myogenic weakness is probably the result of a complete rupture of a tendon.

The most common condition causing weakness down the arm is nerve root compression – usually C7 – by a displaced fragment of disc. In orthopaedic medicine the most important non-mechanical causes of weakness down the arm are mononeuritis of the suprascapular nerve, vertebral metastases, Tl nerve root lesion, neuralgic amyotrophy, traction palsy of C5 and neurofibroma.

Mechanical disorders of the cervical spine affect the structures of the locomotor system. They are often related to the consequences of the ageing spine. Degenerative changes at the level of the intervertebral discs may lead to disc displacements and also to anatomical and biomechanical changes in ligaments, capsules, nervous tissue and vascular structures. In addition to this degeneration being responsible for the development of certain disorders, injuries and overuse may also lead to soft tissue lesions in the region of the neck (Box 8.1).

Mechanical disorders are activity-related, which means that their symptoms are influenced by movement and/or posture. Questions in the history taking, such as 'What brings your symptoms on?' or 'What makes your symptoms disappear?' elicit answers that may suggest the type of condition from which the patient suffers.

Degeneration and anatomical changes

Degenerative changes in the cervical spine are part of the normal ageing process and are almost ubiquitous in older people.[1,2] Very often they remain asymptomatic.[3,4] Therefore diagnoses such as 'degeneration', 'arthrosis', 'osteophytosis', 'spondylosis' or 'spondylarthrosis' based on incidental radiological findings are still too easily made. Throughout the literature, a discrepancy between the discovery of structural changes and the presence of symptoms is a consistent finding.[5]

Ageing of the cervical spine

As a result of weight bearing in bipedal humans, the axial spine is submitted to increased forces acting on the different structures. The disc, being entirely avascular, suffers most from this situation; degeneration starts quite early in life and progresses with age. The degenerative process in the intervertebral disc is followed by other structures of the spine, such as bone, ligaments, capsules and zygapophyseal joints.

Ageing of the cervical disc

In healthy individuals the cervical intervertebral disc has a structure which is very similar to that of the lumbar disc: an annulus fibrosus which contains a nucleus pulposus. As long as the disc is not submitted to excessive asymmetrical forces, the hydraulic mechanism within the disc functions perfectly. It becomes deficient as the result of excessive forces occurring during everyday activities, or following absence of movement. The annular fibres become strained and sprained, and the nucleus starts to dry out. This is a characteristic sign of disc degeneration.

It has been shown that, in the first two decades of life, lateral tears occur in the annulus fibrosus. They tend to develop joint-like structures – the uncovertebral joints – that then begin to undergo transformation.[6] In the second and third decades, the lateral tears enlarge towards the medial part of the disc, often ending in a complete transverse splitting of the disc into equal halves. These anatomical changes cause instability of the

Mechanical disorders of the cervical spine

Disc disorders
- Disco-dural interactions
- Disco-radicular interactions

Degenerative disorders
- With localized pain
  - Arthrosis at the upper two cervical joints, leading to ligamentous contracture: morning headache in the elderly
  - Subacute arthritis of the atlantoaxial joint
  - Arthrosis at a facet joint
- With radicular pain: osteophytic root compression
- Cervical spondylotic myelopathy

Capsuloligamentous disorders

Musculotendinous lesions
- Lesions of the semispinalis or splenius capitis muscle
- Lesions of the longus colli muscle (retropharyngeal tendinitis)

disc and favour the possibility of cartilaginous displacements, either of the annulus fibrosus or of the nucleus pulposus (see below: disc displacements).

In the fourth and fifth decades, the nucleus pulposus dries out further because of the loss of proteoglycan matrix with, as a result, diminution of the height of the intervertebral space and flattening of the lordotic curve. The uncovertebral joints start to bear weight and tend to flatten. Degenerative changes at this level threaten the spinal nerve and the vertebral artery.

From the fifth and sixth decades on, the disc tends to collapse, further diminishing its height. The borders of the vertebral bodies come into apposition, with the formation of hyperostosis and osteophytes as a reactive result. The spine stiffens and the articular segments stabilize again.

See Chapters 31 and 32 for an extensive explanation of the function and behaviour of the lumbar disc, which is highly comparable to the situation in the cervical spine.

Consequences of disc ageing for surrounding structures

Effects on the ligaments

Instability of the intervertebral joints results in instability of the entire segment. The excessive and irregular movements of the related vertebrae lead to traction at the site of osseous attachments of the annulus fibrosus to the vertebral body. Lifting of the anterior and posterior ligaments results in spur formation at the anterior and posterior borders of the vertebral body, and subsequently to the formation of osteophytes. In addition, the ligamentum flavum is submitted to traction forces. It becomes deformed and enlarged, and will buckle into the spinal canal during extension.

Effects on the facet joints

The prevalence of cervical facet joint degeneration is very high in individuals aged 50 years and more, with a tendency to increase in severity with age. Diminution of the height of the disc and the subsequent reversal from lordosis to kyphosis result in a greater transmission of shearing forces to the facet joints. They start to bear weight and this furthers the degenerative process. This is characterized by fibrillation and erosion of the articular cartilage, partial or complete denudation of the cartilage, and new bone formation.[7] Later in life, subperiosteal osteophytes with periarticular fibrosis develop, resulting in a gross decrease in mobility.[8]

All levels of the middle and lower cervical spine are affected to almost the same degree, whereas in the lumbar spine there is an increase in degeneration towards the lower levels.[9]

Effects on the uncovertebral joints

With progressive diminution of disc height, the bony protuberances about the uncovertebral articulations approach each other and are pressed together. The intervening (pseudo-) articulations degenerate, leading to osteophytes that enlarge the joint surfaces and project from the posterior edge of the vertebral body into the disc space and the intervertebral foramina. Compromise of adjacent neurovascular structures (nerve root and vertebral artery) is a potential complication.

Effects on the spinal canal

Circular disc displacement, as is seen when the disc has degenerated entirely, may further the development of osteophytic outcrops on all sides, and thus also into the spinal canal, threatening the spinal cord.[10] Once the bony parts formed by the uncovertebral joints touch each other, further loss of height can only happen anteriorly. Because of the decrease in height in the anterior column of the cervical spine, cervical lordosis may diminish and even disappear, resulting in the typical position of the degenerated neck – the chin projected forwards. Retrolisthesis in the mid-cervical area (C3–C6) is a common finding in spondylarthrosis. Also, buckling of an enlarged ligamentum flavum narrows the spinal canal, especially during extension of the neck.[11,12]

Effects on the intervertebral foramen

The association of diminished intervertebral space, osteophyte formation at both the uncovertebral and zygapophyseal joints, and hypertrophy of the facet joint capsules causes diminution of the intervertebral foramen and eventual neural foraminal encroachment.[13] Further diminution of the foraminal space is caused by the backwards slip of the upper vertebra during extension.[14]

Radiological changes

Degenerative changes of the cervical spine are common in both symptomatic and asymptomatic adults. At the age of 50, spondylosis is visible on plain X-rays in more than 50% of asymptomatic people.[15] A magnetic resonance imaging (MRI) study on 500 asymptomatic subjects could detect disc

degeneration in 17% of discs in men and in 12% of those of women in their twenties, and 86% and 89% of discs in both men and women over 60 years of age. Posterior disc protrusion with demonstrable compression of the spinal cord was observed in 7.6% of subjects over 50 years of age.[16,1] The clinical question is whether the patient's symptoms are caused by the changes that are seen on imaging. Unfortunately, even the most sophisticated imaging studies do not show pain, but only structural abnormalities that may or may not be the cause of the patient's symptoms.[4,17]

Pathology

Disorders of the disc: disc displacements

Symptomatic disc displacements in the cervical spine are more common than is generally believed. They can occur at any age from childhood onwards but present with different clinical syndromes, depending on the age group.[18]

Cartilaginous displacements are most frequent at the C6–C7 and C5–C6 joints. They are occasionally found at the C4–C5 or C7–T1 joints, and rarely at the C2–C3 or C3–C4 joints.[19] Nuclear prolapses are very uncommon, except in young people. It was to Cyriax's credit that he recognized the clinical pictures associated with disc displacements and made an inventory of symptoms and signs. A distinction can be made between posterocentral and posterolateral displacements resulting respectively in discodural and discoradicular interactions. It is important to remember that diagnoses are made on clinical grounds, following the patient's history and the functional examination. Technical investigations that rely only on anatomical findings lead very easily to misinterpretation.[17] They can sometimes be used to confirm a diagnosis, rather than to make one. Discs may displace in two ways: either they move posteriorly to compress dura and/or cord, or they move posterolaterally to compress the nerve root.

Posterocentral displacement

Posterior migration of disc tissue beyond the posterior limits of the intervertebral joint space causes pressure on the posterior longitudinal ligament and, via the ligament, on the anterior part of the dura mater. This produces multisegmental pain with dural reference, mostly in the trapezius and scapular area but possibly towards the head and/or pectoral area (see Ch. 7). The pain is the result of a discodural interaction: irritation of the anterior structures in the spinal canal is responsible for the dural symptoms. Pure posterocentral compression gives rise to pain felt centrally and/or bilaterally. Compression just laterally from the midline will result in pain that is felt unilaterally but is still multisegmental. The internal derangement in the intervertebral joint provokes articular signs demonstrable on functional examination.

Posterolateral displacement

If the extruded disc material runs into the nerve root canal, discoradicular interaction occurs. This posterolateral migration of disc tissue causes pressure on the nerve root, which results in a series of symptoms: first segmental pain following compression of the dural sheath (root pain), then segmental paraesthesia and/or neurological deficit as the result of the parenchyma becoming pinched. The disc displacement may be primary or secondary.

Secondary posterolateral displacement

This is the most common situation. The patient has suffered from a few posterocentral displacements with neck, trapezius and/or scapular pain in the past. During the most recent attack, as the disc fragment moves from the centre to one side, the pain shifts from the neck to the upper limb. Segmental root pain builds up while the multisegmental neck pain disappears.

Primary posterolateral displacement

From the outset the pain is felt in the forearm. There has been no previous neck pain because originally there was no compression of the dura mater but rather of the nerve root directly. The segmental pain can be accompanied by paraesthesia and/or neurological deficit. Because this condition is rather uncommon, differential diagnosis should be made with non-discal nerve root compression or with intrinsic conditions of the nervous system.

Stages of disc displacement

Disc displacements also behave according to their actual status of degeneration. Cyriax described seven stages of disc lesions, each one typical of a certain age group and characterized by a typical history (Fig. 8.1).[20]

Stage 1

Acute torticollis in adolescents or young adults: acute neck pain, with total immobilization and gross deviation. This is

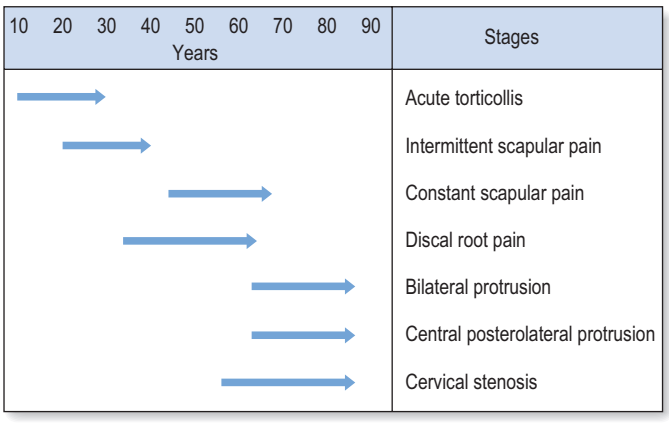

Fig 8.1 • Stages of disc displacement.

the result of a large discodural interaction, usually of the nuclear type. The lesion undergoes spontaneous cure within 10 days.

Stage 2

Intermittent scapular pain, mostly unilateral but not always on the same side. The patient is in his/her late 20s or older. The symptoms may last several weeks.

Stage 3

Constant scapular pain in a patient over 50. Due to developed spondylosis and stiffness of the neck, there is no spontaneous reduction of disc material.

Stage 4

Pain in the upper limb after initial scapular pain. The patient is between 35 and 65. The pain typically increases during the first 2 weeks then remains unchanged over the next 4–8 weeks, recovering spontaneously after 8–12 weeks. There may be paraesthesia and neurological deficit.

Stage 5

In elderly patients, a bilateral protrusion may cause aching in both upper limbs and paraesthesia in all the fingers.

Stage 6

Constant bilateral aching in head, neck and scapulae may be experienced in elderly patients as the result of a fixed posterocentral protrusion that leads to constant discodural interaction.

Stage 7

The disc compresses the spinal cord. This results in paraesthesia in the hands and/or feet.

Osteophytes may obliterate the anterior spinal artery, leading to progressive paraplegia.

Findings on examination

It is believed that disc degeneration and disc displacements are of themselves painless events. It is only when pain-sensitive structures in the neighbourhood pick up on the disc abnormality and translate mechanical pressure and inflammatory changes into pain that signs and symptoms originate. The reader is referred to Chapter 33 – the 'dural concept' – for a thorough description of this dural hypothesis.

Disc displacements in the cervical spine will give rise to the same set of signs and symptoms as in the lumbar spine. However, in contrast to the lumbar spine, disc lesions at the cervical spine may threaten the spinal cord. Therefore, not only the usual dural, articular and root signs and symptoms, but also cord signs and symptoms may be present here and must be sought.

Dural symptoms

When a fragment of disc (at any level) protrudes posterocentrally, it may compress the dura mater either in the midline, which results in central or bilateral pain, or slightly to one side, leading to pain felt unilaterally. The dura mater, being a multisegmentally innervated tissue, translates this compression into multisegmental pain (see Ch. 1). Pain reference from the cervical dural mater may thus spread up to the head and down to the mid-thoracic region, and may be felt anywhere in this area (Fig. 8.2). However, the pain is most commonly experienced in the region of neck, trapezius and scapula (Fig. 8.3a). Occasionally it is felt in the clavipectoral area or in the axilla (Fig. 8.3b).

Patients often mention a tender spot, usually somewhere at the superior border of the trapezius, which they identify as the source of their pain. On palpation the examiner indeed finds localized tenderness. However, during the examination, movements designed to test the trapezius muscle are found to be negative. Furthermore, the tender spot may shift during neck manipulation and disappears when a full and painless range is

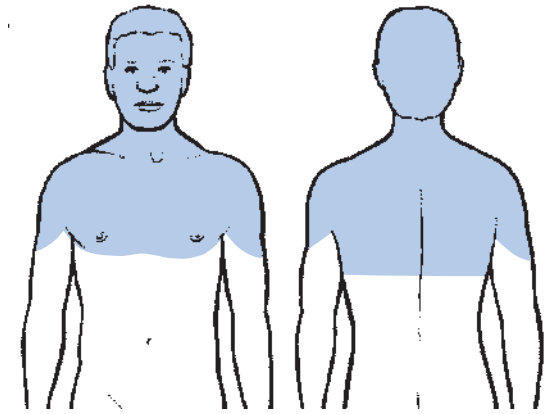

Fig 8.2 • The boundaries of multisegmental reference of pain of cervical origin.

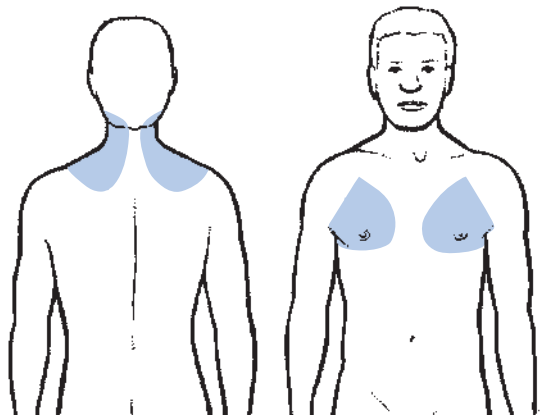

Fig 8.3 • Multisegmental pain: (a) the most common distribution involves trapezius and interscapular area; (b) less commonly, pain is felt in the pectoral and axillary areas.

obtained. This confirms that the tenderness is clearly a referred phenomenon (see Ch. 1) without localizing or diagnostic value. This multisegmental tenderness is one of the dural symptoms and results from dural compression at any level.

In contrast to a lumbar discodural problem, a cough seldom hurts. Very exceptionally, swallowing may be uncomfortable, although the mechanism causing this symptom is unclear.

Dural signs

Dural signs are not found on examination. Although neck flexion stretches the dura mater, the pain very often experienced during this movement must be regarded as an articular sign rather than a dural one. Neck flexion can only be regarded as being a dural test if it stretches the dura from a distance, which is not the case here. There is also no equivalent to the straight-leg raising test in the lumbar examination where a simple movement (hip flexion with an extended knee) allows differentiation between dural pain, root pain and muscular tightness. Some nerve roots (C4–C6) are tethered to the gutter of their respective transverse process,[21] but apparently not to the foramen.[22] Some authors have developed and discussed 'upper limb tension tests' (ULTT) as a valuable examination procedure for patients with neck problems with or without radiation down the upper limb.[23,24] The aim would be to create stress, transmitted to the structures in the spinal canal via the peripheral nerves (median–radial–ulnar). The peripheral nerves in the upper limb however, have, unlike those in the lower limb, a more complex course. It is therefore more difficult to carry out 'pure' movements and, although these tests stress the neurological tissues, they also stress some contractile and inert tissues in neck, shoulder girdle and arm. Because of their low specificity, [25–27] they are not integrated into the standard functional examination of the cervical spine.

Articular symptoms and signs

The symptoms are activity-related: pain is elicited or influenced by movements, activity and posture. Sometimes there are twinges during movement of the neck.

On examination, a partial articular pattern of internal derangement is found: some active movements are painful and limited or cause pain at the end of range, while others are negative or clearly less positive. The asymmetrical pattern that occurs may vary from very subtle, with hardly any limitation, to very pronounced with some movements completely blocked, forcing the head in a deviated position. A minimal partial articular pattern (Fig. 8.4a) emerges when the internal derangement is minor and the discodural interaction slight. It is hypothesized that pronounced signs result from a severe discodural interaction (Fig. 8.4b). Passive movements usually hurt more than active ones, though cases may be encountered in which passive movements ease the pain. Resisted movements are negative, except perhaps resisted flexion. The latter may slightly increase the pain in more acute cases, presumably as a result of the consequent compression strain on the affected joint.

When neck flexion elicits pain in the upper thoracic area, further examination of neck, shoulder girdle and thorax must

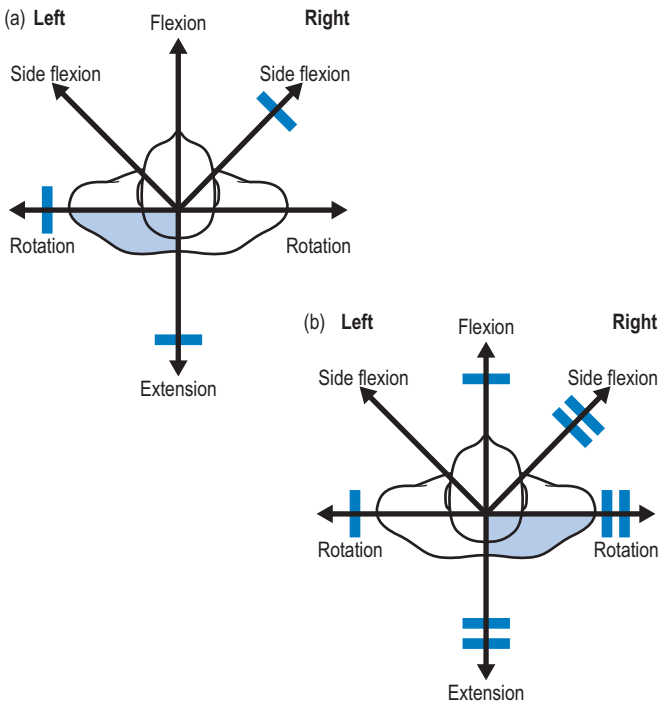

Fig 8.4 • Examples of partial articular patterns: (a) minimal; (b) severe (colour indicates pain).

differentiate between a cervical lesion with pain reference to the upper thorax and a lesion in the shoulder girdle or upper thoracic spine. The movement is an articular sign for the cervical spine but is also regarded as a dural sign for the thoracic spine. During neck flexion the dura mater is stretched and drawn forward against an eventual upper thoracic protrusion (see Ch. 25).

A painful arc may be found on active or passive testing. This sign sometimes occurs during rotation movement in patients with unilateral symptoms and during extension in patients with central or bilateral pain, and is pathognomonic of a disc lesion.

If only one movement proves positive, it is usually rotation towards the painful side. Caution must be taken when the only painful movement seems to be side flexion away from the painful side. This sign may occur in any costoscapuloclavicular lesion, but may also suggest a lesion at the apex of the lung. Further investigations are necessary.

In discodural problems either the normal leathery end-feel is expected or, in more severe cases, the more typical end-feel of muscle guarding ('crisp'). This is clearly unlike the hard end-feel of arthrosis or the muscle spasm end-feel of more serious disorders.

Root symptoms and signs

By analogy with the lumbar spine, where backache may evolve into sciatica, cervicoscapular pain may be replaced by brachial pain. The original multisegmental cervicoscapular pain disappears and severe and strictly segmental pain down the arm supervenes. The examiner must be aware that patients sometimes omit to mention the original pain in the trapezius or scapular area but concentrate only on the severe symptoms at

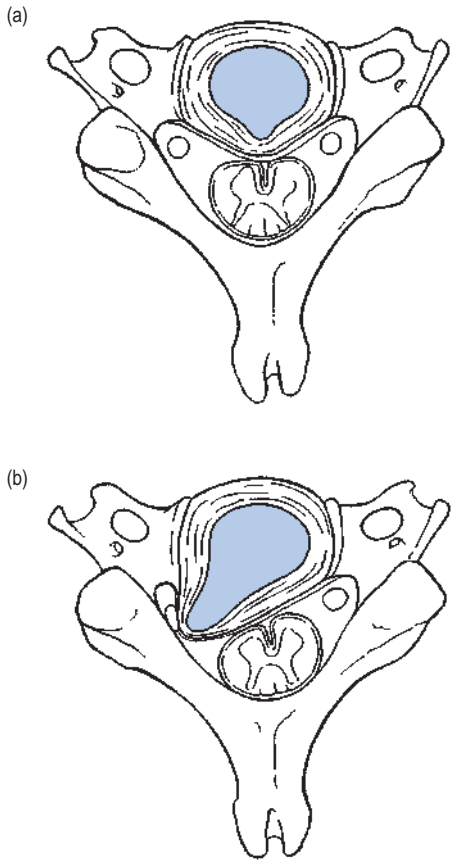

Fig 8.5 • Pressure on the dura mater (a) ceases when the disc moves laterally and compresses the nerve root (b).

presentation. This change in pain localization is the result of the disc moving laterally (Fig. 8.5). Pressure on the dura mater ceases when the dural sleeve of the nerve root becomes compressed and radicular pain appears. Increasing compression of the nerve root is translated into increasing symptoms and signs. Paraesthesia and/or numbness point towards involvement of the nerve root fibres and are usually felt in the distal part of the corresponding dermatome.

Conduction may become impaired, leading to neurological deficit, which manifests as a minor motor palsy (paresis), a sensory palsy (cutaneous analgesia) or both. Reflexes may become sluggish or absent. Because the cervical nerve roots emerge horizontally, the symptoms and signs are strictly monoradicular, in contrast to the situation in the lumbar spine where the nerve roots have an oblique course and one disc displacement may compress several nerve roots. However, the C6 and C7 nerves are sometimes slightly more oblique and may become compressed by two discs.

Additional tests to provoke radicular pain can be added. During the Spurling test, the patient side-flexes the head to the affected side first, followed by the unaffected side. Meanwhile the examiner presses straight down on the head.[28] A test result is classified as positive if pain radiates into the arm towards which the head is side-flexed during compression. Alternatively the head is rotated and side-flexed to the same side during compression.[29] This is called the 'maximal cervical compression test'. Great care is needed while performing this test as it also compresses the vertebral artery.

Table 8.1 Findings on examination

	Symptoms	Signs
Dural	Multisegmental pain Multisegmental tenderness (pain on coughing)	
Articular	Pain on movement/posture Twinges	Deviation Partial articular pattern Painful arc Crisp end-feel
Root	Segmental pain Segmental paraesthesia Segmental numbness	Motor deficit Sensory deficit Sluggish reflex
Cord	Paraesthesia in all limbs Lhermitte's sign Sensory disturbance in feet	Gait disturbance Spastic palsy lower limbs Hyperreflexia – clonus Positive Babinski–Hoffmann

Cord symptoms and signs

In posterocentral disc protrusion, the spinal cord may also become compressed. Pressure on the cord itself is not painful. It leads to multisegmental paraesthesia, usually felt in both hands and/or feet and very often provoked or influenced by active or passive neck flexion. Sensory disturbance soon supervenes. In more severe cases, the gait will become disturbed, the plantar reflex may become positive (Babinski's sign) and the patient may develop spasticity, incoordination and extensive weakness in the lower extremities.

Findings on examination are summarized in Table 8.1.

Common syndromes

The following clinical pictures are all caused by cervical disc protrusions. Symptoms and signs are determined by size, localization and degree of degeneration of the displaced discal fragment and the nature of the involved structures.

Acute torticollis: unilateral pain with asymmetrical picture

Unilateral acute torticollis is caused by a discodural interaction that is quite common between the ages of 15 and 30. An acute torticollis under the age of 12 is rarely caused by a disc (see Differential diagnosis).

History

Most patients wake in the morning with a stiff neck. Pain and stiffness increase as soon as they adopt an upright position. Any attempt to move the neck results in unilateral pain, radiating to trapezius and/or upper scapular area. Occasionally the symptoms come on suddenly as the result of a certain

movement (e.g. bending over a washbasin), trivial trauma (e.g. a blow to the head[30]) or coughing.

Neck movements make matters worse, and even arm movements may cause considerable pain. The pain diminishes when lying down with the neck supported but it is very difficult to change position and the patient has to hold the head firmly between the hands to do so.

Previous attacks, not necessarily with symptoms on the same side, may be mentioned. Many patients also feel giddy during an attack of acute torticollis.

Inspection

The patient holds the head in an asymmetrical position. In acute torticollis that results from a disc lesion, the deviation is usually purely lateral, in most cases away from the painful side and without any rotatory component. Slight deviation in flexion occasionally occurs.

Examination

On examination, gross and obvious articular signs are found: a striking and extremely painful limitation of one rotation and one lateral flexion towards the same side, usually the painful side. Often no movement is possible in either of these directions (Fig. 8.6). The other movements are much less painful and are scarcely limited, except possibly extension. The end-feel is empty or one of severe muscle guarding.

Resisted movements may be painful and even weak. The patient stops the contraction because muscular action causes a momentary change of pressure in the intervertebral disc and intensification of pain.

Arm movements may also be impaired. On active elevation of the ipsilateral arm, a false painful arc may be present and in very acute cases the patient may even be unable to bring the arm up voluntarily above the horizontal. These secondary signs are clearly the result of transmitted stress: when the arm reaches the horizontal, the muscular effort is at its greatest and secondary tautening of the cervical muscles takes place, leading to such pain that the arm falters and a false shoulder sign appears. There are no root or cord signs.

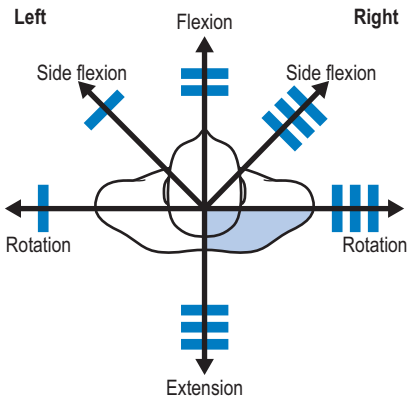

Fig 8.6 • The partial articular pattern in acute torticollis (colour indicates pain).

Diagnosis

The pattern of limitation is diagnostic. Acute torticollis is the most striking example of a partial articular pattern, which indicates that part of the joint is blocked by an intra-articular displacement. In most instances the displacement is nuclear: the nucleus has oozed out slowly during the night, while the patient has being lying for some hours with the neck in side flexion or rotation. The dura mater becomes compressed and irritated, which causes the cervicoscapular pain. A sudden onset suggests an annular displacement. It usually occurs in patients over 30. This mechanism was hypothesized by Cyriax more than 50 years ago and was recently proven by two MRI studies. Maigne *et al* performed MRI in a 15-year-old male adolescent, a few hours after the onset of torticollis. Increased signal intensity compatible with a fluid collection was seen in the right uncovertebral region at C2–C3, causing excessive lateral pressure and pushing C2 outwards. A new MRI taken 3 weeks after resolution of symptoms was unremarkable.[31] Another MRI study performed by Gubin *et al* in ten children and adolescents with acute torticollis showed similar findings: high-intensity zones were seen near uncovertebral zones C2–C3 or C3–C4. The zones were always on the side where the patients felt pain and disappeared spontaneously after a few days.[32]

The characteristics of acute unilateral torticollis are listed in Box 8.2.

Box 8.2

Summary of unilateral acute torticollis

Definition

- Acute torticollis is a sudden attack of severe cervicoscapular pain, owing to a large posterior shift of disc material, compressing the dura mater and resulting in a discodural interaction

Onset

- Sudden: annular (age >30)
- Slow: nuclear (age <30)

Symptoms

- Articular
  - (Twinges)
  - Pain on active movements
- Dural
  - Dural pain: large reference

Signs

- Deviation in side flexion (or flexion)
- Gross partial articular pattern

Treatment

- >30 years: manipulation under traction
- <30 years: progressive sustained movements

Spontaneous recovery

- Takes 7–10 days

Differential diagnosis

Discogenic torticollis is the most common form of twisted neck or 'wry neck' and should be differentiated from many other types of torticollis.

Torticollis in infancy and childhood

This can be congenital or acquired. Congenital types include those resulting from osseous, muscular or neurogenic factors.

Osseous lesions are mostly anomalies of the atlas,[33] such as hemiatlas, partial atlantic aplasia[34] or partial atlanto-occipital fusion,[35] and Klippel–Feil syndrome. Klippel–Feil syndrome is congenital fusion of two or more cervical vertebrae. The classic clinical triad is: lower neckline, short neck, and restriction of head and neck movements.[36] In patients with moderate involvement, this classic triad may not be seen and sometimes there is only some scoliosis deformity or moderate torticollis.[37]

Congenital muscular torticollis (CMT) is caused by shortening of the sternocleidomastoid muscle. This leads the head to bend toward the affected side and the chin to turn to the opposite side, the so-called cock robin position of the neck. CMT is the third most common congenital musculoskeletal anomaly after dislocation of the hip and clubfoot,[38] with a reported incidence of 0.3–1.9%.[39] Various theories have been proposed but the true aetiology of torticollis remains uncertain.[40] As a result of fibrotic changes of the sternocleidomastoid muscle, the unilateral contracture may subsequently result in plagiocephaly, skull and facial asymmetry.[41] When diagnosed early, CMT can be managed conservatively and seldom requires surgery.[42] In fact, a simple stretching programme leads to spontaneous resolution in most patients.[43] In children older than 1 year, corrective surgery has both cosmetic and functional benefits, the best outcomes being obtained between the ages of 1 and 4. After the age of 5, the form and efficacy of treatment are controversial.[44]

Acquired torticollis in children should always be taken seriously, as it may result from a number of underlying causes, some of which are severe and life-threatening. Spontaneous subluxation of the atlantoaxial joint following peripharyngeal inflammation is known as *Grisel's syndrome*. Children between 5 and 12 years are most frequently affected. However, the condition has been reported in patients ranging from infancy to the seventh decade of life.[45] Torticollis may occur shortly after the onset of the underlying infection or it may follow mild trauma to the neck. The syndrome has been reported in association with rhinopharyngitis,[46] cervical osteomyelitis, rheumatic conditions, and following surgical procedures such as tonsillectomy or adenoidectomy,[47] choanal atresia repair and mastoidectomy. It is hypothesized that distension and abnormal laxity of the ligaments surrounding the atlantoaxial articulation result from direct spread of inflammation from the pharynx and nasopharynx.[48] This leads to C1–C2 instability with subluxation and (sometimes) devastating neurological sequelae (between 10 and 15% of patients have neurological signs or symptoms, with serious consequences including quadriplegia and sudden death[49]). The condition begins with a spasm of the irritated sternocleidomastoid muscle. This contraction leads to a typical position of the head, which is easily differentiated from the position in acute discogenic torticollis. In a disc lesion, the deviation is purely in lateral flexion or flexion or a combination of both. When a spasm of the sternocleidomastoid muscle is responsible, the neck is held in flexion, side flexion towards and rotation away from the painful side (signe du merle or 'blackbird's sign') (Fig. 8.7).[50]

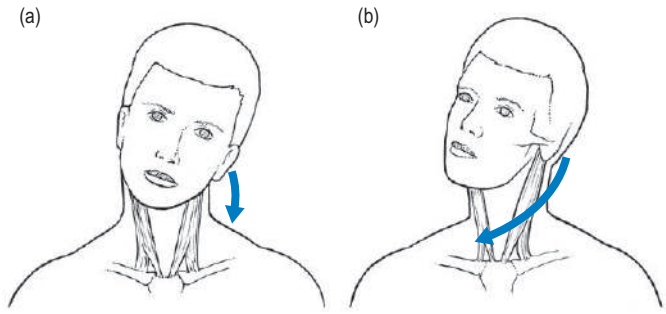

Fig 8.7 • (a) Discogenic torticollis – the deviation is pure in lateral flexion. (b) Grisel's syndrome: spasm of the sternocleidomastoid muscle forces the head in side flexion towards and rotation away from the painful side.

The diagnosis of atlantoaxial subluxation requires radiological investigation. Plain radiographs of the cervical spine may show asymmetry between the facet joints on the anteroposterior projection and an increased atlanto–dens interval on the lateral projections.

Initial treatment consists of collar immobilization and broad-spectrum antibiotic therapy. In the case of persistent torticollis with no improvement following 1 week of conservative treatment, the patient should be referred for neurosurgical consultation.

Benign paroxysmal torticollis is a relatively uncommon, self-limiting condition occurring during infancy. It resolves by the age of 2–3 years. Periodic episodes of torticollis may randomly alternate from side to side and be associated with vegetative symptoms. The aetiology is unknown and no treatment is effective.[51]

Spasmodic torticollis

Spasmodic torticollis or cervical dystonia is the most frequently occurring focal dystonia, with an incidence of 8.9 per 100 000 people.[52] Dystonia is defined as sustained, involuntary muscle contractions, which often cause twisting or repetitive movements or abnormal postures. The origin of the symptoms is still unclear. The condition often results in cervical pain and disability as well as impairments affecting postural control.[53]

The inspection is diagnostic. The patient is seen to rotate the head suddenly, always in the same direction, by an apparently irresistible active movement. This involuntary movement can be prevented by manual pressure, which can also be used to overcome the muscles and rotate the head back into the neutral position. The muscles give way in a manner that suggests neurological hypertonus.

Therapy of spasmodic torticollis includes behaviour modification, such as training the patient to readjust the position of the head, and biofeedback, hypnosis and anticholinergic drugs.[54] When these procedures are not successful, local application of botulinum toxin A offers a highly effective treatment

technique. Botulinum toxin A is injected into the overactive, dystonic cervical musculature to provide a graded, reversible denervation of the neuromuscular junction by preventing the release of acetylcholine from the presynaptic axon of the motor end plate. Botulinum treatment showed success rates ranging from approximately 60 to 90%.[55,56] Surgical intervention is used when a patient has not responded to other interventions. Although a variety of surgical techniques have been studied, the most commonly used approach is selective peripheral denervation.[57]

Psychogenic torticollis

The patient keeps the head and scapula fixed in an impossible position, which immediately demonstrates its non-organic nature: the head is held in side flexion towards the alleged painful side and the scapula at the same side is kept hunched. No organic lesion exists which leads to fixation of the head in side flexion and whereby the patient is obliged to keep the scapula elevated.

On examination, all active and passive movements are very painful and limited. Resisted movements are painful and weak. This again is very suspect. Finally, the end-feel discloses active muscular contraction but sustained passive pressure during persuasion soon leads to a full range of movement and a normal end-feel, which confirms the diagnosis.

Parkinsonism

The neck may gradually become stiff and painful because of muscle rigidity that is the result of increased extrapyramidal tone. The passive range being much larger than the active one affords a clue, and inspection of the face is confirmatory, as are other typical findings (e.g. tremor, gait).

Cervical scoliosis

The presence of a compensatory thoracic curve following cervical scoliosis indicates the possibility of adolescent scoliosis, unilateral cervical rib, Klippel–Feil deformity[58] or previous thoracoplasty.

Meningitis

The differential diagnosis is not very difficult. In meningitis, the patient develops acute pain in the neck with headache. There is nausea and sometimes vomiting and fever. The neck is fixed in extension. On examination very pronounced dural symptoms and signs are found: even straight-leg raising is positive (Kernig's sign and Brudzinski's sign).

Natural history

Untreated, the pain is constant and severe for 2 or 3 days; the condition recovers spontaneously over the course of the following week.

Treatment

Treatment is by manipulation. The technique is adapted according to the clinical picture. Acute torticollis in patients under 30 often behaves in a nuclear manner; these patients should be treated with 'nuclear' techniques – progressive sustained rotation and/or lateral flexion, whereby an attempt is made to push the displaced nuclear material slowly back. The less common annular cases should be treated with the usual 'annular' manipulation techniques (see Ch. 11).

Unilateral cervicoscapular pain

This is the most common neck complaint. Symptoms may start from the late 20s on and can occur at all ages. The pain has a recurrent character with varying localization and eventually becomes more or less chronic.

History

The patient describes periods of unilateral cervicoscapular pain, which may come on spontaneously or after a minor trauma. The pain may be localized, usually at the mid- or lower neck, or refers to the trapezius area, scapular area, shoulder region or head. The multisegmental character of the reference shows the pain to be of dural origin. The pain is aggravated by certain movements – a common complaint is difficulty in twisting the head to one side so as to reverse a car. Certain postures, especially flexion maintained for a certain time (e.g. when reading), may increase the pain. There is usually no pain at night, except on turning in bed. The painful episode lasts a few days to several weeks and disappears spontaneously. There is no pain between the bouts. A new attack is not always felt on the same side. Over the age of 50, pain may not disappear completely between two episodes of aggravation.

Examination

A mild partial articular pattern is found (Fig. 8.8). As a rule, two, three or four movements out of the six are painful, and four, three or two prove painless. Passive movements are usually more painful than active ones. There may be minor limitation, or a painful arc is found. The end-feel is rather crisp, indicating the muscle guarding typical of a disc lesion, but it is not uncommon to find a normal, capsular end-feel. Root and cord signs are absent. It is not easy to determine the level at which the

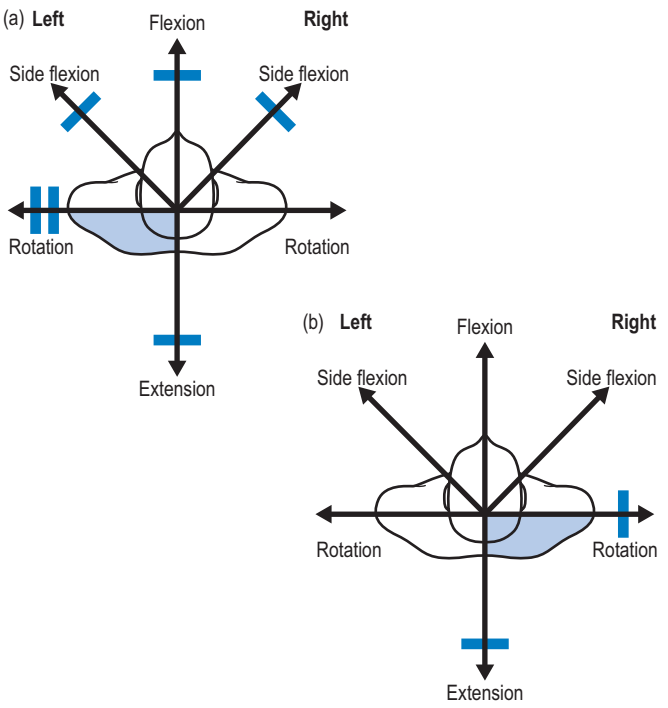

Fig 8.8 • Examples of partial articular patterns in unilateral cervicoscapular pain (colour indicates pain).

protrusion lies, because any disc at any level gives rise to the same symptoms (multisegmental pain) and signs (partial articular pattern). Oscillatory techniques on a sitting or prone lying patient or anteroposterior gliding movements with the patient lying supine may sometimes provoke the pain and give an idea as to the level but this cannot always be relied upon.

Diagnosis

The diagnosis is based on the typical history, together with a partial pattern on examination. The history is that of pain, coming and going in episodes and influenced by particular movements and postures. The pain is of the multisegmental type and spreads over several dermatomes. The asymmetrical pattern of painful movements shows that part of the intervertebral joint is blocked by a displaced fragment of disc, usually annular.

Differential diagnosis

The differential diagnosis includes lesions in the shoulder girdle (e.g. posterior sternoclavicular syndrome, see online chapter *Interpretation of the clinical examination of the shoulder girdle*), in the upper thoracic area (see Ch. 26), internal disorders (e.g. in the heart, lungs or diaphragm, see Ch. 28) and neurological conditions (e.g. long thoracic or spinal accessory neuritis, see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Natural history

In patients under 50, there is a tendency to spontaneous cure in a few weeks. Nevertheless a number of patients are not completely cured and are left with a minor ache between the periods of aggravation.

Treatment

Unilateral pain in the cervicoscapular area is highly suitable for manipulation. Usually a few sessions suffice to restore a full and painless range of movement. The patient must be informed that the disc may move again, however, and that recurrences are not uncommon. Each new attack should be treated in a similar way. However, when there is a tendency to recurrence, prophylactic measures should be taken (i.e. position at work, sleeping position, collar, exercises – see Ch. 13).

See Box 8.3 for a summary of unilateral pain in the neck, trapezius or scapular area.

Unilateral root pain

Root pain as the result of a disc protrusion pressing on the dural investment of a cervical nerve root is quite common. It has an incidence rate of 1/1000 per year with a peak age between 45 and 54. The lesion very seldom occurs in adolescence. In younger patients suffering from cervical root pain, other disorders must be excluded before a disc lesion is considered. Over the age of 60, root pain caused by a discoradicular interaction is also rare, whereas an osteophytic or metastatic compression becomes more likely (Box 8.4).[59]

History

As a rule, the patient has had a history of recurrent bouts of unilateral cervicoscapular pain over the past years. The present symptoms start with the usual scapular pain, but this time they do not resolve spontaneously. On the contrary, one day the scapular pain may have become much worse and strictly unilateral, subsequently shifting to shoulder and arm (Box 8.5). The scapular pain then disappears or diminishes to a degree that it is no longer worthy of mention, whereas pain in the arm increases and remains severe for 1–2 months. The ache is sharp and permanent, and prevents the patient from sleeping. Sometimes the patient can only achieve rest by bringing the arm above the head – a position that relieves tension on the roots but also widens the intervertebral foramen and diminishes the pressure.[60,61] This sign is highly suggestive of a discoradicular conflict, but is unlikely to be present in radiculopathy caused by spondylosis.[62] The arm pain may be accompanied by pins and needles in some fingers, later followed by numbness. In order to make the differential diagnosis with other lesions that provoke paraesthesia, it is vital to collect more information

Box 8.3

Summary of unilateral pain in the neck, trapezius or scapular area

Definition

- An attack of moderate pain in the cervical, trapezial or scapular area as the result of a posterior shift of disc material intermittently compressing the dura mater and resulting in a discodural interaction
- Pain is usually unilateral but may change sides

Onset

- Sudden: annular
- Slow: nuclear

Symptoms

- Articular
  - Pain on movements
- Dural
  - Multisegmental pain reference possible

Signs

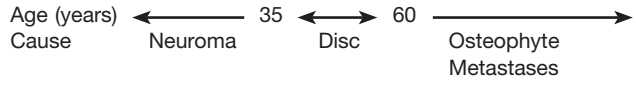
- Moderate or slight partial articular pattern
- Crisp end-feel

Treatment

- Manipulation
- (Traction)
- Prevention

Box 8.4

Cause of root pain according to age



Box 8.5

Discoradicular symptoms and signs

Symptoms	Signs

• Moving pain: scapular pain is replaced by root pain
• Sequence of radicular symptoms:
  • Segmental pain, followed by
  • Localized paraesthesia and
  • Distal numbness
	• Minimal articular sign
	• Neck movements provoke radicular pain/paraesthesia
	• Segmental motor deficit
	• Segmental sensory deficit

about its behaviour: how far proximally does the paraesthesia spread, which fingers and what parts of them are involved, and when precisely are the pins and needles felt? A typical feature is that the paraesthesia has neither edge nor aspect within the fingers. Stroking the skin may provoke or increase pins and needles but moving the digits has no influence. Paraesthesia comes and goes, day or night, in an erratic fashion, appears without any definite reason and does not last for more than an hour at a time. In difficult cases, diagnostic traction may help: if the paraesthesia disappears during manual traction at the head and comes back when traction is released, the cause is clearly cervical.[63] In most cases pain and paraesthesia disappear spontaneously, 6–10 weeks after the onset of the brachial pain. It may take months for the numbness to disappear completely.

Inspection

In very acute cases a pain-avoiding posture may be present: the head is held in side flexion, mostly away from the painful side. Severe root pain may force the patient to keep the arm at the side, well supported by the other hand.

Examination

The patient is asked about the precise location of the pain, which will enable the examiner to determine the dermatome and affected root. However, it is important to mention that the localization of the arm pain is not always a reliable localizing sign. Due to the high incidence of intradural connections between the dorsal rootlets of C5, C6 and C7 segments, there can be overlap between dermatomes, with one dermatome encompassing one or two adjacent segments.[64,65] It may therefore be possible for an individual to have a dermatomal distribution that fails to match the classic pattern precisely. A better pointer to the level of compression is paraesthesia, and therefore, if the patient mentions pins and needles, more details should be sought about their localization.

Articular signs may be present but are not paramount. Usually only a slight partial articular pattern of internal derangement is seen; as the protrusion lies more outside the joint and the articular movements no longer interfere with it, articular signs are less important than root signs. Some active and passive movements may provoke or increase pain in the scapular area. The end-feel is crisp. It is possible, although not at all common, for neck movements to influence the pain and/or the pins and needles down the arm. The Spurling manœuvre (a downwards pressure on an extended and rotated neck) may also elicit radicular pain and paraesthesia.[28] Resisted movements of the head are negative.

At the end of the normal course of the disorder, neck movements become completely painless but the arm still hurts considerably. At this point the best diagnostic clue (apart from the history) is the characteristic pattern of root palsy on examination of the upper limb.

Weakness indicates which nerve root has become compressed. The degree of motor deficit can be very subtle. The examiner should therefore compare both sides carefully.[65] Gross weakness (3+ or 4) is a warning sign, indicating that the lesion is very probably non-discogenic in nature. Cutaneous analgesia is sought at the fingers and the reflexes are tested. An uncomplicated discoradicular interaction does not cause cord signs.

Diagnosis

The history shows the typical evolution of a posterolateral disc displacement: initial attacks of multisegmental cervicoscapular pain, shifting to segmental pain, down the upper limb. As the pain increases, the accompanying symptoms follow a strict chronology:

pain → paraesthesia → numbness → weakness

The examination confirms the history: the combination of a partial articular pattern and positive root signs.

Different root syndromes and their differential diagnosis

The nerve roots most frequently compressed by a disc are, in order of frequency, C7 (56–70%), C6 (19–25%), C5 (2–14%) and C8 (4–10%).[66] Each nerve root lesion, whatever its cause may be, gives rise to pain felt in the skin area corresponding with the segment to which the nerve root belongs. The pain is the result of involvement of the dural sheath surrounding the nerve fibres. When the nerve parenchyma becomes affected too, paraesthesia will be felt down the nerve distribution in the arm. However, variations in the nerve distribution may occur,[67–69] and pain and paraesthesia may be felt in areas which do not totally correspond to one specific dermatome. More involvement of the nerve fibres causes weakness of the muscles belonging to the same segment and cutaneous analgesia in some (mostly the distal) part of the dermatome. One should bear in mind that other (non-neural) soft tissue lesions may lead to exactly the same segmental pain.[70] Therefore resisted tests, undertaken to examine nerve root conduction, also serve to test for alternative causes of pain down the limb.

C1 and C2 nerve roots

The absence of discs at the first two cervical levels implies that nerve root compression by discs cannot occur. Reference of pain to the C1 or C2 dermatomes (headache; Fig. 8.9) does not always mean that C1 or C2 nerve roots are involved; the pain may be multisegmental and the result of compression of the lower cervical dura by a posterocentral disc protrusion.[71,72]

True segmental C1–C2 pain may be found in elderly people and is usually bilateral. It is hypothesized to be the result of arthrosis at the upper cervical joints involving the capsular and ligamentous structures.

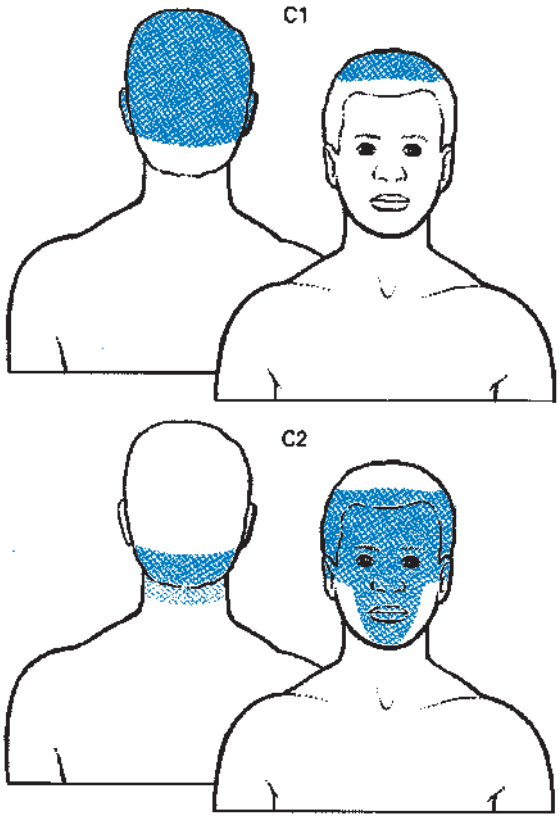


Fig 8.9 • The C1 and C2 dermatomes.

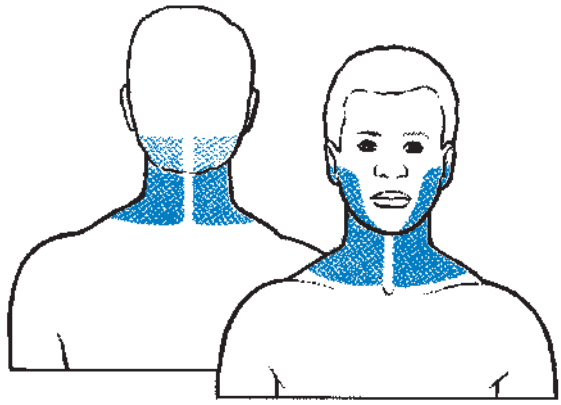

Fig 8.10 • The C3 dermatome.

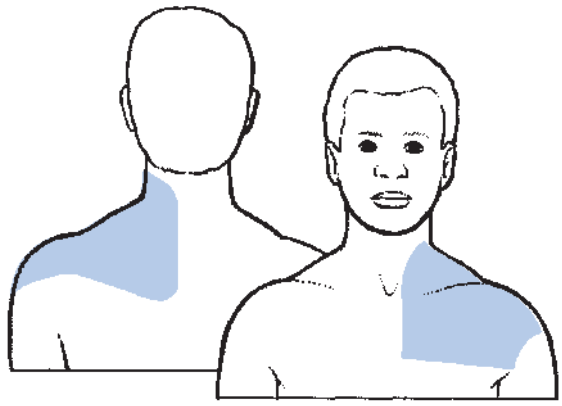

Fig 8.11 • The C4 dermatome.

The C2 spinal nerve has a close proximity to the lateral capsule of the atlantoaxial (C1–2) zygapophyseal joint and innervates the atlantoaxial and C2–3 zygapophyseal joints; therefore, trauma to or pathologic changes around these joints can be a source of referred headache. This occurs especially in elderly patients with gross unilateral arthrosis of the atlantoaxial joint. It causes unilateral deep or dull pain that usually radiates from the occipital to parietal, temporal, frontal and periorbital regions. Ipsilateral eye lacrimation and conjunctival injection are common associated signs.[73] Clinical examination shows a marked full articular pattern in which rotation is especially limited.

C3 nerve root

Compression of the third cervical nerve root by a posterolateral disc displacement is very rare.

Pain is felt at the lateral aspect of the neck and is referred to the occipital and temporal regions and the posterior part of the cheek. Pins and needles or numbness may be present (Fig. 8.10). Weakness is clinically not detectable. Cutaneous analgesia is uncommon, but if it occurs, it occupies any part of the lateral aspect of the neck.

Differential diagnosis. Most C3 pain stems from the C2–3 zygapophyseal joint. This joint and the third occipital nerve appear most vulnerable to trauma from acceleration–deceleration ('whiplash') injuries of the neck.[74] Pain in this region may also result from pressure on the dura mater at any level and is then multisegmental. Heart disease may also give rise to reference of pain in the C3 dermatome. Another possibility is a trigeminal neuritis, which is characterized by paroxysms of severe, lancinating, electric bouts of pain restricted to the distribution of the trigeminal nerve.[75]

C4 nerve root

Discogenic lesions of the fourth cervical nerve root are rare. Pain spreads from the lower half of the neck towards the point of the shoulder (Fig. 8.11). Paraesthesia seems not to occur at this level. In theory, weakness of the trapezius muscle should be found but in practice muscular weakness is not detectable. A horizontal band of cutaneous analgesia may be found along the spine of the scapula, the mid-deltoid area and the clavicle.

Differential diagnosis. It is important to remember that the upper scapular area is very often the site of multisegmental dural pain, resulting from a discodural interaction at any level. Upper scapular pain also occurs in: (a) disorders within the shoulder girdle, e.g. posterior sternoclavicular syndrome or a lesion of the first costotransverse joint; (b) some neurological conditions, e.g. mononeuritis of the long thoracic, spinal accessory or suprascapular nerves; and (c) some pulmonary or visceral disorders, e.g. inflammation of the gallbladder. Pain felt at the shoulder on deep breathing is typical in diaphragmatic pleurisy.

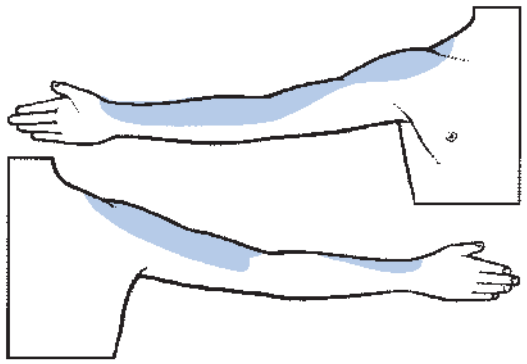

Fig 8.12 • The C5 dermatome.

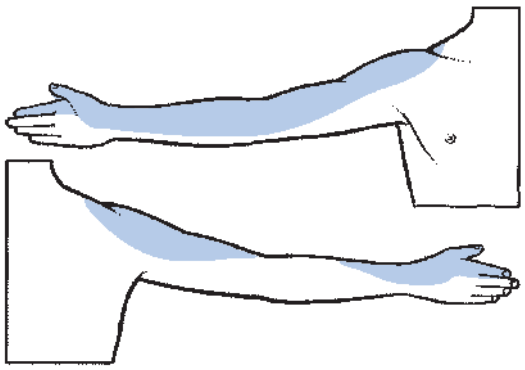

Fig 8.13 • The C6 dermatome.

C5 nerve root

A C5 nerve root involvement is usually not the result of a disc lesion but is often the outcome of either a traction injury or compression by an osteophyte. Traction palsy of the C5 nerve root occurs after an injury that depresses the shoulder girdle and osteophytic palsy caused by encroachment into the fourth intervertebral foramen. Both result in gross weakness of the C5 muscles without pain.

Pain is felt along the lateral aspect of the arm and forearm as far as the base of the thumb (Fig. 8.12). Pins and needles do not seem to occur in C5 nerve root compression.[76] Weakness may be found in supraspinatus, infraspinatus, deltoid and brachial biceps. A C5 sensory palsy from a disc is rare. The biceps jerk may be sluggish or absent; the brachioradialis jerk is sluggish, absent or inverted.

Differential diagnosis. The differential diagnosis (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*) includes some peripheral nerve lesions and all pathology of the shoulder (see Chapters 14 and 15):

- *Axillary nerve palsy after dislocation of the shoulder*: this results in painless weakness and atrophy of the deltoid muscle and consequent weakness of abduction of the shoulder. Rotation movements remain strong.
- *Mononeuritis of the spinal accessory nerve*: there is painless weakness of the trapezius muscle which results in slight limitation of active elevation of the arm.
- *Mononeuritis of the long thoracic nerve*: this presents with painless weakness of the serratus anterior muscle. Active elevation of the arm is grossly limited.
- *Mononeuritis or traumatic palsy of the suprascapular nerve*: there is painless weakness of the infraspinatus (and supraspinatus) muscles.
- *Neuralgic amyotrophy*: this leads to gross weakness in several muscles.
- *Herpes zoster*: there is pain and a typical skin eruption in the C5 dermatome.
- *Shoulder arthritis, supraspinatus tendinitis or infraspinatus tendinitis*: pain down the C5 dermatome can be referred from the joint capsule or from a rotator cuff tendon.
- *Rupture of the supraspinatus muscle*: partial rupture leads to painful weakness and complete rupture to painless weakness of abduction at the shoulder.
- *Rupture of the infraspinatus muscle*: lateral rotation is painful and weak in partial rupture, and weak only in complete rupture.
- *Metastases or fracture in the scapula*: passive mobility of the scapula is limited and the muscles attached to it are weak.
- *Myopathy*: bilateral wasting of the supraspinatus and infraspinatus muscles is suggestive of myopathy. Arthritis from immobilization of the shoulder is then a painful complication.

C6 nerve root

The sixth cervical nerve root can become compressed by the C5 disc or by osteophytic outcrops originating from the uncovertebral joint or from the facet joint.

Pain runs along the anterior aspect of the arm, the volar aspect of the forearm and the radial side of the hand as far as the thumb and index finger (Fig. 8.13). Pins and needles are felt in the thumb and index finger.[77] There is weakness of the biceps, brachialis, supinator brevis and the extensors of the wrist. Sometimes the subscapularis muscle is affected too. Cutaneous analgesia is sometimes detectable at the tips of thumb and index finger. The biceps jerk is sluggish or absent.

Differential diagnosis. The differential diagnosis is from the following disorders:

- *Thoracic outlet syndrome*: nocturnal pins and needles in one or both hands are often a conspicuous feature. Searching for the release phenomenon by scapular testing provides the clue (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Compression of the median nerve in the carpal tunnel*: there are pins and needles in the three and a half radial fingers. The history is indicative (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Palsy of the radial nerve from compression at mid-humerus*: there is paralysis of the extensors of wrist and fingers, together with weakness of supination of the elbow and of extension of the thumb (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Tendinitis or partial rupture of the biceps muscle*: there is pain or painful weakness on resisted flexion of the elbow (see Ch. 15).

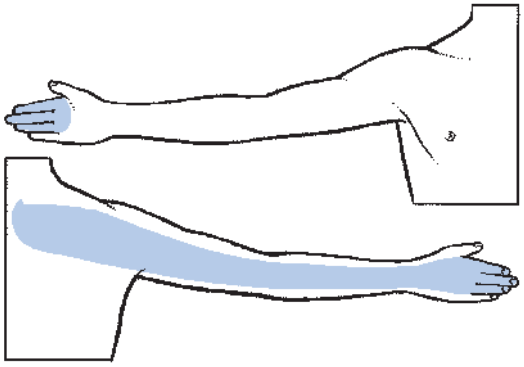

Fig 8.14 • The C7 dermatome.

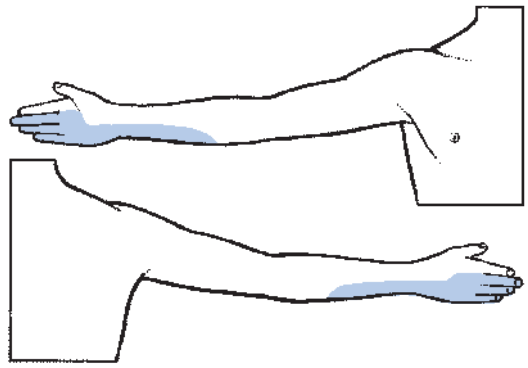

Fig 8.15 • The C8 dermatome.

- *Tennis elbow*: tendinitis at the origin of the extensor carpi radialis brevis may be so acute that the patient often winces and lets the hand go when asked to extend it against resistance (see Ch. 19).

C7 nerve root

Compression of the seventh cervical nerve root by the C6 disc is far more common than compression at any other level.[66]

Pain is felt at the posterior aspect of the arm and the dorsal aspect of the forearm as far as the second, third and fourth fingers (Fig. 8.14). Rarely, pain is experienced at the anterior and upper aspect of the chest and not in the arm. Pins and needles are mostly felt in the index, middle and ring fingers. The most conspicuous feature is weakness of extension of the elbow (triceps muscle). Flexion of the wrist may also be weak (flexor carpi radialis). In severe cases, resisted adduction of the arm is slightly weak and there may even be some visible wasting of the mid-portion of the pectoralis major. The examiner also notices that voluntary elevation of the arm is lacking over the final 5°. In the unusual circumstance of a larger part than usual of the serratus anterior muscle being derived from the C7 segment, winging of the scapula may be seen.[78] Cutaneous analgesia is sought at the dorsal aspect of the index and middle fingers. The triceps jerk is seldom affected, even in quite severe cases.

Differential diagnosis. Differential diagnosis is from the following disorders:

- *Lead poisoning*: one of the first signs is often bilateral weakness of extension of the wrist (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Carcinoma of the bronchus*: this may also lead to bilateral weakness of extension of the wrist.
- *Tennis elbow*: a painful twinge with weakness of extension of the wrist may be found in acute cases (see C6 root).
- *Golfer's elbow*: pain on resisted flexion of the wrist is the primary sign (see Ch. 19).
- *Tendinitis of the triceps muscle*: there is pain on resisted extension of the elbow (see Ch. 19).
- *Fracture of the olecranon*: resisted extension of the elbow is painful and weak but this picture is complicated by articular signs at the elbow joint (see Ch. 18).

C8 nerve root

The eighth cervical nerve root emerges between the seventh cervical and first thoracic vertebrae and can be compressed by the C7 disc.

Pain is felt at the inferior part of the scapular region and the ulnar aspect of the hand, over the middle, ring and little fingers and the ulnar and distal aspect of the forearm (Fig. 8.15). Pins and needles are experienced in the middle, ring and little fingers). The condition is easily confused with ulnar nerve problems ('pseudo ulnar palsy').[79]

Both extensors of the thumb are weak. Other muscles affected are the ulnar deviators of the wrist, the adductor pollicis, the common extensor of the fingers and the abductor indicis. Occasionally the triceps muscle is also slightly weak. Cutaneous analgesia is found at the little finger.

Differential diagnosis. The differential diagnosis includes:

- *Thoracic outlet syndrome*: this may result in pins and needles in the ulnar fingers and sometimes in weakness of the intrinsic muscles of the hand too (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Metastases in the C1 or T1* vertebra: involvement of the C7 and C8 nerve roots at the same time is very suggestive of malignant disease.
- *Angina pectoris*: heart disease should always be considered when pain radiates to the left arm, especially to the ulnar aspect of the hand and forearm.
- *Traction palsy of the lower trunk of the brachial plexus*: this also affects the fibres derived from the C8 nerve root (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Frictional neuritis* of the ulnar nerve at the elbow or pressure on the ulnar nerve at the wrist (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Thrombosis of the subclavian artery*: there is pain in the upper limb and an absent radial pulse.

T1 nerve root

This segment includes the upper limb and is therefore examined with the neck. Compression of the first thoracic nerve root by a T1 disc protrusion is very uncommon and never leads to a palsy.

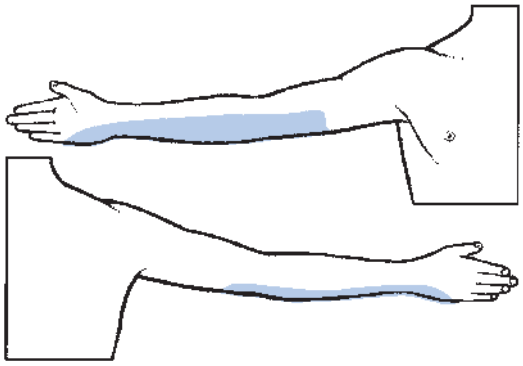

Fig 8.16 • The T1 dermatome.

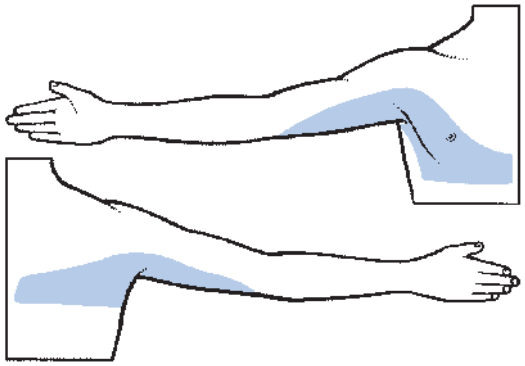

Fig 8.17 • The T2 dermatome.

T1 pain is felt in two distinct sites: the pectoroscapular area and the ulnar aspect of the forearm (Fig. 8.16). The thoracic pain may be influenced by coughing and neck flexion. The T1 root is stretched by a forward movement of the scapulae, and by abducting the arm and flexing the elbow so that the hand comes to lie behind the neck.[80] Pins and needles are felt at the ulnar side of the hand. A T1 palsy is characterized by weakness of the intrinsic hand muscles, but is never caused by a disc lesion. Also, numbness in the T1 area is always the result of a non-discal condition. A first thoracic palsy, together with Horner's syndrome, is one of the main symptoms in Pancoast's tumour[81] and also vertebral metastases may involve the T1 nerve root.

Differential diagnosis. Differential diagnosis of a T1 lesion should be made from the following conditions (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*):

- *Cervical rib*: this may compress the lower trunk of the brachial plexus, which is partly derived from the T1 nerve root.
- *Compression of the median nerve*: in carpal tunnel syndrome, pain may sometimes spread to the forearm. Most of the muscles in the hand that are supplied by the median nerve are also partly derived from the T1 nerve root.
- *Compression of the ulnar nerve*: this may cause pins and needles in the ulnar border of the hand. All the small muscles of the hand that are innervated by the ulnar nerve are also partly derived from the T1 nerve root.
- *Amyotrophic lateral sclerosis*: weakness and atrophy of the small intrinsic muscles of the hand is often one of the first signs of amyotrophic lateral sclerosis.[82]

T2 nerve root

The second thoracic nerve root is examined with the neck because it gives rise to symptoms felt in the upper limb.

A disc lesion at this level is extremely rare. If it does occur, it gives rise to pectoroscapular pain radiating down the inner aspect of the arm as far as the elbow (Fig. 8.17). The pain is influenced by neck flexion, approximation of the scapulae and sometimes stretching of T1.

Natural history

In discoradicular interactions, spontaneous cure is the rule for both pain and neurological deficit.[83] Patients with neurological deficit usually recover in about 3 months, and those without in 4 months, reckoned from the onset of the pain down the arm. The more marked the palsy, the more quickly the pain abates. Muscle strength will almost certainly have returned to normal 3–6 months after the pain ceased. The only exception is the C8 root, which may take 6 months or more to recover. The sensory disturbance recovers very gradually over a year. Mochida *et al* performed follow-up studies, both clinical and with MRI, on 38 patients with lateral cervical disc herniations. All of them were treated with conservative therapy. The authors' conclusion was: 'migrating, lateral-type herniations regress so frequently that conservative treatment should be chosen not only for patients with radicular pain, but also for those with upper limb amyotrophy.'[84]

Treatment

There are a number of approaches to treatment of nerve root problems.

Prophylaxis

Root pain can be avoided when the original cervicoscapular pain is recognized as the early stage of a disc protrusion and treated with manipulative reduction.

Manipulation

This can be tried in patients without neurological deficit and with favourable articular signs (neck movements hurt in the scapular area). Reduction in a few sessions is possible in the first 2 months after the onset of the brachial pain. After this period, the results are poor. Manipulation is almost impossible in patients with unfavourable signs (neck movements hurt down the arm or provoke pins and needles in the hand).

When the root pain has been present for some time or neurological deficit has set in, it is better to explain the mechanism of spontaneous cure to the patient and to wait for it. In the meantime, nerve root blocks are given to control the pain. Unilateral scapular pain and root pain of more than 6 months' standing can often be helped with two or three manipulation sessions. The scapular pain ceases and the mechanism of spontaneous cures is restarted.

Infiltration

In those patients in whom manipulation fails or is no longer indicated, 1–6 infiltrations with 2 mL of a steroid solution at the nerve root may afford considerable relief. Pain and

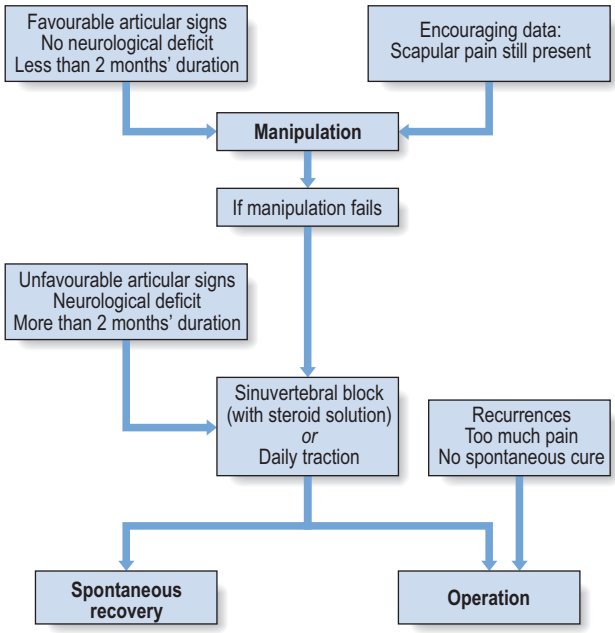

Fig 8.18 • Treatment of cervical nerve root involvement.

Box 8.6

Cervical disc syndromes

Common

- Discodural interactions
  - Acute torticollis – equivalent of acute lumbago
  - Cervicoscapular pain – equivalent of discodural backache
- Discoradicular interaction
  - Cervical root pain – equivalent to sciatica

Less common

- Acute torticollis with central pain and symmetrical picture
- Chronic central cervicoscapular pain

inflammation are diminished during the period of spontaneous healing.[85]

Daily mechanical traction and sometimes wearing a collar for 2–3 weeks may also help to make the pain tolerable.

Surgery

Neck surgery for discoradicular interactions is performed far too often. The condition has such a favourable spontaneous cure rate that surgical intervention should only be considered in exceptional situations: when the condition recurs, when pain is intolerable or when spontaneous cure fails to occur. Furthermore, the long-term results of surgery are no better than when spontaneous cure has been awaited.[86]

Recurrences

These are rare after spontaneous recovery from root pain with neurological deficit but are otherwise not infrequent.

Treatment of cervical root nerve involvement is shown in Figure 8.18. The characteristics of root syndromes in the neck and upper limb are summarized in Figure 8.19.

Summary

These three clinical syndromes are most common (Box 8.6) and may be compared to the three pictures found at the lumbar spine (see chapter 33).

Less common syndromes

The syndromes described in this section are also based on disc lesions that, in contrast to the lumbar spine, may imperil the spinal cord. Cyriax believed that posterocentral disc protrusions may form the first step in the evolution towards spinal stenosis. An unreduced central disc displacement exerts continuous pressure on the posterior longitudinal ligament. The latter draws the periosteum away from the vertebral bone. Bone grows towards the periosteum and osteophytes form. These diminish the anteroposterior diameter of the spinal canal and spinal stenosis syndrome develops (see p. 164).

The clinical pictures that appear during the first stage of this development are still reversible by simple manual techniques. Once bony narrowing of the spinal canal has started, however, reduction is impossible.

Acute torticollis with central pain and a symmetrical picture

History

A young or middle-aged person develops severe central neck pain, either spontaneously or as the result of trauma, usually a whiplash injury. The pain fixes the head in a flexed position. Shortly afterwards, both upper limbs may also become painful with a feeling of weakness. Paraesthesia appears distally in both arms or in all four limbs.

Examination

In acute cases, the neck is usually fixed in flexion, which may be so extreme that the chin touches the sternum, extension being totally impossible. The movement pattern is symmetrical, with both rotations and both lateral flexions equally limited. Active elevation of both arms is painful and sometimes limited. There are no root signs. Cord signs are usually absent, except in extreme cases where pyramidal tract signs may be found.

Diagnosis

Diagnosis rests on the history (sudden onset) and on the clinical examination, which shows an extreme limitation of extension.

Differential diagnosis

Differential diagnosis includes conditions that present with a full articular pattern: for example, fracture of a vertebral body and other bony disorders. A similar pattern with gross limitation of extension is also seen in severe ankylosing spondylitis.

Natural history

This type of torticollis tends to recover spontaneously, although very slowly.

Treatment

Manipulative reduction is the treatment of choice but rotation manœuvres are avoided. The therapist should choose the techniques with great care and perform them very cautiously to avoid further displacement towards the spinal cord or stretching of the posterior longitudinal ligament.

Central or bilateral pain in the neck, trapezius or scapular area

The condition causes central neck pain, with or without bilateral radiation to occiput, trapezii and scapulae, although slow painless development also occurs. Pain is the result of the pressure exerted on the dura mater (Fig. 8.20). Cord symptoms indicate involvement of the spinal cord. Cord signs point to irreversible impairment of conduction. The evolution from pain, through cord symptoms to irreversible cord signs may take several years to develop.

History

Patients are usually middle-aged. They start complaining of central neck ache, which later spreads bilaterally from the occiput to both trapezii. Gradually the pain expands, radiating down to the interscapular area and both scapulae. There may come a time when both upper limbs start to ache. Pain in the arms may alternate: if it is more severe on one side, it is correspondingly less so on the other. By the time the pain has become constant, pins and needles may start, first in both hands, some time later in both feet too. Neck flexion may bring on or increase the pins and needles.

In the middle-aged or elderly patient, the whole process may be entirely painless. It starts with pins and needles in all four limbs: first in both hands, later radiating into the lower limbs, from the front of both knees to the feet. Gradually the gait may become disturbed and weakness appears in both hands.

Examination

Articular signs may be quite inconspicuous. Pain is constant but is not very much influenced by articular movements. If the patient is elderly, a full articular pattern of limitation may be found with a hard, arthrotic end-feel. If any movements are painful, these are usually flexion and extension. As long as the pressure on the spinal cord is not considerable, symptoms alone dominate the presentation and there are no root or cord signs.

Increased compression leads to the manifestation of the clinical syndrome of cervical myelopathy (see p. 165): a positive plantar reflex, incoordination and spasticity of the lower limbs and weakness of the upper limbs.[87]

Diagnosis

The history is very important, especially at the beginning of the process, before cord signs and symptoms have supervened. The patient will probably have had attacks of torticollis or of unilateral cervicoscapular pain in the past. Centralization of the pain as age advances, together with a painless full articular pattern on examination, suggests this type of disc lesion. When involvement of the spinal cord is suggested (multisegmental paraesthesia, gait disturbance), examination becomes decisive.

Differential diagnosis

When central or bilateral pain is present, great care should be taken to make a differential diagnosis from other lesions that may cause similar symptoms: arthrosis, ankylosing spondylitis, rheumatoid arthritis, recent fracture, postconcussional syndrome, and bone disease. In the presence of bilateral paraesthesia, differential diagnosis must be made from sensory stroke and disseminated sclerosis.

Natural history

There is a tendency towards spontaneous cure but regression of the disc protrusion is slow.[88]

Treatment

Posterocentral disc protrusions not compressing the spinal cord can be reduced by manipulation, provided rotatory manipulations are avoided. The manipulation must be performed under sufficient traction and by an experienced therapist. When symptoms and/or signs of spinal cord compression are present, manipulation is strongly contraindicated and surgery is called for.

Degenerative disorders

Arthrosis of the cervical spine is usually referred to as cervical spondylosis or spondylarthrosis. It starts very early in life with disintegration of the disc. The ageing of the cervical disc and the consequences for the surrounding structures have been discussed earlier in this chapter. Degenerative changes in vertebrae and discoligamentous structures are found in 75–90% of people aged over 50.[15,16,89] From middle age on, degeneration is evident on plain X-rays and on MRI in more than 50% of asymptomatic people.[90,91] Therefore, most authors emphasize that there is no consistent correlation between abnormal radiographic appearances and symptoms.[92,93] The conclusion that pain originates from degeneration of the cervical spine is all too often made by looking at imaging alone. The importance of arthrotic changes is overestimated because, in most instances,

the degenerative condition is not painful in itself and leads only to some stiffness. It is the clinician's task to determine the possible relationship between the degenerative changes and the patient's symptom.[94]

Non-symptomatic arthrosis at the cervical spine shows painless limitation of movement in the capsular proportions whereby the movements are merely uncomfortable at the end of range. The end-feel is hard.

Symptomatic cervical spondylosis should be diagnosed purely on clinical grounds, through history and clinical examination. When cervical movements influence the patient's symptoms, the problem clearly lies within the spine but this does not necessarily imply that arthrosis is responsible. Although degeneration is not painful of itself, it can lead to symptomatic conditions such as: ligamentous contracture, overstretching of a facet joint, radicular compression by osteophytes or cervical spinal stenosis. The diagnosis of these lesions should be made on clinical grounds and not on imaging.[95]

Local pain

Pain in the neck, either unilateral or bilateral, and with or without radiation to the head, occurs in degenerative conditions affecting the upper cervical ligamentous complex or the facet joints. This takes place in arthrosis of the upper two cervical joints, in subacute arthritis of the atlantoaxial joint, in facet joint arthrosis or in traumatic osteoarthrosis.

Morning headache in the elderly

'Morning headache' in the elderly is believed to stem from ligamentous contracture at the atlanto-occipital and atlantoaxial complexes. The hypothesis relies on the typical distribution of pain in the C1–C2 dermatomes,[96,97] the leathery end-feel on clinical examination and the uniformly good results with mobilization.

As age advances, increasing pain develops in the C1–C2 dermatomes: the middle of the upper neck and the occiput, the temples and the forehead (C2). Local pain may be totally absent, so that the patient complains of occipitofrontal headache only.[98] The headache is only on waking and happens without fail every morning. After some hours the pain begins to diminish and by midday all symptoms have ceased, only to return the next morning. Later in the course, the pain may last longer into the day.

On examination a full articular pattern is found. The movements are not very painful but merely stiff and uncomfortable. The end-feel is hard but not bone-to-bone; rather it is leathery, showing capsular contracture. Radiography demonstrates a certain degree of arthrosis, normal for the patient's age.

The differential diagnosis is between traumatic arthrosis and postconcussional headache. In both, the history is distinctive (see pp. 164 and 168).

The condition is very easily cured by manipulation: 1–4 sessions of slow capsular stretching make all symptoms disappear. Age is not a contraindication to manipulation but the older the patient, the more gradually the therapist must work: fewer manœuvres are carried out in one session and the interval between the sessions is longer (see Ch. 11 and summary in Box 8.7).

Box 8.7

Morning headache in the elderly

- Headache on waking

- Good response to slow stretching manipulation

Subacute arthritis of the atlantoaxial joint

Subacute arthritis of the atlantoaxial joint is rare. The patient, aged between 25 and 40, develops stiffness and discomfort in the middle of the upper neck, and over the following weeks these symptoms gradually increase. On clinical examination, extension, both side flexions and flexion movements are full and painless. Both rotations are equally painful and very limited – only 10–20% is possible. Even in a supine position, the range remains unchanged. The end-feel is soft. This combination of symptoms and signs is clearly a warning sign but further investigations, such as blood tests and imaging, remain negative. The aetiology remains unclear but the disorder recovers in a couple of months with anti-inflammatory therapy.[99]

Arthrosis of a facet joint

The prevalence of cervical facet joint degeneration is very high in individuals aged 50 years and more, with a tendency to increase in severity with age. Contrary to the lumbar spine, where there is an increase in degeneration towards the lower segments, in the cervical spine all levels of the middle and lower cervical spine are affected to almost the same degree.[100] However, the relation between the high prevalence of radiographic zygapophyseal arthrosis and neck pain is not clear.[101] It is not well understood why arthrosis at a facet joint becomes symptomatic in one person and not in another. Cyriax hypothesized that pain results from the formation of adhesions and a 'self-perpetuating inflammation', which follows overstretching of the arthrotic joint capsule.[20]

Diagnosis of a facet joint lesion is not easy and is always tentative. Some elements from the history and clinical examination may help in differentiating a facet joint lesion from a discodural conflict. In doubtful cases, local infiltration with lidocaine may prove diagnostic.[102]

The pain has a spontaneous onset, is unilateral and does not spread. When the facets are bilaterally affected, the pain is bilateral, sparing the centre of the neck. Dural symptoms are absent. Pain is felt when certain positions have to be maintained for a period of time.

On examination, a partial articular pattern is found: some movements, especially passive ones, hurt. The end-feel is rather hard. The fact that the pain is quite localized and does not radiate indicates the possibility of a facet joint lesion. Troisier[82] distinguishes a 'convergent' and a 'divergent' pattern of painful movements (Figs 8.21 and 8.22). In the first, there is pain on extension and on lateral flexion and rotation towards

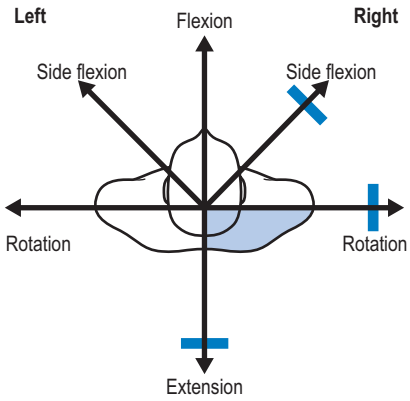

Fig 8.21 • The convergent partial articular pattern in arthrosis at a facet joint (colour indicates pain).

the painful side. In the second, the opposite is found: flexion, lateral flexion and rotation away from the painful side hurt. Such a pattern is compatible with facet joint involvement but does not exclude a discodural interaction. Differentiation between these lesions is always difficult.

This condition responds to deep transverse massage at the joint capsule and slow stretching manipulation. Infiltration with a steroid suspension is an alternative (Box 8.8).

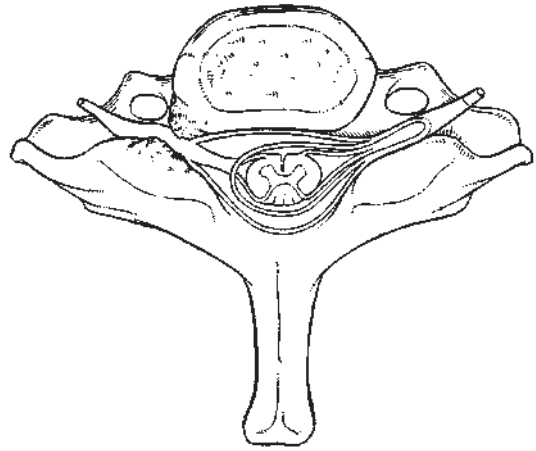

Fig 8.23 • Osteophytic nerve root compression.

Radicular complaints: osteophytic root compression

A nerve root can become compressed by osteophytes and bony spurs in the neural foramen. The root normally occupies about one-third of the space in the foramen and is accompanied by radicular arteries and veins. The spinal nerve root is vulnerable to compression, anteriorly by an osteophyte derived from the uncovertebral joint and posteriorly by one originating from the facet joints, or from both (Fig. 8.23). These phenomena are secondary to degeneration of the intervertebral disc, with subsequent dehydration and collapse. This disintegration causes increased mechanical stress at the uncovertebral joints and the facet joints, leading to the formation of subperiosteal bone and osteophytic outgrowth, and finally resulting in narrowing of the intervertebral foramen and encroachment of the nerve.[103,104]

Symptoms of osteophytic radiculopathy usually develop insidiously, but are sometimes triggered by trauma. The patient is over 50 and complains of paraesthesia and weakness in the arm, sometimes pain. Contrary to a disc that causes radicular pain, in osteophytic root compression there is or was not much pain in the neck or scapular area, merely some stiffness. Also the root pain is very moderate, though it may be present for several months. The main complaints are paraesthesia in the arm or fingers and a gradually increasing weakness of the arm.

On examination, a full but painless articular pattern with a hard end-feel is found, indicating arthrosis. If any movement does hurt, it is usually side flexion towards the affected side, and a twinge may travel down the arm. Alternatively, waves of paraesthesia may be felt in the distal part of the relevant dermatome and are clearly the result of the osteophyte being pushed against the nerve root. The Spurling manœuvre (a downward pressure on an extended and rotated neck) may also elicit radicular pain and paraesthesia.[28] Isometric testing of the upper limb shows segmental weakness. The most frequent localization is C4–C5. A combination of higher uncinate process, smaller anteroposterior diameter of the intervertebral foramen, and a longer course of the nerve root in close proximity to the uncovertebral joint may explain the predilection of

Table 8.2 Differential diagnosis between discal and osteophytic root compression

	Disc	Osteophyte
History	>35 years of age	Elderly: >50 years of age
	Shifting pain (scapula > arm)	Arm pain
	Typical evolution	No evolution
	Intense pain	Slight pain
	Pain > weakness	Weakness > pain
Examination	Partial articular pattern	Full articular pattern
		Compression pain
	Subtle weakness	Serious weakness
	C7 root	C5 root

nerve root compression at this level.[105,106] The C5 nerve root thus becomes compressed, identified by the difficulty or sometimes even inability to bring the arm up. In severe cases, the deltoid may become wasted.[107]

The differential diagnosis is from root compression by a disc protrusion or by a neuroma or metastases, and can usually be made on a clinical basis (Table 8.2). The osteophyte grows slowly and lies quite far laterally so that it does not exert pressure on the dural investment of the nerve root. Therefore intense pain, as would occur in a discoradicular interaction, is seldom present. The patient complains mainly of paraesthesia and of a progressive weakness of the upper limb developing over the course of a few months. Nerve root compression by a disc protrusion is characterized by a definite chronology: a period of bouts of multisegmental pain, referred to the scapular area, is followed by the occurrence of segmental pain, followed by segmental paraesthesia and often moderate neurological deficit of the muscles belonging to the same segment. The condition undergoes spontaneous cure in 2–3 months. A neuroma usually starts in the opposite way: distal paraesthesia first, followed by pain that starts distally and spreads in a proximal direction. Root pain due to a neuroma typically occurs in younger people, while root pain from a disc lesion occurs more frequently in the middle-aged. A tumour or metastasis leading to root compression usually has a quicker progression than an osteophyte. Further differential diagnosis includes all the upper limb entrapment syndromes and neuralgic amyotrophy (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

The diagnosis can be confirmed by radiography. Anteroposterior and oblique views show the encroachment. The uncovertebral osteophytes are best seen on an anterior view and the posterior osteophytes on an oblique one. Computed tomography (CT) is often used to complement radiography because it provides superior imaging of bone and better defines the anatomy and size of the neural foramen.[108] When the clinical diagnosis of an osteophytic root palsy has been made and the X-ray confirms its presence, the diagnosis is clear. Nevertheless, it should be borne in mind that the prevalence of asymptomatic osteophytes is very high. Therefore, the clinical examination is decisive.

Manipulation is, of course, contraindicated. Two infiltrations of triamcinolone suspension around the nerve root – nerve root block – at an interval of 2 weeks may be tried. It alleviates the inflammation at the level of the compressed nerve root, so that the pressure diminishes.[109,110] The discomfort disappears but the anatomical situation has not changed. When there is gross muscular weakness or weakness has a tendency to increase, surgical treatment is indicated. During the last few decades, a minimally invasive posterior cervical foraminotomy technique has been developed[111] that is highly effective and results in long-lasting pain relief.[112]

Box 8.9

The mushroom phenomenon

- Elderly patient
- Increasing pain in any position, except lying
- Diminution of symptoms under traction
- Full articular pattern
- Radiographic evidence

Compression phenomenon: the mushroom phenomenon

This phenomenon is extensively described in later chapters on the thoracic and lumbar spine (see Chs 27 and 35) and is summarized in Box 8.9. A cervical mushroom phenomenon is very rare. It occurs in advanced degeneration of the disc, which displaces mainly in the anterior and anterolateral directions. The intervertebral space becomes so narrow that the vertebral bodies lie in apposition. This phenomenon, together with folding of the posterior longitudinal ligament and enlargement of the arthrotic facet joints, can cause considerable narrowing of the spinal canal and the lateral recess, which may result in compression of dura or nerve root during axial loading.

An elderly patient will state that there are no symptoms as long as recumbency is maintained: in that position the head can be moved easily in every direction without any problems. However, on standing or sitting for a certain amount of time, vague, central and bilateral pain in the neck develops and spreads to both arms and hands. All symptoms disappear when traction is applied or the head lifted upwards with the hands. On examination, a full articular pattern is found: painless limitation of movement with a hard end-feel. There are no radicular signs and no cord signs; consequently the diagnosis rests mainly on the history. A radiograph shows severe arthrosis with gross narrowing of the intervertebral space.

The patient can be helped either by a weight-relieving collar or by surgery (arthrodesis).

Cervical spondylotic myelopathy

Cervical spinal myelopathy (CSM) is defined as spinal cord dysfunction, secondary to intrinsic compression from degenerative disease of the cervical spine. It is the most common cause of spinal cord dysfunction in patients who are aged over 55.[113] The presence of a congenitally narrow spinal canal is a critical predisposing factor in patients with spondylotic

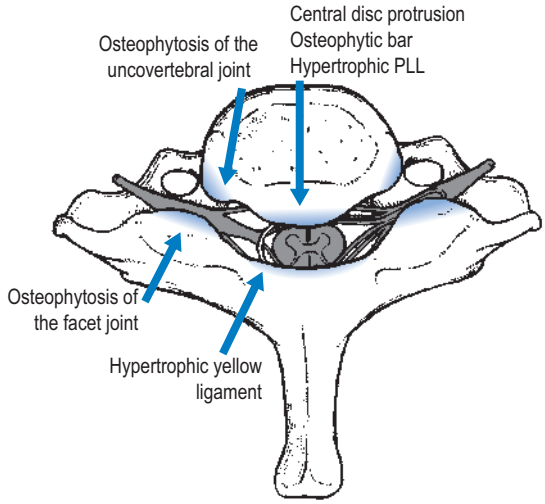

Fig 8.24 • Mechanical factors involved in cervical spondylotic myelopathy (coronal section). PLL, posterior longitudinal ligament.

myelopathy.[114] The anteroposterior diameter of the cervical spinal cord is 10 mm on average and normally the sagittal diameter of the spinal canal averages ± 18 mm. It is therefore generally accepted that a spinal canal with a diameter between 10 and 13 mm is at risk and can only sustain a narrowing of 2–4 mm before developing myelopathy.[115,116]

Pathogenesis

Symptoms of myelopathy occur in a wide variety of combinations. In its most severe form the clinical presentation is a spastic gait. There may be atrophy, sensory disturbance and spasticity in the hands. Sometimes impairment of sphincter function also occurs.[117] The variable clinical picture reflects the many complex factors that may affect the spinal cord. The primary pathophysiologic abnormality is a reduced sagittal diameter of the spinal canal. In that narrowed canal, two different mechanisms – a mechanical and a vascular one – can cause pathological changes in the spinal cord. White and Panjabi[118] divide the mechanical factors involved in the pathogenesis of CSM into two groups: static and dynamic. Static factors include the well-known arthrotic changes that narrow the canal: a spondylotic bar anteriorly, degenerative osteophytosis of the uncovertebral joints and facet joints laterally, and hypertrophic ligamenta flava posteriorly (Fig. 8.24).[119,120] Dynamic factors are abnormal forces placed on the spinal column and spinal cord during flexion and extension. Diminution of the diameter of the spinal canal occurs during extension (because of folding of the posterior longitudinal ligament and of the yellow ligament[121]) and during flexion (the spinal cord is pulled against the osteophytes).[122] Also degenerative cervical spondylolisthesis may cause excessive movement.[123,124] During extension, backward gliding of the vertebrae, in combination with folding of the posterior ligaments, may result in cervical cord encroachment (the pincer effect) (see Fig. 8.24).[125]

Another mechanical theory is that CSM is caused by tensile stresses transmitted to the spinal cord from the dura via the dentate ligaments.[126] A spondylotic bar pushes the spinal cord posteriorly, but this displacement is resisted by the dentate ligaments that are anchored by the dural root sleeves in the lateral foramen.[127] This theory could explain the neuropathological findings in CSM where damage to the spinal cord is most severe at the lateral columns, and in them the involved areas are often wedge-shaped, with the apex medial and the base lateral.[128]

Other authors consider spinal cord ischaemia to be a major cause of CSM, either through compression of the anterior spinal artery and its branches in the spinal cord, or through the radicular arteries in the intervertebral foramina. This vascular theory is not widely accepted and most believe that a combination of both mechanical and vascular causes has to be considered (Box 8.10).[129,130]

Box 8.10

    - Compression during flexion and extension
    - Traction via the dentate ligaments
- Vascular factors
  - Ischaemia of the anterior spinal artery
  - Ischaemia of the radicular arteries

Diagnosis

CSM usually develops insidiously, although episodes of abrupt deterioration can occur.

Symptoms

A subtle gait disturbance is usually the first and most common presentation.[131] Although CSM can cause a variety of signs and symptoms, spastic gait occurs first, followed by upper extremity numbness and clumsiness. There is loss of fine motor control of the hands and difficulty in writing. Surprisingly, neck pain is not as common a symptom as one might expect, maybe because some pain and stiffness is accepted as normal for the person's age.

After some years, when the situation gets worse, patients develop a typical 'spastic gait' that is broad-based, hesitant and jerky. This gait is one of the main characteristics of cervical myelopathy. Nurick has classified CSM largely on the basis of gait abnormality – typically the most common clinical concern of the patient (Table 8.3).[132]

There are also sensory changes in the lower extremities, which the patient typically describes as 'walking on cotton wool'. Bowel and bladder dysfunction may supervene; according to Epstein *et al*, 20% of patients with CMS over the age of 65 have bladder dysfunction, mostly associated with urinary retention.[133]

Table 8.3 Nurick's classification of disability in spondylotic myelopathy

Grade	Symptoms and signs
0	Root symptoms and signs No evidence of cord involvement
I	Signs of cord involvement Normal gait
II	Mild gait impairment Able to be employed
III	Gait abnormality prevents employment
IV	Able to ambulate only with assistance
V	Chair-bound or bedridden

Signs

Examination of the neck is usually not very painful but reveals a gross full articular pattern of limitation with a hard end-feel, suggesting severe arthrosis. Flexion and extension may elicit electric shock sensations in the extremities (Lhermitte's sign[134]), which is present in about one-quarter of myelopathic patients.[135,136]

Neurological examination

Compression of the spinal cord typically leads to 'upper motor neurone' findings distal to the level of compression (i.e. spasticity, hyperreflexia, clonus, positive Babinski and Hoffmann signs). These often occur in combination with 'lower motor neurone' findings at the level of compression (e.g. weakness, hyporeflexia and atrophy). For example, in a lesion at C4 level, with compression of both C5 nerve roots and of the spinal cord at that level, everything above C5 is normal. C5 shows weakness of abduction and external rotation of the shoulder and some weakness of flexion of the elbow. There is no spasticity and the biceps jerk is sluggish or absent. Below C5 there is spasticity, with clonus and hyperreflexia: an exaggerated triceps jerk and clonus at the patella and the ankle.

Other functional tests can be performed and, when positive, are very suggestive of CSM, though none of these tests in itself has pathognomonic value. Ono *et al*, for instance, observed a characteristic abnormality in the hands of patients with CSM. There was inability to extend the ulnar two or three fingers, despite the relatively well-preserved function of the wrist, thumb and index finger. Rapid extension of the fingers was impossible, even in patients with less advanced disease.[137] Also Hoffman's sign is very often positive. The sign is described as follows.[138] The pronated hand is supported so that it is completely relaxed and the fingers partially flexed. The middle finger is firmly grasped and partially extended, and the nail is flicked by the examiner's thumbnail. The flicking should be done with considerable force. The sign is present if quick flexion of both the thumb and the index finger results. A positive sign is highly indicative of possible pyramidal tract pathology.[139] Shimizu *et al* described the scapulohumeral reflex, which is positive in more than 95% of patients with high cervical cord compression.[140] The scapulohumeral reflex is elicited by tapping the tip of the spine of the scapula and acromion in a caudal direction and is positive when elevation of the scapula or abduction of the humerus is seen. The reflex centre of the scapulohumeral reflex is clinically presumed to be located between the posterior arch of C1 and the caudal edge of the body of C3. A hyperactive scapulohumeral reflex therefore provides useful information about dysfunction of the upper motor neurones cranial to the level of the C3 vertebral body. As the disease develops, Babinski's sign and its variants, Chaddock (stimulation below the external malleolus causes extension of the great toe) and Oppenheim (stroking down the medial side of the tibia causes extension of the great toe), become positive.[141]

In addition, sensory disturbances are very often present. There may be loss of contralateral pain and temperature sensation because of compression of the spinothalamic tract. The neurological level is several segments below the area of compression. Ipsilateral proprioception and vibration sense may be disturbed as a result of a lesion of the posterior columns. Dermatomal sensation (appreciation of light touch as well as tactile discrimination in pinprick tests) can be affected by a dorsal nerve root compression.

Differential diagnosis

The differential diagnosis of CSM is not easy. It is important to exclude both multiple sclerosis and upper motor neurone disease (amyotrophic lateral sclerosis), as their presentations are very similar to that of CSM.[142] A thorough neurological examination is therefore necessary. Most importantly, CSM does not affect the cranial nerves or the normal jaw reflex, whereas the other two disorders may. Other disorders in the differential diagnosis include spinal tumours, cerebrovascular disorders that cause spastic hemiplegia and peripheral neuropathy.

Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis (ALS) is a disorder of the anterior horn cells and of the pyramidal tract (first motor neurone).[143] The disease starts between the ages of 40 and 70 in one (commonly upper) limb and advances progressively to the contralateral upper and later the lower limbs. Depending on the localization in the upper or lower motor neurone, spastic or weak paralysis will predominate. The classic triad is atrophic weakness of the hand and forearm muscles, minor spasticity of the legs and generalized hyperreflexia, but without sensory changes; as a pure motor neurone disease ALS does not affect sensation. A diagnosis of ALS is further favoured if there are muscular fasciculations in the face, tongue or lower extremities. The diagnosis is supported by typical findings on electromyography (EMG).[144]

Multiple sclerosis

Multiple sclerosis (MS) is a chronic inflammatory disease of the central nervous system with the morphological hallmarks of inflammation, demyelination, axonal loss and gliosis. The spinal form of MS in particular may mimic the clinical course of CSM: there is a generalized spastic paralysis and clonus, and the patient also experiences paraesthesia. However, the patient is younger – the average age of onset is 30 years. Diagnosis relies on EMG findings, typical appearances on MRI[145] and cerebrospinal fluid analysis.

Radiographic studies

In the past, the radiological diagnosis of CSM was dependent on radiography, myelography, CT and CT myelography. More recently, MRI has proven to be the most valuable tool, not only to depict anatomically how the spinal cord is compressed, but also to demonstrate the pathologic changes in the spinal cord.[146] Takahashi *et al* described the MRI findings of intramedullary high signal intensity (SI) on T2-weighted MR images in CSM. They include oedema, ischaemia, demyelination, gliosis and cavities.[147]

Natural history

The natural history seems to be one of static neurological deficit or episodic progression. The course is quite variable. Often, symptoms are mild and do not progress. Such cases are best treated conservatively with a cervical collar and physical therapy. However, once clinical CSM is evident, progression may occur despite the best of treatments. Elderly patients often experience faster progression of symptoms and more serious neurological impairment.[148] It was found that those who deteriorated were more likely to be female and to have significantly more cervical mobility when compared to those patients whose disability remained static. It is proposed that measurement of cervical mobility may help to select patients who are more likely to deteriorate and thus more likely to benefit from surgical intervention.[149]

Treatment

Minimal symptoms without hard evidence of gait disturbance or pathologic reflexes warrant non-operative treatment, but surgery should be recommended to arrest progression of myelopathic symptoms in patients whose general condition is satisfactory.[150] Both anterior and posterior approaches have been utilized for surgical treatment of cervical myelopathy. Anterior decompression frequently requires corpectomy at one or more levels and strut grafting with bone from the ilium or fibula. Multilevel laminectomies were initially used for posterior decompression but now are either combined with fusion or replaced by laminoplasty.[151]

Prognosis is good when the diagnosis is made early in the course but poor in late diagnosis, when myelopathy has become more severe. It is therefore important to operate on patients with CSM as early as possible before neurological deficits are too pronounced.

Patients who are treated by surgery seem to have fair outcomes. The progression of myelopathy is arrested in about 95% and the improvement rate of the gait is estimated to be around 51–85%.[152,153]

Some recommend preventive decompression surgery in individuals who have spondylotic encroachment on the cervical spinal cord without clinical signs and symptoms of myelopathy. The reasoning is that these patients are at increased risk of spinal cord injury if they experience minor trauma. A recent meta-analysis of the literature, however, concluded that there is insufficient evidence for an increased risk and that recommendations for preventive decompression surgery cannot be made.[154]

The characteristics of CSM are shown in Box 8.11.

Box 8.11

Summary of cervical spondylotic myelopathy

Definition

- Spinal cord dysfunction, secondary to intrinsic compression from degeneration of the cervical spine

Onset

- >55 years

Pathogenesis

- Narrowed canal: developmental
- Static factors
- Dynamic factors

Symptoms

- Spastic gait
- Clumsy hands
- Sensation of walking on cotton wool
- Sphincter dysfunction

Signs

- Upper limbs: lower motor neurone signs
- Lower limbs: upper motor neurone signs

Differential diagnosis

- Amyotrophic lateral sclerosis
- Multiple sclerosis
- Spinal tumours
- Cerebrovascular disorders

MRI

Treatment

- Surgery

Capsuloligamentous disorders

Capsuloligamentous disorders of the cervical spine are sometimes described under the heading 'postconcussional syndrome'. This is a term used to describe the occipital headache and/or upper cervical pain that remain after a concussion which may have sprained the upper cervical ligaments and, less often, the muscles. The pain is believed to be caused by ligamentous adhesion formations.

However, the diagnosis is often tentative and, as the patient is very often claiming compensation, the examiner has to take into account the possibility of neurosis or aggravation. Careful history taking and clinical examination should enable the examiner to come to a precise diagnosis. When the patient presents a history with inconsistencies or unlikely combinations of findings and this is followed by an examination during which the signs do not correspond, the patient is probably confabulating. However, when adhesions in the occipito-atlantoaxial ligaments are responsible, the picture is one of pain at the extremes of extension, both rotations and both lateral flexions.

The condition can easily be treated by mobilization. One to three sessions of quick stretch manipulations break the adhesions, after which all symptoms should disappear.

Disorders causing pain on resisted movements of the neck

Musculotendinous lesions

The presence of a clear contractile tissue pattern is suggestive of a musculotendinous lesion but this is not common in the region of the neck. Only two conditions are rarely encountered: a lesion of the semispinalis or splenius capitis muscle and a lesion of the longus colli muscle, so-called retropharyngeal tendinitis.

Lesions of the semispinalis or splenius capitis muscle

It is understandable that a patient who has had an accident severe enough to cause concussion may also suffer from musculotendinous lesions in the suboccipital muscles. This is infrequent but after recovery from concussion the patient may be left with unilateral or bilateral occipital pain, sometimes radiating to the head. In most instances, a lesion of the occipital muscles does not occur in isolation but in combination with a lesion of the occipito-atlantoaxial ligaments.

On examination, resisted movements are positive. In unilateral pain, resisted extension and resisted side flexion towards the painful side are both painful. In bilateral cases, resisted extension and resisted flexion to both sides may be positive. Palpation shows the lesion to lie at the insertion of the semispinalis capitis muscle, rarely at that of the splenius capitis.

Treatment consists of two or three sessions of deep transverse massage. In more chronic cases, up to 6 weeks' treatment may be required.

Lesion of the longus colli muscle (retropharyngeal tendinitis)

Retropharyngeal calcific tendonitis, also known as acute calcific prevertebral tendinitis, is a clinical syndrome that was described originally by Hartley in 1964,[155] and was later demonstrated to be secondary to calcium hydroxyapatite deposition in the longus colli muscle.[156] This muscle is a paired neck flexor that comprises the prevertebral space (Fig. 8.25). Classically, calcification affects the superior oblique portion of the longus colli muscle at the C1–C2 level (Fig. 8.26). The condition affects adults within a reported age range of 21–81 years, with its greatest distribution between 30 and 60 years. The incidence of this condition is rare, although its true incidence is probably higher than previously thought.[157]

The history and clinical examination are very characteristic. The patient quite suddenly develops a severe, bilateral pain occupying the whole head and neck area and can hardly move the head. Swallowing is very painful and hurts so much that the head is held with both hands. The pain is felt not in the throat, but in the neck. There is no fever. After a few days the pain diminishes, and disappears completely after a few weeks.

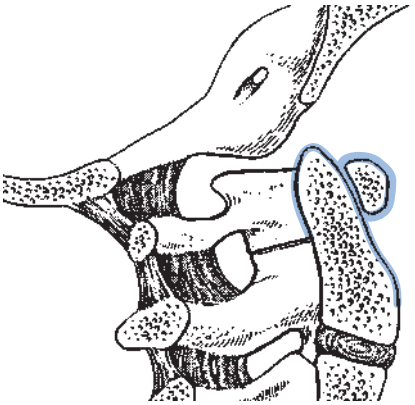

Fig 8.25 • The superior oblique fibres of the longus colli muscles are involved in acute calcific prevertebral tendinitis.

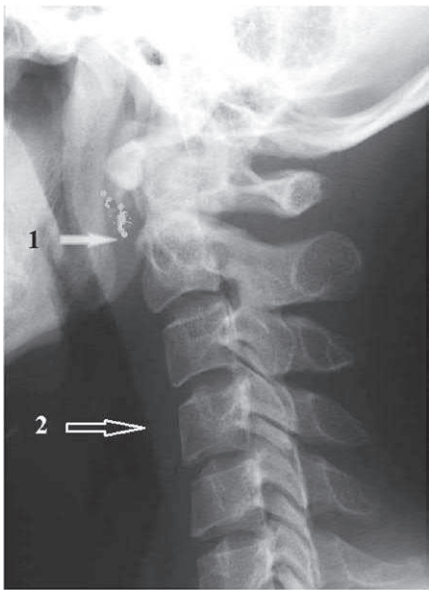

Fig 8.26 • Retropharyngeal tendinitis: localization of the calcium deposits. Arrow 1 indicates amorphous calcification anterior to C2. Arrow 2 indicates swelling of the retropharyngeal space.

On examination a full articular pattern of limitation of movement is found on active testing. Passive movements show a different pattern: when they are done gently, flexion and both side flexions can be performed to full range; extension and both rotations remain very limited and the end-feel is spastic. Resisted rotations and resisted flexion are painful.

The lateral radiograph shows swelling of the retropharyngeal space and amorphous calcification anterior to C1–C2. The thickening of the shadow thrown by the longus colli muscles is such that it increases from the usual 3 mm to 10 or 15 mm.

CT shows the pathognomonic tendinous calcifications within the longus colli and can also demonstrate sterile fluid smoothly expanding the retropharyngeal space.[158] In the presence of a fluid collection, the possibility of infection must be considered, specifically abscess from lymphadenitis.[159]

The differential diagnosis includes traumatic fracture/dislocation of the vertebra, retropharyngeal abscess, meningitis and infectious spondylodiscitis.

Treatment consists of rest and administration of oral non-steroidal anti-inflammatory drugs for 1–2 weeks. The condition undergoes spontaneous cure in 2–3 weeks; pain eases, motion returns, and swelling and calcification disappear almost simultaneously.

Serious disorders

Resisted movements of the neck may be painful and/or weak in more serious conditions, because the muscular contraction pulls at an affected structure (i.e. bone) or squeezes a tender structure (i.e. inflamed lymph glands or abscess). This combination of signs has to be considered a warning sign. The possible conditions are:

- Vertebral metastases
- Fracture of the first rib
- Fracture of the spinous process of C7 or T1
- Wedge fracture of a vertebral body
- Glandular fever
- Retropharyngeal abscess
- Postconcussional syndrome
- Lesion of the sternoclavicular joint (see the online section *The shoulder girdle*).

Disorders causing symptoms on active and/or resisted shrugging of the shoulders

Examination of the shoulder girdle is part of the scan examination of the cervical spine. Some conditions in the scapular area and shoulder girdle may provoke positive signs during this examination. These lesions are extensively discussed in the online section *The shoulder girdle*. They are:

- Lesion of the costocoracoid fascia
- Lesion of the sternoclavicular joint
- Lesion of the first costotransverse joint
- Lesion of the conoid/trapezoid ligament
- Lesion of the subclavian muscle
- Lesion of the levator scapulae muscle
- Thoracic outlet syndrome
- Upper lung disorder (warning sign).

Non-mechanical disorders: warning signs

9

CHAPTER CONTENTS

Warning signs 171
Warning signs disclosed by the history 171
Warning signs disclosed by the functional examination 172
Pathology: see the online content

Most cervical spine syndromes are activity-related or mechanical. They result from disc lesions and/or degeneration of the spine. Syndromes that are not activity-related are called non-mechanical disorders. They stem from inflammatory diseases, tumours and metabolic disorders. Though they can influence mobility, they are intrinsic diseases of the cervical structures and do not have a mechanical origin.

Warning signs

Mechanical lesions of the cervical spine usually demonstrate very typical behaviour. They present with so-called 'inherent likelihoods' – the sequence of symptoms and signs that make up the clinical picture of a certain pathological disorder and that are likely to be found. Hence, when symptoms and signs come forward during the clinical assessment which show rather unlikely behaviour, examiners should be on their guard. Such symptoms and signs are called 'warning' signs. The examiner should consider them as the hallmark of a (serious) non-mechanical disorder until there is proof to the contrary. An unusual disorder is immediately suspected and further complementary investigations (blood tests, radiography, CT scan, bone scan, MRI) should be requested.

Warning signs disclosed by the history

Gradually increasing pain

Mechanical lesions tend to present with acute pain, as episodic pain that comes and goes in a rather irregular way, or as a constant, unchanged pain over a considerable length of time. Sometimes with a disc lesion, pain gradually increases over a short period of time, after which it remains unaltered for a certain period and then diminishes again. If, in contrast, the intensity of the pain increases progressively over a couple of weeks, then a serious lesion is likely.

Expanding pain

Pain typically changes location with a disc lesion. In a discodural conflict the pain moves within the zone of multisegmental reference, and when the conflict becomes discoradicular it shifts from the neck or scapular area to the arm. In other words, it shifts from one area to another. In the case of expanding pain, however, the evolution is different: for example, the pain starts in the centre of the neck, then becomes bilateral and spreads to the scapular area, and may finally radiate down one upper limb or both limbs. Another possibility is pain that develops in one dermatome and gradually spreads beyond its borders into other dermatomes. Increasing scapular pain together with an increase of brachial pain is also suspect. Pain that expands very often indicates a lesion that expands (a tumour or metastasis).

First-time neck pain in an elderly person

A middle-aged or elderly patient who, for the first time in life, complains of neck pain or who describes rapidly increasing pain and neck stiffness, coming on in the course of 1 or 2 months, should be suspected of having malignancy in the cervical spine.

Bilateral arm pain

A discal lesion seldom causes pain in both arms. Either the disorder is discodural, causing bilateral cervicoscapular pain, or there is a discoradicular conflict, in which case pain will be felt in one arm only. A disc displacement that is large enough to cause pain in both arms would certainly also threaten the spinal cord. Other possibilities are: large osteophytes at one particular level and other bony lesions of the cervical spine. Bilateral arm pain is therefore a warning sign for a serious disorder.

Arm pain in a person younger than 30

Root pain as the result of pressure by an ordinary cervical disc is very rare in people under the age of 30. Therefore, if there is evidence of radicular pain and the patient is younger than 30, another cause has to be sought.

Arm pain lasting longer than 6 months

Most lateral disc protrusions tend to resolve spontaneously. For lumbar disc lesions this may take up to 12 months (see Ch. 33). For cervical disc protrusions causing discoradicular pain, the process is faster and most protrusions will have disappeared after 2–4 months, depending on the size of the protrusion (the larger the protrusion, the faster it fades).[1] Therefore, if the pain lasts longer than 4 months, it is unlikely that an ordinary discoradicular lesion is responsible and another cause should be sought.

Wrong time sequence

The symptoms that result from discoradicular root pain follow a typical timeline. Initially there is cervicoscapular pain that later moves distally to become strictly segmental pain. Other symptoms follow: first pins and needles and later numbness. When the reverse is true – root pain starting distally and later moving proximally, or distal paraesthesia occurring before the root pain starts – examiners should again be on their guard because this time sequence makes a discal problem very unlikely.

Warning signs disclosed by the functional examination

Full articular pattern

A full but painless articular pattern with a hard end-feel is normal in elderly patients, and results from the normal degeneration of the cervical spine. However, a full articular pattern that is painful and has a more spastic end-feel points to a serious disorder and warrants further investigation.

Muscle spasm on passive movements

Muscle spasm is a defence mechanism. It is an involuntary muscular contraction that stops the passive movement, thereby protecting the cervical spine against further painful and possibly harmful movement. The muscles contract with a sudden vibrant twang, even when the movement is performed gently. This phenomenon is typical of very acute conditions, like acute arthritis or fractures, and never occurs in ordinary disc lesions; therefore it is always suspicious.

Resisted movements of the neck that are painful and weak

Resisted movements may be painful in acute discal conditions but are never weak. If an attempt to contract the muscles against the examiner's resistance is immediately stopped because it is too painful, full strength is not perceived and the movement is thus interpreted as being weak. This is always a sign of a serious disorder. Painful weakness is mainly caused by a pull on bony lesions (tumours and metastases).

Side flexion away from the painful side as the only painful movement

As mentioned earlier, this partial articular pattern is always suspicious and suggests a costoscapuloclavicular lesion (see online section *The shoulder girdle*) or a visceral lesion in the upper part of the thorax: the apex of the lung or mediastinum.

Limited scapular elevation

Limitation of active elevation alone is extremely rare. In theory, it could result from a C4 palsy or from a spinal accessory palsy, but in practice this is not detected. Limitation of both active and passive elevation of the scapula points to a lesion of the shoulder girdle and not to a cervical lesion. When this sign is found, the examiner should perform a more thorough examination of the shoulder girdle and upper thorax.

Horner's syndrome

This syndrome is caused by an interruption of the sympathetic nerve supply to the eye and is characterized by the classic triad of miosis (constricted pupil), partial ptosis, and loss of hemifacial sweating (anhidrosis). Horner's syndrome may result from several nervous conditions: a lesion of the primary neurone, a brainstem stroke or trauma to the brachial plexus. When the syndrome is accompanied by cervicoscapular pain, the cause is involvement of the cervical sympathetic ganglia at the base of the neck that results from a tumour of the lung apex (e.g. Pancoast)[2] or a dissecting carotid aneurysm.[3]

Hoarse voice

Paralysis of the vocal cords gives rise to typical hoarseness (when a lot of air is released). The cause may be local lesions or involvement of the recurrent laryngeal nerve by an invasive lesion in the neck or upper thorax (bronchial and oesophageal carcinoma, malignancy of the mediastinal lymph nodes and aortic aneurysm).

T1 palsy

Palsy of the first thoracic nerve root leads to atrophy and weakness of the intrinsic hand muscles. The palsy is never caused by a disc lesion. Therefore, the detection of weakness in the

adduction movement of the little finger is always a sign that must be taken seriously. It is one of the first signs of amyotrophic lateral sclerosis, but is also often present in the initial stages of cervical spondylotic myelopathy and in brachial plexus lesions.

Excessive loss of power

Root compression as the result of a protruded disc results in a slight muscular paresis (stage 1 or 2). When more extensive paralysis is found, the condition is, by definition, serious.

Involvement of two or three nerve roots

Unlike in the lumbar spine, root syndromes resulting from cervical discoradicular lesions are always monoradicular. It may be, however, that a radicular weakness does not precisely match the classic pattern. This is somewhat exceptional and is explained by intradural connections between the ventral rootlets of C5, C6 and C7 segments. So it is possible for an individual to have some overlap between myotomes, with one myotome encompassing one or two adjacent segments.[4] It may also be possible to have two disc lesions at two (consecutive) levels at the same time. These situations are rare, however, and therefore, when there is involvement of two or more nerve roots, a more serious lesion should be assumed until there is proof to the contrary.

Muscular weakness in the absence of root pain

In a discoradicular interaction, segmental pain is one of the most striking features and results from a compressed and inflamed dural nerve root sleeve. It is only when the compression continues and increases that paraesthesia and neurological deficit will also follow. For a parenchymatous lesion to develop in the nerve root that is large enough to cause neurological damage, there must have been considerable pressure and pain. Silent radicular weakness therefore means that the cause of the damage is not acute external pressure from a protruded disc.

Warning signs and symptoms are summarized in Box 9.1.

Box 9.1

Warning signs and symptoms

Warning symptoms	Warning signs
• Gradually increasing pain • Expanding pain • First time neck pain in an elderly person • Bilateral arm pain • Arm pain in a person younger than 30 • Arm pain lasting longer than 6 months • Wrong time sequence	• Full articular pattern • Muscle spasm on passive movements • Resisted movements of the neck that are painful and weak • Side flexion away from the painful side as the only painful movement • Limited scapular elevation • Horner's syndrome • Hoarse voice • T1 palsy • Excessive loss of power • Involvement of two or three nerve roots • Muscular weakness in the absence of root pain

Warning signs and imaging techniques

It is the clinical approach that suggests serious disorders. If history and/or clinical examination show one or more warning signs, the examiner should consider the disorder as a serious, non-mechanical disorder until there is proof to the contrary. The presence of a normal X-ray or computed tomographic scan is not always a guarantee of the absence of a serious lesion; nor is the presence of degeneration, bulging discs or herniated discs proof of a symptomatic mechanical lesion.

Previous accounts used different terms – whiplash injury, hyperextension injury, acceleration injury, soft tissue neck injury, cervical strain, cervical sprain – to describe the lesion that may occur after and the consequences of a typical car accident: a rear-end motor vehicle collision.

When a vehicle is struck from the rear, the occupants rarely have any warning and do not brace the muscles to prevent head movement. As a result, the body is propelled forwards and the neck hyperextends backwards well beyond the normal range of allowable movement (Fig. 10.1). This violent motion is followed by a less rapid forwards recoil into flexion that can often result in a head injury if the head impinges on the windscreen.

Although rear-end impacts are most common and result in hyperextension–hyperflexion injuries, other types of car accident may also cause whiplash-type injuries and, in any trauma, complex head and neck movements may occur, leading to different lesions that resemble whiplash.

Definition

Medical literature, in an attempt to find a proper definition, has so far described 'whiplash injury' in terms of the mechanism of the accident, the type of lesion that is caused or the clinical appearance after the injury. In 1995[1] the Quebec Task Force (QTF) proposed the following definition:

> Whiplash is an acceleration–deceleration mechanism of energy transfer to the neck. It may result from rear-end or side-impact motor vehicle collisions but can also occur during diving or other mishaps. The impact may result in bony or soft tissue injuries (whiplash injury), which in turn may lead to a variety of clinical manifestations (whiplash-associated disorders).

The term 'whiplash-associated disorders' (WAD) indicates the clinical features that result from an accident in which two elements – acceleration, followed by deceleration – are responsible for the traumatic forces that act on the cervical spine and related structures.

Incidence

As the result of increases in availability and use of cars worldwide, motor vehicle accidents have become very frequent with, as a result, an enormous increase in whiplash-type trauma. It is one of the most common mechanisms of injury to the cervical spine.

© Copyright 2013 Elsevier, Ltd. All rights reserved.

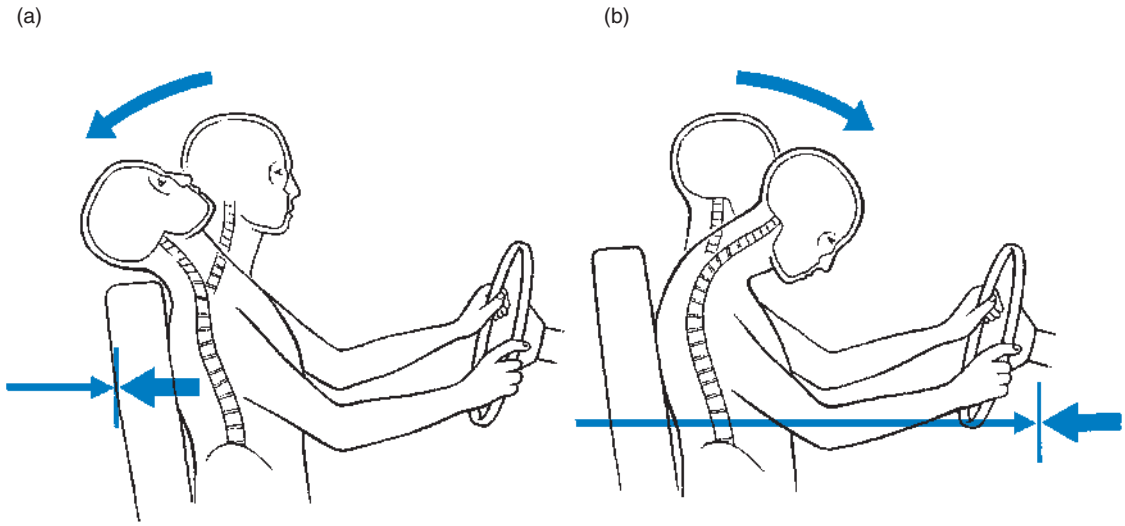

Fig 10.1 • Whiplash injury: (a) hyperextension on impact, followed by (b) recoil into flexion.

The incidence is not precisely known. A figure of 1 per 1000 people per year has been suggested.[2]

The QTF mentions figures on whiplash injuries in Canada. In 1987 in the province of Quebec there were approximately 131 whiplash injuries per 100 000 vehicles per year – 70 injuries per 100 000 inhabitants. This cost the Canadian government CAN $19 000 000, of which 70% was income compensation. The female : male ratio is about 1.5 : 1 and the main age group 20–24 years.

Other studies in Canada mention 5000 whiplash cases a year in the province of Quebec, accounting for 20% of all insurance claims after motor vehicle accidents.[3,4]

In the United States 11 300 000 car accidents were reported for the year 1991, of which 2 690 000 were rear-end collisions and caused 85% of all whiplash injuries.[5]

Classification

The QTF, persuaded that proper diagnosis is difficult to achieve, has proposed two classifications: one according to the severity of the symptoms and signs (grades) (Box 10.1) and one according to the time elapsed since the accident (stages) (Box 10.2).

Neither classification suggests what lesion is present nor stipulates the type of tissue damage. They reflect only the clinical appearances that occur after acceleration–deceleration injury.

Pathology

Depending on the movement of the head during the accident, several lesions may occur, ranking from severe to moderate to slight. Hyperextension is the most common mechanism, followed by hyperflexion and lateral flexion.[6]

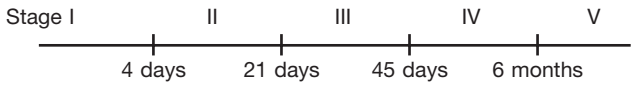
Box 10.1

Clinical (Quebec) classification of whiplash-associated disorders

Grade	Clinical presentation
0	No neck complaint No physical sign(s)
I	Neck complaint involving pain, stiffness or tenderness only No physical sign(s)
II	Neck complaint AND Musculoskeletal sign(s)
III	Neck complaint AND Neurological sign(s)
IV	Neck complaint AND Fracture or dislocation

Box 10.2

Classification according to the time elapsed since the accident



Severe lesions

Hyperextension and distraction of the neck may rupture the anterior longitudinal ligament as well as some discs. A ruptured disc can lead to backward displacement of the vertebra lying

above it – the upper facets then slide downwards on the lower – with damage to the spinal cord as a result.[7] Spinal cord injuries after motor vehicle accidents occur most often in young car users in the 15–24 year age group.[8,9]

Pure hyperextension may also cause compression of the spinal cord in those cases in which retrolisthesis or spinal stenosis already existed. In other instances, compression fractures of the posterior elements may occur.

Hyperflexion injury may lead to fractures of the vertebral body – most fractures of the atlas[10] and of the axis[11] are the result of motor vehicle accidents – and/or to disruption of posterior ligaments and occasionally facet joint luxation.

Less frequently, lesions of arteries, veins, neural structures, oesophagus and retropharyngeal tissues may occur.

Other lesions

Less severe lesions are much more frequent and may involve the intervertebral discs, the zygapophyseal joints, and the cervical ligaments and muscles. These lesions may occur in isolation but are more often combined and therefore are sometimes difficult to recognize. The common complaint is neck pain.

Discodural and discoradicular interactions

Recent retrospective studies have shown that the occurrence of disc lesions after whiplash injury is quite high[12,13] and one prospective study indicates the value of clinical diagnosis.[14] Most disc lesions are endplate avulsions and ruptures of the anterior annulus fibrosus.

As the result of the hyperextension element during the trauma the disc may have fissured. The subsequent flexion or hyperflexion element causes displacement of disc material in a posterior direction. Davis *et al* describe a number of posterolateral disc lesions with radicular symptoms as the result of a hyperextension whiplash trauma.[12] These herniations seemed to develop only after the acute phase and it took a few weeks for the radicular symptoms to appear. In postmortem studies Taylor *et al* describe the intervertebral disc as the most frequently damaged structure.[15–17] Jónsson *et al*[18] Also confirmed the large number of disc lesions after whiplash, and during surgery were able to confirm the findings from magnetic resonance imaging (MRI).

Posterocentral protrusions lead to central, bilateral or unilateral pain in a multisegmental distribution: pain in the neck, trapezius and upper scapular area. On examination a symmetrical (mimicking a full articular pattern) or asymmetrical pattern of limitation is found. In acute cases the picture may be torticollis-like. For a detailed description of disc pathology, see page 145.

Facet joint problems

Whiplash may also lead to problems at the level of the zygapophyseal joint capsules.[19] Lord *et al* undertook a placebo-controlled prevalence study after whiplash and found that chronic cervical facet joint pain was common.[20]

Pain is felt unilaterally and is usually quite localized. A convergent or divergent motion pattern may occur, although any asymmetrical pattern is compatible. (Facet joint pathology is discussed on p. 163).

Ligamentous lesions

Ligaments can become overstretched, leading to minor lesions,[12] or may become adherent as the result of post-traumatic immobilization. They present with vague stretching pain felt at the end of range of those movements that stretch the ligament (see p. 168).

Muscular lesions

Muscular lesions, mostly anteriorly, are described in clinical studies,[21,22] on echography,[23] in experiments in animals[24,25] and in postmortem studies.[26] Muscles, particularly their occipital insertions, can be strained during injury. The subsequent pain will be quite localized and can be elicited during either contraction or stretching – the contractile tissue pattern (see p. 169).

Medicolegal consequences

As WAD automatically involve compensation claims, they have considerable consequences. If a significant number of patients remain with some disability – and this number still seems to be increasing – the costs of diagnosis, treatment and indemnity become progressively higher.

The different parties involved in the approach to WAD are:

- The patient who is seeking help and a refund of money. For most patients the two elements do not influence each other but for a number of people the compensation claim is essential. This may result in absence from work, illness behaviour, social disability, malingering and fraud.
- Doctors who are looking for a diagnosis. Physicians treating the patient wish to reach a diagnosis and to confirm it with technical investigations. They also – because of the often-complex nature of the syndrome – use an extensive pattern of treatment techniques. Doctors who work for the insurance company are sometimes biased and tend to over-diagnose the condition as 'psychogenic' or 'simulation'.
- Insurance companies who are trying to minimize their payments. As the result of the lack of consensus about diagnosis and treatment of WAD, insurance companies see their compensation payments and indemnities rise considerably. They exert pressure on governments in order to keep these expenses under control.
- Lawyers who are protecting either the insurance company or the patient. Discussions about confirmation of the lesions and the consequences for patients' professional activities lead to an increase in litigation.

It is clear that eligibility for compensation for pain and suffering furthers the perseverance of symptoms and a tendency to

chronicity. Where this compensation can be eliminated, a decrease in incidence and an improved prognosis are seen.[27]

Psychological problems

Most WAD start as an ordinary trauma followed by purely physical disturbance. When subsequent treatment is unable to rehabilitate the patient after a short period of time, secondary emotional and psychological changes may supervene. They raise the patient's awareness of neck pain and subsequently aggravate and perpetuate the pain, or even turn a simple neckache into chronic pain and disability.[28]

Diagnosis

Clinical picture

Making a diagnosis in patients who have undergone a whiplash-type injury is no different from other patient groups. It requires proper history taking, inspection and careful functional examination, including a neurological evaluation.

Severe lesions should be recognized and the patient immediately treated as necessary. Most of these conditions are classified as grade IV and fall outside the scope of this book. They will probably be recognized clinically when warning signs are present but certainly be detected by performing the necessary technical investigations: radiography, computed tomography (CT), scintigraphy and/or MRI.

Technical investigations in post-traumatic neck patients are mandatory but the decision as to which imaging technique to use should be based on clinical grounds. Radiographs in patients with soft tissue injuries are often negative: no fractures or luxations are found. The finding most commonly obtained is loss of the normal cervical curvature on a lateral view.[29] CT and MRI are not very helpful in recent cases but may become important when the condition persists, although their use is still controversial. Scintigraphy may be useful to screen for occult fractures.[30]

The reader is referred to the section on non-discogenic disorders (see Ch. 9) for further information about the diagnosis of non-mechanical conditions.

In most cases the condition is *not severe* and clinical examination initially suggests some of the above-mentioned conditions, although the picture may sometimes be vague and difficult to interpret.

Diagnostic difficulties

Most patients present a genuine clinical pattern. The symptoms and signs are clear and not too difficult to interpret. Some patients give a more diffuse picture, probably because there is a combination of lesions. The examiner should then concentrate on the features that are understood and compatible with a known syndrome.

Most difficult are those patients who exaggerate or simulate their symptoms. They pretend to have problems in the hope of persuading the examiner or of making people believe their story. The examiner should look for inherent unlikely details and inconsistencies in the history and functional examination, which will enable a positive diagnosis of 'psychogenic pain' or 'malingering' to be made.

Symptoms

Immediately after the accident the patient is stunned and confused, and complains mainly of any head problem that is present. A feeling of discomfort in the neck, often associated with some degree of nausea, may develop. Although not usually reported, up to 60% of patients have evidence of concussion with momentary loss of consciousness. Examination in a hospital emergency department may not reveal any positive signs and discharge follows. In the following hours and days, a cluster of symptoms may then develop: soreness, tenderness and swelling in the anterior neck region, stiffness and restriction of movement at the neck, headache, visual and auditory disturbances, dizziness, concentration and memory disturbances, pain in the upper thorax, scapular area, shoulder and arms, and numbness or paraesthesia in the upper limbs, accompanied by a feeling of heaviness and weakness. Most symptoms gradually disappear but the majority of patients are left with pain in the neck, radiating to the scapular area or to the shoulder region.

The examiner should enquire about the mechanism and velocity of the trauma so that a judgement can be made about the severity of the injury and so that a prognosis can be reached.[31] Other important information relates to the time interval between the accident and the onset of symptoms, which often is 2–3 days.[32] Many patients have associated low back pain[33] and this is noted and assessed later.

Important information can be obtained by asking the patient to describe exactly the localization of the symptoms: central or bilateral symptoms suggest a condition lying at the midline, whereas unilateral symptoms may stem from either a central or a unilateral condition.

The examiner also concentrates on the inherent likelihood of a certain type of lesion: for example, multisegmental pain in disc lesions, segmental pain in facet lesions, and local pain in muscular lesions. When a patient continuously presents inconsistencies or an improbable combination of symptoms and this is later confirmed during the functional examination, examiners should be on their guard.

Signs

Inspection of the position of the patient's neck may indicate an acute condition: for example, when a torticollis-like picture is found or when muscle spasm is present.

When the head is fixed in flexion with central or bilateral pain, a posterocentral disc displacement is clearly present.

Articular signs – pain on movement with or without limitation – suggest involvement of the intervertebral joint or the facet joints, certainly when movement is shown to be restricted. Discodural or discoradicular interactions are considered when articular signs are accompanied by dural or radicular signs (see p. 145). When there is no dural or nerve root involvement, the possibility of a condition involving the facet joint exists; the pain is purely unilateral, i.e. when either a convergent or a divergent pattern is found. Limitation of movement indicates that the joints are responsible.

End-range pain is typical of ligamentous or muscular conditions, the latter also giving rise to positive resisted movements (see p. 169).

Because combined lesions are not at all uncommon, the clinical picture may become difficult and therefore hard to interpret. It should be looked at in the light of the anatomical findings and compared to the clinical pictures known to occur in the cervical spine (see Ch. 8).

Natural history

The natural history of WAD is difficult to predict. An extensive study in Switzerland found that 30% of patients still complained of symptoms, even 4–7 years after the accident.[34] Another study showed that increasing age and the severity of the initial neck pain were predictors of lasting symptoms after 6 months.[35] Objective neurological signs and degenerative changes on radiographs or MRI (spondylosis, diminution of the diameter of the spinal canal) may be associated with a poor prognosis.

In 30–40% the condition needs up to 1 year to recover, ache diminishing quite considerably in the first 2 months. The pain usually disappears but, when no treatment is given, movements may remain restricted.

Chronicity

Not all patients will develop chronic symptoms after whiplash injury. In most instances it is a benign, self-limiting condition. All patients destined to recover will do so in the first 2–3 months after trauma. Those who do not may claim symptoms for several more years. Recent studies have indicated that between 14 and 42% of patients develop chronic symptoms and that about 10% have permanent difficulties,[36–42] although patients may improve even after many years.[43] A predisposing factor for chronicity could be pre-existing spondylosis.[44]

The QTF study clearly demonstrates that the most common whiplash injury – without bony or cord lesions – is essentially a benign and self-limiting condition. A small number of patients are refractory and responsible for the enormous costs incurred by the injury: about 50% of all costs are spent on an eighth of the total number of victims.

Of the 1 000 000 whiplash injuries per year in the USA, the majority of patients become asymptomatic after a limited number of weeks or months. According to certain statistics, 20–40% continue to have invalidaty symptoms for several years.

In those countries where the entity of 'chronic pain' resulting from rear-end collisions is not known and consequently there is no fear of long-term disability leading to indemnity and litigation, symptoms after whiplash injury are self-limiting, lasting for only a short period of time, and there is no evolution towards the chronic stage.[45]

Therapeutic approach

There is still some discussion about how to approach patients with lasting symptoms from WAD. It is difficult to find objective signs and physicians are therefore divided into two groups: those who believe the patients and those who think in terms of psychogenic pain, personality and chronicity because of concerns about financial compensation.

There is some consensus about the possibility of encouraging the patient to develop an active and positive attitude towards the problem. In those patients who do not present with intensive neck pain immediately following the accident, who do not show clinical signs of cord or root compression and in whom routine radiographs show no bony abnormalities, all further extensive and expensive examinations should be avoided.

Patients should be encouraged to remain active and functional. In the acute phase analgesics and anti-inflammatories should be administered but only temporarily. A collar should not be used for more than a few days and should be replaced by early mobilization of the cervical spine. The patient should be taught how to perform active movements, and prolonged physiotherapy must be avoided in order not to push the patient into a passive disabled attitude.

Such an approach is also recommended by the QTF in order to avoid prolonged disability.[46] An early return to work is advocated as one of the best measures to avoid chronicity. Immobilizing measures such as bed rest and collars are best avoided.

Specific treatment

In those cases where the diagnosis is clear, the condition must be treated properly along with the lesion.

When a discal pattern is found and thus a discodural or discoradicular interaction is present, manipulation is performed immediately because it is unwise to leave the displacement untreated; posterocentral protrusions draw out osteophytes fairly quickly, and this may lead to a situation in which extension or one rotation becomes permanently blocked. Because a posterocentral protrusion is present, great care must be taken in the choice of techniques and operation; rotation movements are avoided and the therapist must be experienced. In acute cases with gross deviation, manipulation is performed every day. Traction in the direction of the deviation, followed by pure traction manipulations without articular movement, quickly leads to full recovery. The more moderate and long-standing cases require more treatments, performed once or twice a week over a few weeks. The techniques for posterocentral

protrusions are used: straight pull, lateral flexion, anteroposterior gliding and traction with leverage (see p. 201).

Facet joint lesions can be treated either with steroid infiltration or with deep transverse massage; in more chronic cases slow stretching is used (see p. 201).

Ligamentous lesions are best treated with deep transverse massage, unless there are adhesions which can be manipulatively broken. Muscular lesions respond to deep transverse friction or infiltration with local anaesthetic. If a combination of ligament and muscle damage exists, the muscle should be treated first.

Proper treatment and re-examination on a regular basis are the guarantees of a maximal therapeutic result.

Treatment of non-discogenic lesions . . . 201
- Manipulation/capsular stretching . . . 201
- Deep transverse friction . . . 202
- Injection/infiltration . . . 203

Before treatment of any kind is undertaken, a correct diagnosis should be made and indications and contraindications carefully considered.

Most discodural and discoradicular interactions are approached by either manipulation or traction. Prophylactic measures may then help to avoid recurrence. In non-reducible discoradicular lesions, nerve root blocks or epidural injections can be used or surgery may prove necessary. Simply waiting for spontaneous cure may also be an option. Non-discogenic disorders may respond to mobilization, manipulation or deep transverse massage. On occasion infiltration and partial immobilization may be required and in exceptional cases surgery is called for.

Treatment of discodural and discoradicular interactions

The purpose of treatment in these disorders is to stop the conflict between the displaced discal fragment and the involved sensitive structure. Because the disc displacement not only affects the dura mater or the nerve root but also disturbs the function of the intervertebral joint, it is logical to try to influence the disc first. Reducible discs can be managed by manipulation or continuous traction, the choice depending on the nature of the displacement: annular displacements are treated by manipulation, nuclear ones by traction. In those instances where, for some reason, reduction has become impossible, measures are taken to sedate the pain during the period of spontaneous recovery. Surgery is called for when the pain becomes intolerable or when a posterocentral protrusion threatens the spinal cord.

Manipulation

Controversy

Manipulation of the cervical spine has become very controversial and its popularity depends on the school of thought of the practitioner. In more orthodox medicine, manipulation as a treatment for spinal conditions is hardly ever used. At the other end of the spectrum are chiropractors whose main treatment is chiefly manipulative. Osteopathy, the McKenzie school and manual therapy are somewhat in between these extremes. Also Cyriax placed his method somewhere in the middle, using manipulation in some well-defined instances – about half of all mechanical spinal conditions – and avoiding it in all the rest.

In light of numerous reports of complications after manipulation of the cervical spine (see below), different schools have

© Copyright 2013 Elsevier, Ltd. All rights reserved.

published in their own class of journal, and manipulation is either defended or rejected as a useful therapeutic measure. Different schools sometimes have totally opposing approaches to the many spinal disorders and arrive at different diagnoses. They then adapt their treatment to what they think is the cause of the symptoms and may therefore manipulate for different reasons. Osteopaths and manual therapists use manipulative techniques to restore range in vertebral segments where they have found loss of mobility; chiropractors try to readjust the spine to correct a perceived misalignment between vertebrae; in Cyriax's orthopaedic medicine and in the McKenzie approach, manipulation is used to eliminate an internal derangement caused by a disc displacement.

Cervical manipulations can cause severe neurologic complications, which are both exceedingly rare and generally unpredictable.[1] More than 200 cases of more or less serious complications after manipulative treatment of the neck have been reported,[2] but it is suggested that they are probably under-reported.[3,4] Many authors have therefore become very cautious in accepting the suitability of this modality. The main arguments against manipulation are the possible hazards to the vertebrobasilar system and the spinal cord that are usually irreversible.[5–10] Therapists who are familiar with manipulative techniques continue to use them because they consider the risks to be minimal. However, such conclusions can only be made after comparative scientific studies have proven that the benefits of manipulation outweigh the risks.

Dangers of manipulation

Treatment decisions cannot be based on effectiveness data alone. Another important factor is safety, obviously. Weighing the risks of spinal manipulation against its benefits is therefore an exercise that should be done constantly. Every act in medicine, whether diagnostic or therapeutic, carries a risk of complications; an injection may result in an anaphylactic reaction, the use of anti-inflammatory agents may cause internal bleeding, and surgical procedures may lead to other, serious complications. It cannot be denied that spinal manipulation too, particularly when performed on the upper spine, is sometimes associated with adverse effects, which are usually mild to moderate. However, serious complications, such as vertebral artery dissection followed by stroke or death, myelopathy and epidural haematoma, have also been described. Mild side effects are very common. Surveys have shown that between one-quarter and one-half of all patients reported at least one post-manipulative reaction. The most common were headache, stiffness, local discomfort and fatigue.[11,12] Most of these reactions began within 4 hours and generally disappeared within 24 hours of receiving spinal manipulation.[13] The frequency of serious adverse events is difficult to estimate, but according to several publications it varies between 5 strokes/100 000 manipulations to 1.46 serious adverse events/10 000 000 manipulations and 2.68 deaths/10 000 000 manipulations.[14–18]

The complication that is feared the most is dissection of the vertebral artery, leading to infarction of the brain, cerebellum or brainstem, so-called Wallenberg's syndrome (see online chapter *Headache and vertigo of cervical origin*).

Vertebral artery dissection

Arterial dissection is an uncommon vascular wall condition that typically involves a tear at some point in the artery lining and the formation of an intimal flap, which allows blood to penetrate into the muscular portion of the vessel wall. Blood flowing between the layers of the torn blood vessel then causes the layers to separate from each other, resulting in arterial narrowing or even complete obstruction of the lumen.

Furthermore, pulsatile pressure damages the muscular layer, resulting in a further splitting or dissection, extending in the direction of blood flow.[19] The accrued blood soon develops into a thrombus and deforms the intima, pushing it into the arterial lumen. Blood flow in the cervical arteries can be obstructed either directly by the haematoma or indirectly by the detached emboli that move distally and obstruct the progressively smaller vessels in the brain, resulting in a stroke (Fig. 11.1).[20]

The cervical arteries are innervated with pain-sensitive nerve fibres that may generate neck pain and headache when provoked. Several studies have shown that pain is typically the first symptom associated with vertebral artery dissection (VAD), and a recent study reported that 8% of the patients presented with head or neck pain as their only symptom.[21] Pain related to VAD frequently occurs suddenly and is of severe intensity, involving mostly the ipsilateral occipitocervical area. These symptoms may or may not be followed by ischaemic involvement in the brain, cerebellum or brainstem. The interval of time between the initial pain of VAD and the ischaemic symptoms is quite variable, with reports ranging from almost immediately to several weeks.

Although the pathophysiology of a dissecting vertebral artery is well understood, the underlying cause of intimal tears remains uncertain. Most experts link VAD to trauma of varying

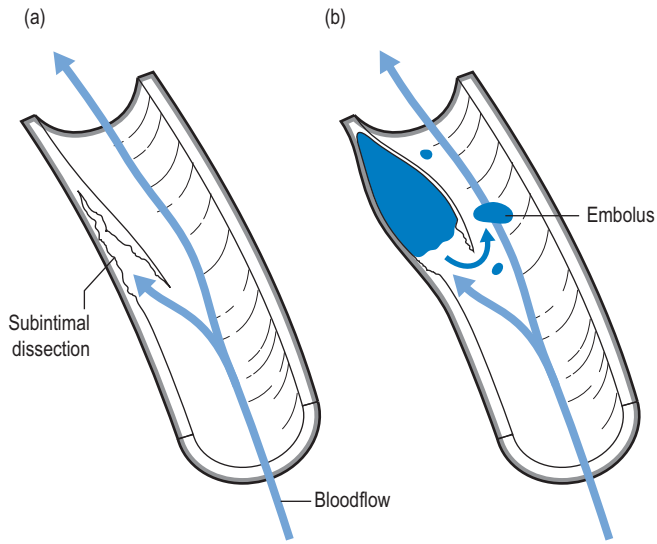

Fig 11.1 • (a) An initial tear in the artery lining allows blood to penetrate into the muscular portion of the vessel wall and causes the layers to separate from each other, forming a subintimal dissection. (b) A thrombus is formed and emboli may detach and travel distally to obstruct progressively smaller vessels in the brain.

degrees of severity and maintain that, because tearing occurs, previous trauma was necessarily involved.[22] A retrospective analysis of 80 patients with vertebrobasilar ischaemia determined to be caused by frank neck trauma reported that 70 of the cases were related to motor vehicle accidents.[23] However, VADs more commonly occur after very minor trauma and even after everyday activities that most people would consider to be non-traumatic. Examples of such trivial 'trauma' include countless everyday activities that involve head and neck movement, such as reversing a vehicle, coughing, vomiting, unusual sleeping positions, having one's hair washed at a beauty salon, and rhythmic movement of the head and neck to music.[24–26] One article listed 68 activities that have been implicated in the development of VAD.[27] Another article reviewing 606 cases of VAD reported that 371 or 61% were spontaneous. The remaining 39% were associated with trivial or other trauma, which included manipulation in 9% of the total number of cases.[28]

So far it remains unclear what the exact precipitating cause of the development of a VAD might be. Given that many VADs are not related to trauma or even abrupt head movements, one must wonder whether a clear cause-and-effect relationship can be established in cases that involve mechanical triggers. It has been suggested that a mechanical trigger is only one of multiple components and that an underlying arterial abnormality is the predisposing factor to dissection.[29,30] This opinion is based on several observations: first, many VADs are not related to trauma and simply occur spontaneously; second, VAD patients frequently have coexisting physiological abnormalities, such as hypertension, recent infection, migraine headache and several others; third, the average person is exposed to trivial events involving the neck on a daily basis, yet most people do not develop VAD.

For the individual therapist who wants to exclude potential disasters, it is extremely important to determine the group of patients at risk and the kinds of manœuvre that are dangerous. Judging from the existing literature, it seems that at this time, neither is possible. Cerebrovascular accidents after manipulation appear to be unpredictable and should be considered an inherent, idiosyncratic and rare complication of this treatment approach.[31] In a retrospective review, Haldeman and co-workers studied 64 medicolegal cases of stroke associated with cervical spine manipulation. The strokes occurred at any point during the course of treatment. Certain patients reported onset of symptoms immediately after the first treatment, while in others the dissection occurred after multiple manipulations. There was no apparent dose–response relationship to these complications. These strokes were noted following any form of standard cervical manipulation technique including rotation, extension, lateral flexion and non-force and neutral position manipulations. The results of this study suggest that stroke, particularly vertebrobasilar dissection, should be considered a random and unpredictable complication of any neck movement, including cervical manipulation. It may occur at any point in the course of treatment with virtually any method of cervical manipulation. The sudden onset of acute and unusual neck and/or head pain may represent a dissection in progress and be the reason a patient seeks manipulative therapy that then serves as the final insult to the vessel, leading to ischaemia.[32] This puts another perspective on the relationship between cervical spinal manipulation and VAD: is VAD caused by the manipulation or is the patient manipulated because of incipient VAD?[33]

Although the risk of serious complications cannot be denied, it should be put into context. The incidence of VAD in relation to cervical manipulation remains very low. One Canadian survey, for instance, reported 23 cases of VAD after cervical manipulation over a 10-year period, representing a rate of 1/584 638 manipulations.[34] Other publications estimate the incidence of VAD to be 1 in a million.[35,36] Furthermore, several authors have made a comparison between the occurrence of injury following manipulation and the complications of other treatments for cervical disorders. The incidence of a serious complication such as a gastrointestinal event after the use of non-steroidal anti-inflammatory drugs is 1 in 1000.[37] After surgical procedures to the cervical spine, 1.6% of complications occur. These figures can be used to argue that risks from other causes such as drug therapy can be between 100 and 400 times greater than after cervical manipulation.[38]

Premanipulative testing

During recent decades, tests have been described to detect vertebrobasilar insufficiency in order to identify those patients who may be at risk of serious post-manipulation complications. These tests are based on the assessment that blood flow to the contralateral vertebral artery is decreased when the cervical spine is rotated and extended to one side.[39,40] This is because, during rotation, the contralateral vertebral artery slides forwards and down, causing it to narrow. However, in normal individuals, collateral vascular supply by means of the circle of Willis is sufficient to assure blood flow and to prevent symptoms (see online chapter *Headache and vertigo of cervical origin*).[41,42]

Mainly under the influence of the Australian Physiotherapy Association, performing a vertebral artery test routinely prior to manipulation has become widely accepted.[43–45] It is believed that the test could determine tolerance to cervical extension and rotation or could differentiate between dizziness caused by vertebrobasilar insufficiency and dizziness caused by other conditions, such as benign paroxysmal positional vertigo and inner ear pathology.[46,47]

Although prudent premanipulative testing seems to reduce the level of risk,[48] both its validity and safety have recently been questioned.[49] Premanipulative testing should not be considered as the ultimate safety precaution; studies have shown a high likelihood of obtaining false negative results, suggesting that the validity of the test is poor.[50–53] Furthermore, it can even be argued that examination procedures are more dangerous than therapeutic manipulation, because the sustained posture required for the test exposes the patient to greater risk than a quick, high-velocity manipulation.[54–56]

The doctor or physiotherapist who intends to manipulate should always be aware that even tests during examination carry a risk and that there will always be a factor of unpredictability even when all premanipulative tests are negative and

even if the patient responded positively to earlier manipulations. Screening for manipulative risks should not rely on the outcome of provocation tests but on the whole clinical picture that emerges after thorough history taking and clinical examination. In this perspective, a recent study that compared the results of a simple questionnaire to a duplex Doppler ultrasound demonstrated excellent sensitivity (1.00) and good specificity (0.78).[57] The questionnaire consisted of the following: 'Do you avoid looking up as if into a high cabinet shelf because doing so causes neurological symptoms such as: visual problems, dizziness, unsteadiness, confusion, headaches and symptoms in the extremities?' The same question was posed in relation to turning the head to the right and to the left, as if reversing a car. Review of the literature, especially of the many case histories that have been described, also leads to the conclusion that a number of serious complications could have been prevented had practitioners recognized warning signs which should have led them to exclude manipulation.[58–60] One review mentions faulty diagnosis, insufficient clinical knowledge or examination, inaccuracy as a result of routine, overconfidence, bad technique and therapeutic obstinacy as the main causes of complications.[61]

In recent years another view of the relationship between cervical manipulative therapy and VAD has emerged. The relationship was usually seen as simple cause and effect, in which manipulation causes a dissection in certain susceptible individuals. Recent evidence, however, suggests that the relationship is not causal, and that patients with VAD often have initial neck symptoms which cause them to seek care; they then have a stroke some time later, independent of the treatment. This new understanding has shifted the focus for the therapist from one of attempting to 'screen' for 'risk of complication with manipulation' to one of recognizing the patient who may have a VAD so that early diagnosis and intervention can be pursued.[62] Again, this recognition can only be achieved by looking at the complete clinical picture and by following the proper diagnostic procedures (Box 11.1).

Box 11.1

Protocol for premanipulative testing

Before manipulation, check the following items:

- Have I taken a proper history and done a thorough standardized functional examination?
- Have I correctly interpreted the examination?
- Have I been able to reach a positive diagnosis of a discodural or discoradicular interaction?
- Have I checked on all possible warning signs?
- Have I checked on all possible contraindications?
- Have I found a clear indication?
- Have I a chance of success?
- Have I done premanipulative testing?
- Have I recalled Cyriax's advice?
- Have I mastered the manipulative technique?
- Do I know the manipulative procedure?
- Do I know the manipulation strategy?

Dangers of not manipulating

The dangers of *not* carrying out manipulation in subjects who need it are as important to consider as the dangers of performing it. Many discodural interactions, especially those causing unilateral or bilateral cervicoscapular pain, have no tendency to spontaneous cure. Unless manipulative reduction is achieved, the patient is left in pain that continues intermittently and that could have been relieved by a few sessions of treatment. Delay is also harmful because there may come a point when a protrusion, originally suitable for manipulation, becomes irreducible or dangerous.

A posterocentral disc displacement that is left untreated exerts constant pressure against the posterior longitudinal ligament. It may slowly become larger or give rise to an osteophyte in the spinal canal as a consequence of ligamentous traction. When the bulge enlarges it may eventually compress the spinal cord as well as the anterior spinal artery (see p. 165). The symptoms and signs elicited may finally become irreversible. For all these reasons it is unwise to leave an early minor disc displacement unreduced.

Evidence: results

Everyone who undertakes manipulation sees good and sometimes spectacular results in daily practice. This is somewhat in contradiction with the results that often emerge from randomized trials.[63,64] The discrepancy is mainly caused by the fact that, in most of the studies, subgroups of patients are not well defined. Prospective randomized trials that take more care with inclusion and exclusion criteria usually result in a stronger trend favouring manipulation. Koes and colleagues, for example, performed a randomized trial on back and neck pain and found promising results for manual therapy and physical therapy in subgroup analyses of patients with neck pain.[65,66] Hoving *et al* conducted a randomized, controlled trial of manipulation, physical therapy, and continued care by a doctor, which confirmed the superiority of manual therapy over physical therapy and continued care.[67] Other authors studied the cost-effectiveness of manipulative treatment. The cost-effectiveness ratios and the cost-utility ratios showed that manipulation was less costly and more effective than physiotherapy or general practitioner care. The manual therapy group showed a significantly faster improvement than the others, with a total cost of less than one-third of that of physiotherapy and general practitioner care.[68] Other randomized clinical trials in patients with mechanical neck pain confirmed clinically and statistically significant short- and long-term improvements in pain, disability and patient-perceived recovery when treated with manipulation.[69–71]

Precautions

In orthopaedic medicine the utmost precautions are taken to avoid any possible complication. Therefore the therapist must follow a strict routine (see Box 11.1). First of all, there should be a firm clinical diagnosis, if necessary confirmed with

technical investigation. Warning signs and contraindications are heeded. Manipulation is only considered if there is an unambiguous indication for it. Prognosis is determined and, if provisionally positive, manipulation is begun with strict methods. The manipulator will only proceed when sure of personal skill. During each manipulative session, constant reassessment is made and the decision as to whether or not to continue is totally dependent on the response obtained so far.

Proper history taking followed by a thorough standardized functional examination

The diagnosis of discodural or discoradicular interaction is made on clinical grounds and therefore a detailed history is necessary, which takes time. The complaints are recorded chronologically from the first appearance of symptoms up to the present. All possible symptoms are noted and a record is made of their behaviour and relationship to activity, movement and/or posture. Functional examination is always complete and no tests are omitted. Movements are examined for pain and range, and muscle strength is ascertained. Neurological features are tested in detail.

Proper interpretation of the examination (clinical reasoning)

The results of the examination, both positive and negative, are then interpreted in the light of anatomical reality (see p. 181). Correlation between history and functional examination is sought (inherent likelihoods): does the behaviour of the pain (onset and evolution, referred versus local) and the paraesthesia (development, presence and pattern) match the clinical findings? Examination features are related to possible articular, root or cord origin. Articular signs are mirrored by specific patterns of limitation. Root involvement may be obvious from motor or sensory deficit or disturbances of reflexes. Evidence of cord involvement is revealed by particular patterns of neurological presentation.

Diagnosis: discodural or discoradicular interaction

These interactions are diagnosed when the whole clinical picture is compatible with that of disc displacement – symptoms and signs are found that incriminate one or several of the following structures:

- *The dura mater and/or dural nerve root investment.* Multisegmental pain and tenderness show the dura mater to be affected; pure segmental pain points towards the investment of the nerve root. Scapular pain on coughing is considered to be a dural symptom.
- *The intervertebral joint.* An asymmetrical pattern of pain and/or limitation ('partial articular pattern') indicates internal derangement in the intervertebral joint. Other features are pain on movement and/or posture, twinges and, in more acute examples, deviation of the head.
- *The nerve root parenchyma.* Segmental (dermatomal) paraesthesia may accompany the root pain. Neurological deficit (motor, sensory and reflexes) is often present.

Box 11.2

Warning signs in cervical disorders

History

- Gradually increasing pain
- Expanding pain
- Bilateral arm pain
- Arm pain in a patient under 35
- Arm pain for more than 6 months

Examination

- Full articular pattern
- Muscle spasm
- Resisted neck movements that are painful and weak
- Side flexion away from the painful side as the only painful movement
- Limited scapular elevation
- Horner's syndrome
- Hoarse voice
- T1 palsy
- Excessive loss of power
- Involvement of two or three nerve roots
- Muscle weakness without root pain
- Wrong time sequence

- *The spinal cord.* Multisegmental paraesthesia in the hands and/or feet is provoked by neck flexion; other signs of motor and/or sensory tract involvement may also be found.

Exclusion of warning signs

During history taking and functional examination, the examiner must remain alert and constantly aware so as not to overlook possible warning signs (Box 11.2). The presence of any one of these red flags indicates a non-mechanical lesion and is an *absolute bar to any active treatment*. The patient should be referred for further investigations immediately.

Exclusion of contraindications

It is crucial to know when a manipulation is unsafe. In this regard, data collected from history and clinical examination are far more important than the outcome of one or more premanipulative tests (see p. 183). Great caution should therefore be observed in detecting potential contraindications during history taking and functional examination (Box 11.3).

Absolute contraindications

The following conditions are absolute contraindications to manipulative treatment: compression of the spinal cord, basilar ischaemia, drop attacks, rheumatoid arthritis, anticoagulant therapy, ankylosing spondylitis and an adherent dura mater.

Compression of the cord

The moment that there is clinical evidence of an upper motor neurone lesion, manipulation must be abandoned. Symptoms are: paraesthesia in the hands and/or the feet influenced by

Box 11.3

Cervical manipulation for disc lesions:

Contraindications

Absolute

- Compression of the spinal cord
- Basilar ischaemia
- Drop attacks
- Rheumatoid arthritis
- Anticoagulant therapy
- Ankylosing spondylitis
- Adherent dura mater

Relative

- Posterocentral disc protrusion
- Acute torticollis in young patients
- Gross deformity
- Manipulation increases root pain

Futile

- No protrusion
- Root pain lasting too long
- Root pain with neurological deficit
- Root pain with swift progression
- Root pain with primary posterolateral development
- Unfavourable neck signs
- Nuclear disc protrusion

neck flexion.[72] Signs are: positive plantar reflex, positive Hoffman sign, spasticity and incoordination.

Basilar ischaemia

A patient who complains of vertigo or dizziness on neck movements or on changing posture should not be manipulated, until further investigations with Doppler ultrasound and/or magnetic resonance imaging (MRI) have shown no vascular lesions. Even then, only techniques under strong traction and with a minimum of articular movement (straight pull and traction with leverage) should be used.

Drop attacks

Drop attacks, whatever their possible cause, constitute an absolute bar to manipulation. The examiner is not only alerted by the history but also can be warned by the end-feel during clinical examination or any attempt at manipulative treatment.

Rheumatoid arthritis

This condition can lead to ligamentous laxity at the upper cervical joints, which creates an absolute contraindication to manipulation.[73] The typical soggy end-feel puts the examiner on his/her guard.[74,75]

Anticoagulant therapy

It is unwise to manipulate a patient who is on anticoagulant therapy because of the danger of an intraspinal haematoma.[76] Only if the therapy can be stopped for the duration of treatment is manipulation possible.

Ankylosing spondylitis

In the inflammatory stage of ankylosing spondylitis or in the unlikely event of a patient with this disorder developing a disc lesion, manipulation is not at all safe, especially in the cervical spine, where luxations, fractures and cord compression have been described.[77,78]

Adherent dura mater

The dura mater may become adherent to the cervical or thoracic vertebrae. This becomes apparent during an attempt to manipulate, even in patients who otherwise seem suitable. When traction is applied, the patient has paraesthesia in the hands. Traction must be released immediately and manipulation abandoned.

Relative contraindications

Other conditions – posterocentral discodural interaction, acute torticollis in young patients, gross deformity, brachial pain during an attempt to manipulate – are not complete restrictions to manipulation but form a contraindication to certain techniques.

Posterocentral disc protrusions

Rotation techniques are contraindicated. The larger the protrusion seems to be, the more the manipulator resorts to techniques without articular movement. Techniques are used under considerable traction, the effects of which help to reduce the fragment of disc (see p. 196).

Acute torticollis in patients under 30 years

Muscular guarding renders manipulation under traction in the direction limited by spasm impossible. Because the condition is the result of nuclear prolapse, the very restricted rotation and lateral flexion initially present are increased by gently sustained pressure. Restoration of movement is thus achieved (see p. 196).

Gross deformity

Significant deviations of the cervical spine, either in side flexion or in flexion, make manipulation under traction impossible. Before the usual techniques can be used, the manipulator must bring the patient's head back to the neutral position. This happens after repeated tractions (whether or not with manipulative thrust) in the line of the deformity (see p. 196).

Manipulation causing brachial pain

The slightest increase in root pain during initial traction shows that the technique chosen is not suitable, because it clearly pushes the protrusion further against the nerve root.

Circumstances in which manipulation is futile

It is inappropriate to manipulate when a disc protrusion is not present, when the root pain has lasted for too long or when neurological deficit has supervened.

Protrusion absent at the time of presentation

It is possible for the patient to give a history indicative of disc trouble but protrusion is not currently present, in which case clinical examination is negative. Manipulation during such a symptom-free period is futile. The patient should wait until the condition relapses or, in the presence of an unstable fragment, measures should be taken to prevent recurrences. It is also inappropriate to use manipulation, as chiropractors often

do, as a prophylactic measure. This approach cannot prevent the disc from shifting again at any time.

Root pain lasting longer than 2 months

Experience has shown that root pain that persists for more than 2 months seldom responds to manipulation. The worst is over, and spontaneous recovery is to be expected within 1 or 2 months. However, in the exceptional circumstance of discogenic root pain lasting longer than 6 months, the apparently delayed mechanism of spontaneous cure can be restarted by manipulation.

Root pain with neurological deficit

The presence of a neurological deficit shows that the discoradicular interaction is too intense. The disc fragment cannot therefore be replaced but a vain attempt to do so is not dangerous. An occasional case with very minimal deficit may, in fact, respond.

Root pain with swift progression

The patient develops cervicoscapular pain, followed by root pain and paraesthesia the next day. The protrusion moves very quickly from a posterocentral position to a fully posterolateral one, and this course cannot be stopped. Neurological deficit may be expected very quickly.

Root pain with primary posterolateral development

When root pain is caused by a unilateral disc protrusion, it does not respond to manipulative reduction because, as in the lumbar spine, the displacement is nuclear.

Unfavourable neck signs

When some neck movements elicit or influence the root pain, the chances that manipulation will work are very small.

Nuclear disc prolapse

These cases are characterized by an elastic recoil, felt during a manipulative attempt and through the discrepancy between active and passive rotation during clinical examination. Acute cases have to be reduced by gradual forcing in the restricted directions. Chronic circumstances need continuous traction.

Recognition of a clear indication

It is not enough to have excluded warning signs and contraindications. It is just as important to make sure that a clear indication is present: a posterocentral or posterolateral disc protrusion causing a discodural or discoradicular interaction (Box 11.4).

Box 11.4

Cervical manipulation for disc lesions:

Indications

- Posterocentral discodural interaction with unilateral cervicoscapular pain
- Posterocentral discodural interaction with central neck pain or bilateral cervicoscapular pain
- Posterocentral discoradicular interaction with bilateral root pain
- Posterolateral discoradicular interaction with unilateral root pain, without neurological deficit

Posterocentral discodural interaction with unilateral cervicoscapular pain

Acute torticollis with side flexion deformity

Acute torticollis constitutes a good indication for manipulation and the patient may be helped within a few sessions. Although the course of this condition runs towards spontaneous cure, treatment helps from the outset to diminish the pain.

A distinction is made between torticollis in the young (under 30 years old), which is usually of the nuclear type, and that in those over the age of 30, who suffer a cartilaginous displacement (see p. 196).

Unilateral cervicoscapular pain

Symptoms of this nature are almost always the consequence of an annular displacement. They can be treated with manipulation at any time and, no matter how long the protrusion had existed, the response is usually good. Full recovery is to be expected after 1–3 sessions. Protrusions at the mid-cervical spine (C2–C3 and C3–C4) with pain felt at one side of the upper neck tend to be more difficult to reduce.

Posterocentral discodural interaction with central neck pain or bilateral cervicoscapular pain

Central or bilateral neckache with or without radiation to the trapezii or scapular areas, but without symptoms of spinal cord compression, can be manipulated, provided the techniques are adapted to the specific situation. The manipulator has to realize that a posterocentral displacement may threaten the spinal cord and therefore great care is needed.

Acute torticollis with flexion deformity

This situation is more delicate because the protrusion is large and can impinge against and threaten the spinal cord. This is a clear contraindication to the techniques usually used in the treatment of unilateral disc displacement (see below), i.e. rotation. Special techniques that avoid too much articular movement are used.

Chronic neckache

Central or bilateral pain can be treated with manipulation, provided that rotatory techniques are avoided.

Posterocentral discoradicular interaction with bilateral root pain

If root pain is thought to be the result of a disc protrusion, no time limit is set for the manipulation to succeed – unlike unilateral cases. Slight bilateral root pain preceded by paraesthesia in both hands tends to respond well, although the discal cause is not always certain.

Posterolateral discoradicular interaction with unilateral root pain, without neurological deficit

The success of manipulative treatment in such circumstances depends on the stage at which the patient is seen. Reduction by manipulation is possible only in the first 2 months of the development of this clinical scenario, as measured from the moment that the root pain sets in. Prognosis is based on the clinical picture: neck movements that elicit or influence the pain in the scapular area rather than down the arm show the protrusion to lie in contact with the dura mater, suggesting that reduction may still be possible; when cervical

movements increase the root pain rather than the scapular pain, the chance of success is very poor.

Once neurological deficit has appeared (muscular weakness, sensory loss and sluggish or absent reflexes) no further benefit can be expected from manipulative treatment, except in the following two situations:

- *When severe scapular pain has remained after the root pain began*: usually the scapular pain and the articular signs disappear or considerably diminish when brachial pain occurs. In the rare event that some movements remain limited and cause severe pain in the scapular area, especially at night, one manipulative session may abolish the scapular pain and restore a full painless range of movement. The root pain remains unaltered and continues its spontaneous course (see p. 157).
- *When root pain lasts for a considerable period*: most root pain progresses to full recovery in the course of 3–4 months – except C8 pain, which may take up to 6 months to recover. Occasionally a patient may be seen with root pain that has lasted longer than 6 months, even up to 1 or 2 years, and investigation has not shown a neuroma or other similar lesion. Manipulation will not immediately influence the root pain; however, a few days after manipulation, the pain starts to diminish and after a second treatment 2 weeks later all symptoms may disappear. This peculiar clinical phenomenon could be explained by the concept that, although manipulation shifts the discal rim back immediately, it takes some time for the swelling and inflammation to abate and thus for pain to diminish.[79,80]

Prognosis: criteria of reducibility – presence of favourable or unfavourable signs

Before manipulation is decided upon, the chances of success should be assessed by considering the following questions. By answering these four questions one can make a reasonable prognosis for a number of clinical situations (Box 11.5).[81]

How large is the protrusion?

Gross deviation indicates that a large fragment of disc is displaced. Reduction may take more sessions of manipulation. The more pronounced the articular signs, the larger the protrusion. However, this does not mean that reduction would be impossible, as, for example, in acute torticollis. Neurological deficit indicates that the shift is too large (prolapse or extrusion) to make reduction possible.

Is the protrusion central, unilateral or bilateral?

A unilateral protrusion usually responds well to ordinary manœuvres, i.e. rotation and side flexion movements under traction.

A central or bilateral protrusion is more difficult and forms a contraindication to rotational manipulation. Other manœuvres are possible, except in severe cases, in which strong traction is applied without any movement.

A central protrusion with spinal cord compression is potentially dangerous and any sign – positive plantar reflex, spasticity, incoordination, gross weakness – must therefore be considered as an absolute bar to manipulation (see p. 185).

Box 11.5

Criteria of reducibility

Protrusion is reducible in:

- Unilateral pain in the neck and/or scapular area without root pain or neurological deficit (one or two sessions are needed)
- Unilateral cervicoscapular pain with root pain but without neurological deficit and with 'favourable' neck signs (mostly reducible)
- Bilateral pain in the cervicoscapular area with 'favourable' neck signs and irradiation down the arms plus paraesthesia in hands and/or feet (50% chance of successful manipulation in 1–4 sessions)
- Unilateral scapular pain with root pain and slight paraesthesia existing for less than 1 month and with good neck signs (sometimes reducible)

Protrusion is irreducible in:

- Unilateral pain in the scapular area, with root pain but no neurological deficit, and with 'unfavourable' neck signs
- Bilateral pain in scapulae and arms and paraesthesia in hands and/or feet with 'favourable' neck signs and without neurological deficit (50% are irreducible)
- Unilateral root pain followed by scapular pain
- Unilateral scapular pain with root pain and slight paraesthesia with 'favourable' neck signs and existing for longer than 1 month but less than 6 months
- Unilateral scapular pain that goes on after the disappearance of root pain, with only one movement being painful
- Unilateral scapular pain and root pain with marked neurological deficit and 'unfavourable' neck signs
- Quick evolution from scapular pain to root pain with paraesthesia and 'favourable' neck signs
- Elastic recoil and limitation of active rotation
- Paraesthesia in hands and/or feet with cord signs

Unilateral scapular pain and root pain for >6 months with reasonable neck signs and in which any neurological deficit is recovering:

- May be manipulated to restart the mechanism of spontaneous recovery: two or three sessions at 2-week intervals suffice

Is the pain influenced by articular movements?

When movements affect scapular pain, this is considered as 'favourable' and manipulation has a fair chance of success. Circumstances in which neck movements augment root pain have to be regarded as 'unfavourable', as the result of manipulation is usually inferior (see p. 187).

How long has the protrusion been present?

Scapular pain or bilateral root pain can be manipulated at any time, unilateral root pain within the first 2 months.

Decision to manipulate: patient's consent, type of patient

The decision to manipulate should be taken after all the safety measures previously mentioned have been considered. Some authors propose asking for a patient's consent, perhaps even in writing. Though this is not standard procedure, it is clear that

patients should be informed about what treatment will be started. Simple, honest and easily understandable information about the risks should be included but only up to a certain point. Some patients are easily scared. If they are given too much information about the possible dangers, they will have difficulties in accepting the treatment or relaxing during the manipulative manœuvres.

The manipulator must, of course, take into account the patient's personality. It is clear that certain patients are not suitable for manipulation because they cannot relax. Others, for some reason, do not want to get better; these patients are not manipulated.

Manipulation technique

General remarks

Position of the patient

The patient lies face upwards on the couch with the occiput just beyond the upper edge. This enables the manipulator to hold the patient's neck either in slight extension or in neutral position during the manipulative manœuvres. Physiological lordosis is maintained and positively influences the direction in which the discal fragment moves. Dentures must not be removed, to avoid uncomfortable overclosure of the mouth.

The patient must try to relax during the entire manœuvre because any muscular tension may result in after-pain. Holding on to the edges of the couch (with the intention of resisting the traction) is not allowed, because this makes the muscles of neck and shoulders contract, so complicating manipulation.

Position of the assistant

An assistant is needed for fixation. Positions are chosen whereby the patient's body does not move when traction is applied to the head. There are a number of possibilities (Fig. 11.2).

Fixation at the patient's feet

This is the most common method of fixation. The assistant stands at the patient's feet, takes hold of the ankles and bends forwards to bring his/her shoulders over the patient's feet. When the assistant's arms are then adducted, the feet are firmly fixed between the assistant's body and upper arms.

Fixation at the patient's shoulder

This is needed during a side-flexion manipulation. The assistant stands at the patient's side, opposite to the direction in which the head will be moved, and passes one arm between the patient's arm and body until the hand lies under the shoulder; the other hand lies on top of the shoulder. The fingers are clasped. The assistant's foot is placed against the leg of the couch and the assistant leans well backwards to resist the traction.

Fixation at the patient's side

This fixation method is used during the lateral gliding technique. The assistant stands at the side of the patient, who is asked to move towards the assistant. With one hand the assistant grasps the patient's opposite upper arm, and with the other hand takes the lower arm. The patient's body is then pulled firmly against that of the assistant, who will thus be able to resist the movements executed at the patient's head.

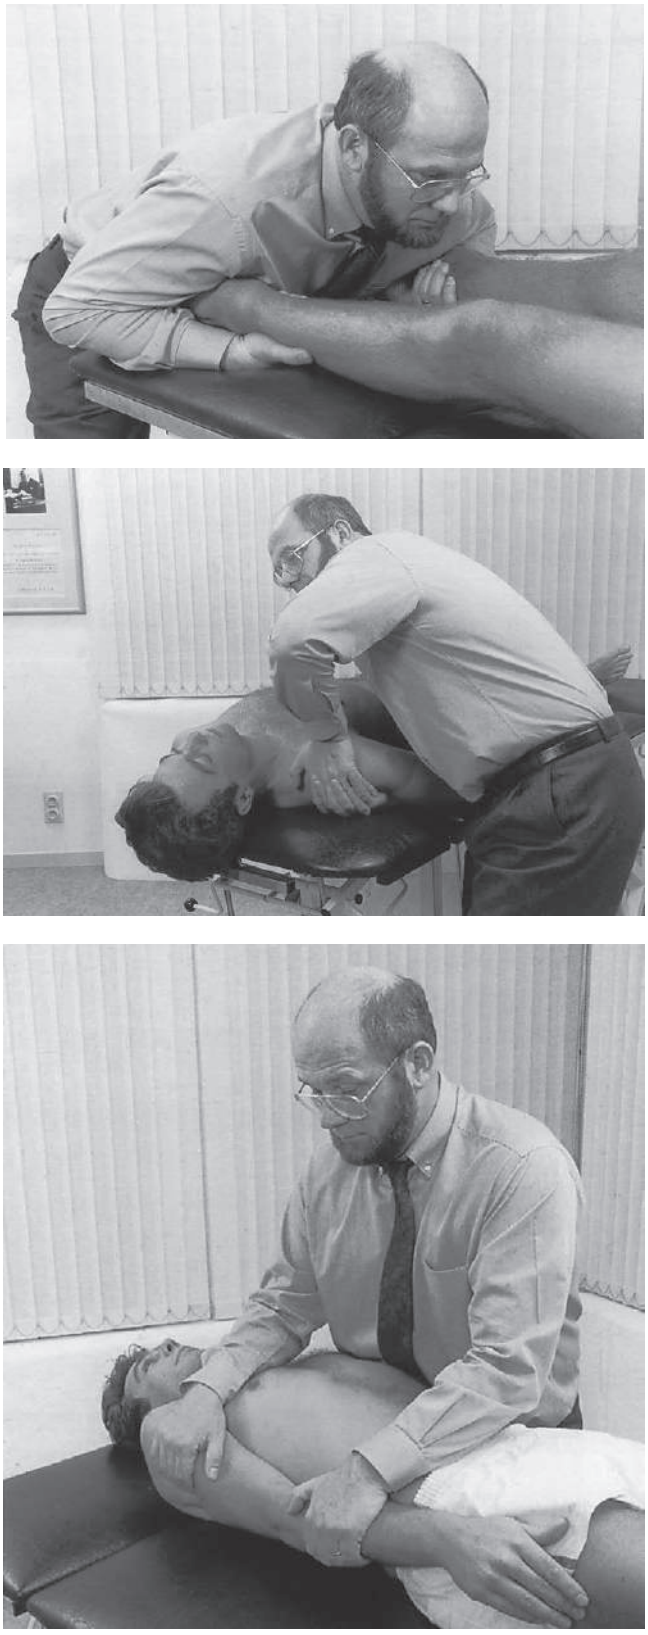

Fig 11.2 • Positions of the assistant for fixation: (a) at the patient's feet; (b) at the shoulder; (c) at the side.

Position of the manipulator

All techniques, except the lateral gliding manœuvre, are performed under *traction*. The maximum traction that is tolerable for the patient and allows relaxation is used. Traction is of vital importance because it has the following beneficial effects:

- Traction induces a subatmospheric pressure in the joint which results in a suction effect – a centripetal force.
- Compression on the pain-sensitive structures exerted by the protruded disc diminishes, with a resulting diminution or even disappearance of the pain. As an additional advantage, the patient will have no problems in relaxing muscles.
- As the muscles are well relaxed, the vertebrae can be distracted by a few millimetres so that the loose fragment has room to move.
- The facet joints are disengaged, which again makes movement easier.
- The posterior longitudinal ligament is taut and helps to exert a centripetal force on the disc.

All these factors combine to push the disc away from the spinal cord and the anterior spinal artery, which are thus protected.

In order to exert traction, the manipulator puts his/her feet against the legs of the couch, after taking hold of the patient's head. One leg is internally rotated and the other externally rotated, so that purchase is possible with the outer mid-tarsal area of one foot and the inner mid-tarsal area of the other. This position enables the manipulator to lean back and to use the body weight for traction.

Traction is built up gradually, which enables the operator to take up the slack when the vertebrae separate. When both feet are positioned against the couch and the manipulator moves away from the patient's head, by extending the knees and arms, maximal traction is obtained. This is not often necessary. The amount of traction depends on the type of patient. It is evident that much less traction will be needed in, for example, a woman of 45 kg than in a man of 95 kg. The traction is adapted to the patient's constitution and also to the ability of the patient to relax. Some patients are inclined to tense their musculature as soon as the head is pulled, others just relax under strong traction because it brings pain relief. The manipulator's experience is crucial in determining the amount of traction.

In order to become accustomed to how to apply traction, novices are advised in the beginning to put one foot further back. The traction force will be less. The foot is then gradually brought forwards until it reaches the couch (Fig. 11.3). The further the foot is brought forwards, the more traction is applied.

One advantage of using traction is that the operator's body, rather than hands, executes the traction element as well as the movement during taking up of the slack. The result is that both elements are much better controlled than if they were performed by the hands only.

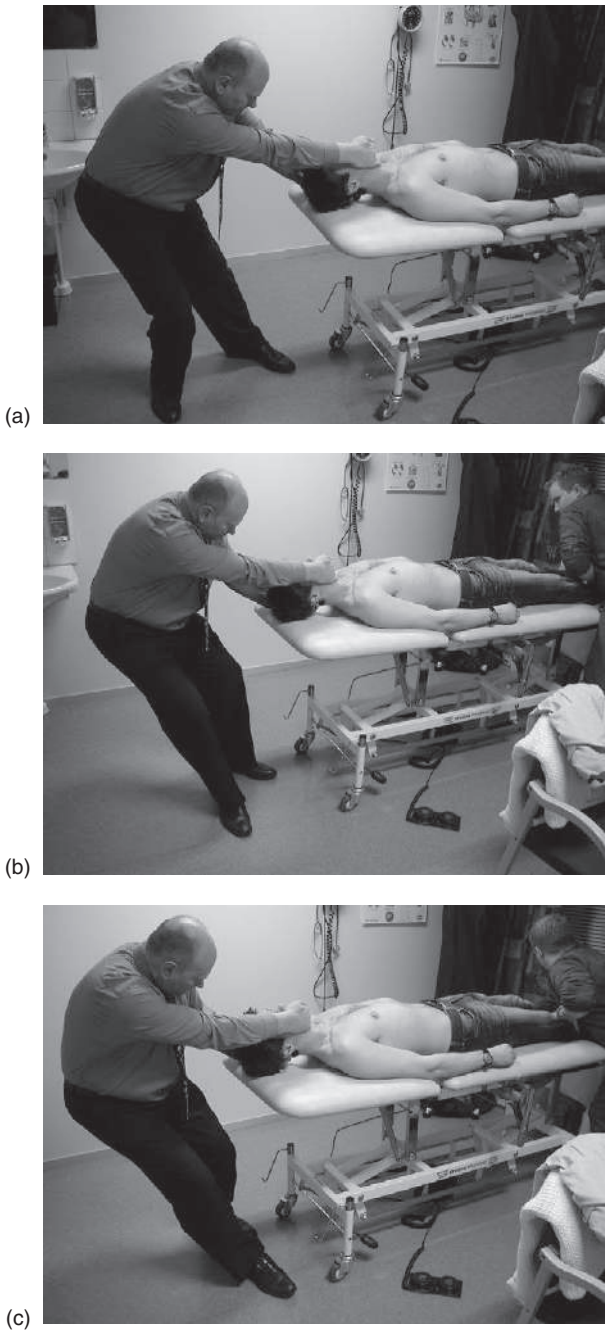

Fig 11.3 • Degrees of traction during manipulation: (a) slight traction, (b) moderate traction, (c) full traction.

Preparative massage to splenius and semispinalis capitis muscles at their mid-cervical extent

Deep transverse massage to these muscles can be used in those patients who have difficulty relaxing during manipulation. Massage will help to inhibit voluntary contraction.

The couch should have an opening near its head, through which the patient can breathe while face down. If this is not available, the patient's head is supported on a pillow.

The patient lies prone and the therapist stands level with the patient's head at the contralateral side. The fingers are placed on the affected area while the thumb supplies counter-pressure at the ipsilateral side of the neck (Fig. 11.4). Massage is imparted for 10 minutes by alternately flexing and extending the wrist, thus moving the fingers over the muscles.

Manipulation follows immediately.

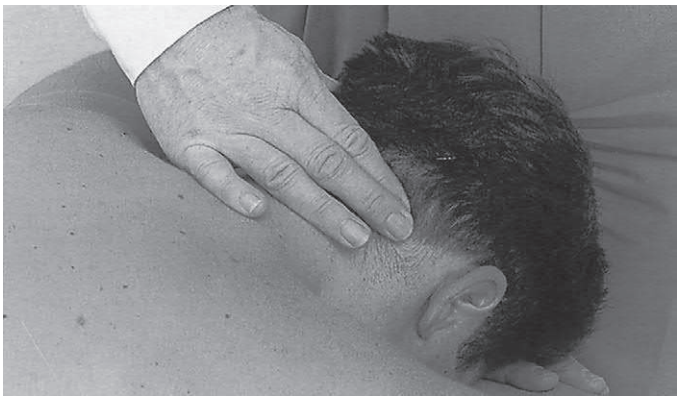

Fig 11.4 • Preparative massage to the splenius and semispinalis.

Techniques

Circumduction during traction

The patient lies supine on the couch, an assistant holding the feet.

After deciding which direction to turn the head in, the manipulator hooks one hand under the patient's chin. For rotation to the right the right hand is used, and the left hand for left rotation. The little finger is held in extension to avoid pressure on the trachea. The other hand grasps the occiput between thumb and fingers and supports the head. When the patient's head is grasped, pinching the chin or the occiput must be avoided. This could be very uncomfortable for the patient and might cause problems with relaxing. The manipulator now puts his feet against the legs of the couch, pointing them in the same direction as the rotation movement to be performed, and leans backwards. Moderate traction is exerted and during this, some slow rotary movements are executed without approaching the full range. This gives some idea of the state of the patient's neck. The patient now realizes what is to happen; confidence is established and the patient can relax.

During the manœuvre some 'cracks' may be felt. After a few movements traction is released.

Practitioner's checklist

- Use to accustom patient to techniques under traction
- Use to enable better relaxation
- Not a real manipulation but a preparative mobilization
- Moderate traction
- No impulse

Straight pull

The patient and assistant adopt the same position as for circumduction during traction. The manipulator hooks one hand under the patient's mandible and the other under the occiput, puts his feet against the couch and leans well backwards. The elbows are straightened as far as possible (Fig. 11.5).

After taking up the slack and assessing the end-feel, the therapist sharply pulls his shoulders backwards. This movement results in a quick manipulative thrust in line with the spine, during which a click may be felt. Traction is now gradually released.

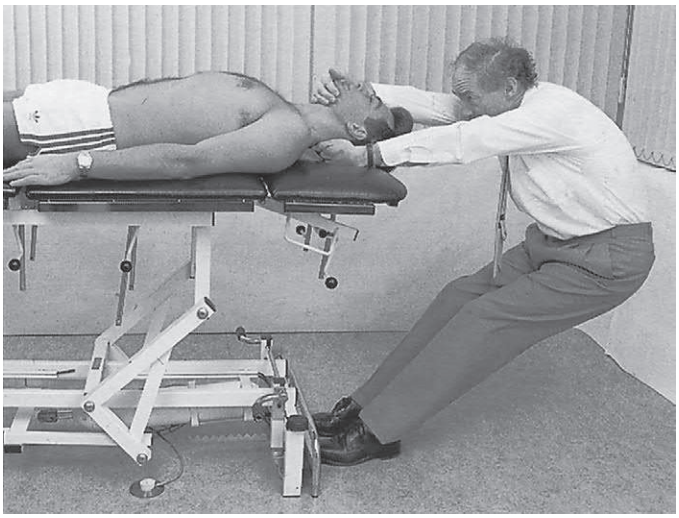

Fig 11.5 • Straight pull.

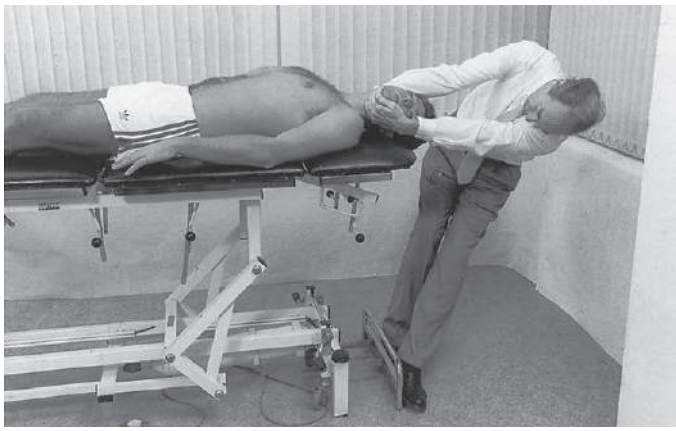
Practitioner's checklist

- Avoid neck flexion
- Use a comfortable grip
- Lean well backwards
- Equal traction by both hands

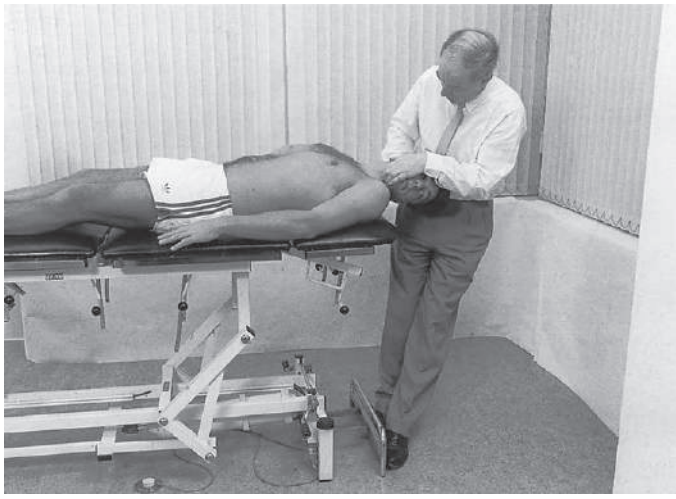
Rotation during traction

The patient and assistant take up the same position as described for the previous two manœuvres. The manipulator takes hold of the patient's head, places his feet against the couch and leans backwards to take up the slack (Fig. 11.6a). For a rotation to the right, the manipulator's right hand is at the patient's chin and the feet point in the same direction. The head is now slowly rotated to the right. This is not done with a hand movement but is the result of the manipulator side-flexing his trunk. The head is turned to half-range on the first occasion, then two-thirds and finally to the end of range. The degree of rotation depends on the response obtained from the patient, which is reassessed after each manœuvre. At full range the end-feel should be assessed and, when this is right, the impulse is given: a quick movement over a very small amplitude (1–2° only). In contrast to the previous trunk movement, this final thrust is performed with the hands only. The head is then brought back to the neutral position and traction is released.

The further the head is rotated, the more chance there is that one or more clicks will be felt. They are relevant when the movement seems to have improved afterwards. When no click is felt, nothing has happened. The end-feel at the end of the manipulative thrust tells the manipulator if further forcing is indicated.



(a)



(b)

Fig 11.6 • (a) Rotation during traction. (b) Full rotation during traction.

Practitioner's checklist

- Direction of rotation determines position of hands
- Feet point in the direction of rotation
- Equal traction during the entire manœuvre
- At the end of range, assess end-feel before manipulation

Full rotation during traction

When repetition of the previous manipulation ceases to afford any benefit, this technique may follow. The traction force will be somewhat less but it will be easier to achieve full rotation (Fig. 11.6b).

The patient and assistant maintain the same position.

For a rightwards rotation the manipulator puts the right hand on the patient's left cheek; the arm is held in pronation, the thenar eminence lies on the maxilla and the fingers are hooked under the chin. The other hand grasps the occiput as previously described for the circumduction during traction technique. After putting his feet against the couch, the operator leans backwards, thus applying traction, and turns the patient's head to full range.

When the end-feel is good, a quick manipulative thrust will be performed. The head is turned back to neutral and traction is relaxed.

Practitioner's checklist

- Thenar eminence on maxilla; avoid chin movement
- Pure rotation, no lateral flexion component
- Assess end-feel before manipulation
- Equal traction during the entire manœuvre

Side flexion during traction

The patient lies supine on the couch. The assistant stands level with the patient's shoulder on the painful side to apply counter-traction (Fig. 11.7) (see p. 189).

The manipulator puts one hand under the patient's occiput. The second metacarpophalangeal joint is applied against the posterior aspect of a facet joint at the mid-cervical area. The thumb is kept in extension to avoid pressure on the external carotid artery and the third, fourth and fifth fingers support the head. The other hand is hooked under the mandible in such a way that the forearm comes to lie anteriorly to the ear. The head will thus be prevented from rotating too much during side flexion (see Fig. 11.7b). The lateral aspect of the ipsilateral foot is now put against the nearer leg of the couch. The other leg is extended out and backwards. Traction in line with the spine is now achieved and this will be facilitated by bending the knee.

After taking up the slack the manipulator now swivels the body, thus bringing the patient's neck into side flexion with the help of the forearm. Simultaneously, counterpressure is applied by the other hand. When the movement comes to an end, the end-feel is assessed and the manipulation performed with a quick adduction movement of the contralateral shoulder. A click is felt, after which the head is brought back to the neutral position and traction released.

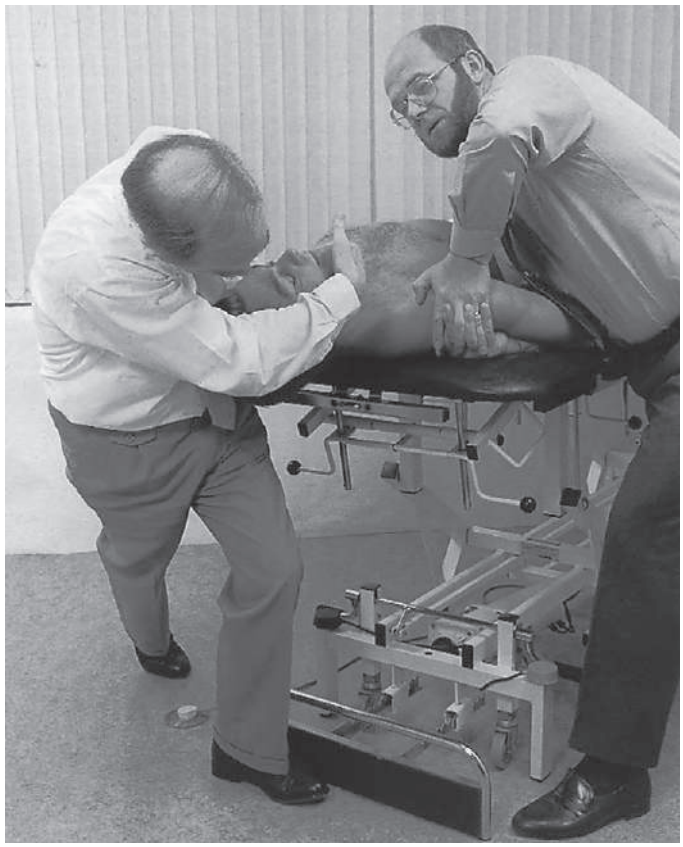
Practitioner's checklist

- Traction in line with the spine
- Avoid rotation
- Counterpressure during lateral flexion movement
- Assess end-feel before manipulation

Anteroposterior glide during traction

The patient lies supine on the couch, the head well over the edge and the shoulder level with it. An assistant holds the feet.

The manipulator stands at one side of the patient's head, facing it. One hand supports the head under the occiput and the other is positioned at the patient's chin using the following grip: the web between thumb and index finger is applied to the chin so that thumb and index finger lie on either side. The forearm is kept vertical. The flexed third, fourth and fifth fingers hook under the chin in order to enable traction. The manipulator now places his feet against the legs of the couch



(a)

(b)

Fig 11.7 • (a) Side flexion during traction. (b) Position of the hands for the side flexion technique.

and leans sideways, using his body weight for traction. After the slack is taken up, the head is gently glided anteriorly with the use of the hands (Fig. 11.8a). It is then glided posteriorly as far as it can go with a manipulative thrust, the result of a sudden flexion of both knees (Fig. 11.8b).

Practitioner's checklist

- Stand at one side of the patient's head
- The patient's head must be well over the edge of the couch
- Traction is obtained by leaning sideways
- Gentle anterior glide, followed by sudden posterior glide
- Avoid flexion–extension movement

Lateral gliding

The patient lies supine on the couch. The assistant stands at the patient's side and firmly fixes the patient's body (see p. 189).

The manipulator stands at the patient's head, feet apart. With the forearms supinated, the hands support the head and, with the thumbs kept horizontal along the cheeks, the thenar eminences are placed anteriorly to the ears on either side. Movement is now carried out without traction. By bringing the body weight over one leg and then back to the other as well as taking the patient's head along with the movement, the neck is moved sideways (Fig. 11.9). The position of the hands should enable the manipulator to maintain the patient's head in line with the body. Side-flexion movements should be avoided and the movement is purely horizontal.

Practitioner's checklist

- Avoid compression of the ears
- No traction
- Avoid side-flexion movements
- Avoid flexion
- Pure horizontal gliding

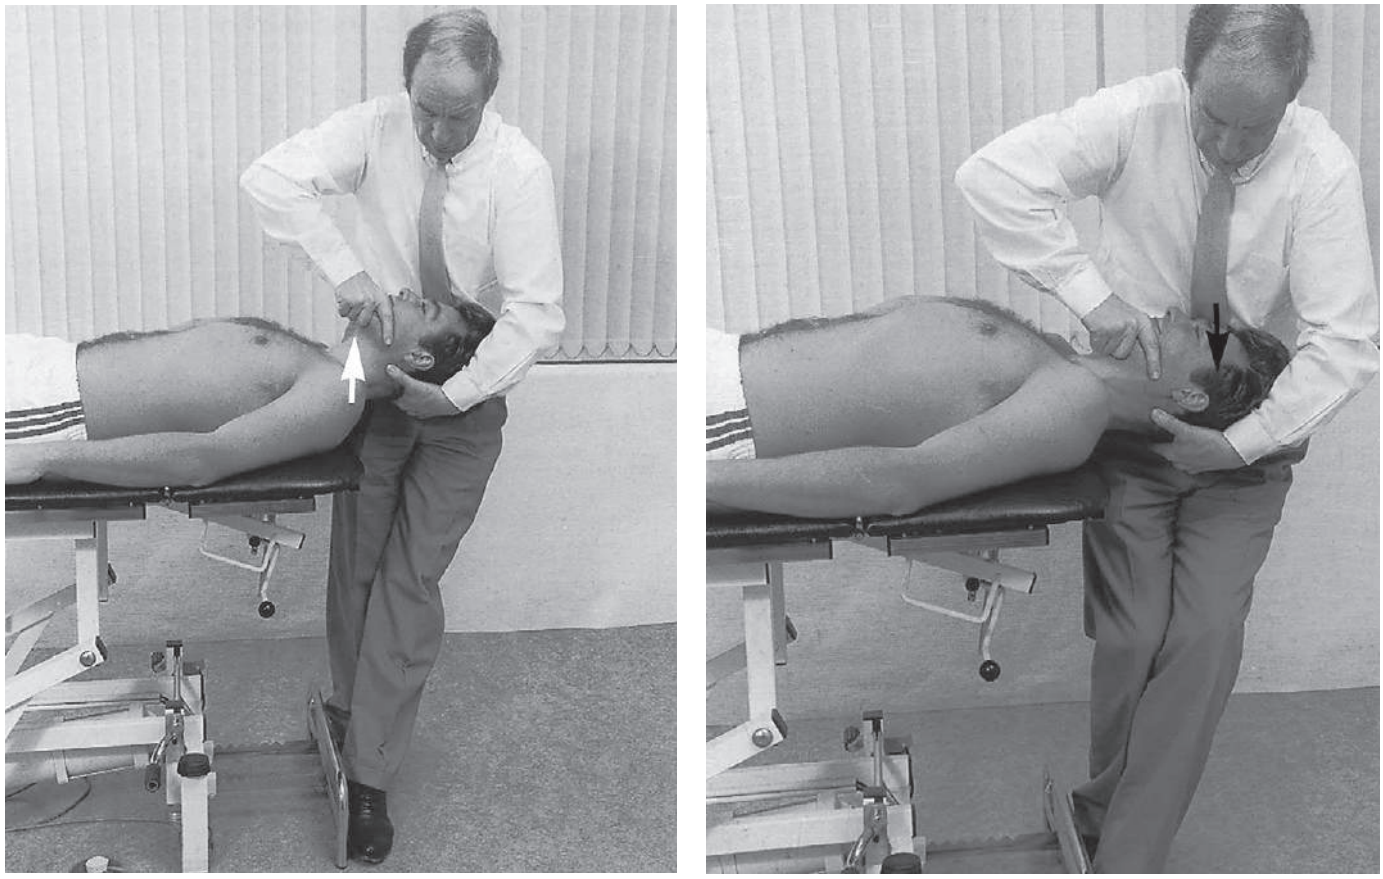
Traction with leverage

The patient lies supine on the couch with the occiput exactly level with the upper edge; an assistant holds the feet firmly so that the body does not move at all during the manipulative thrust.

The manipulator puts one hand, protected by a layer of sponge rubber 2–3 cm thick, under the patient's occiput. The patient's mandible is grasped with the other hand, holding the neck in slight flexion.

Before manipulating, great care is taken in positioning the patient's head in relation to the edge of the couch. An attempt is made to move the head gently further into extension so as to assess how far this movement can go. If extension can take place to a considerable degree, this is because the patient is too high on the couch; if there is no movement at all, this indicates that the patient is too low. It should be possible to place the patient's head in the neutral position where it comes to a stop.

The manipulator then puts the feet against the couch and leans right back until the whole or part of the body weight is sustained by the hand under the chin. Traction is not applied



(a) (b)

Fig 11.8 • Anteroposterior glide during traction: (a) starting position; (b) end position.

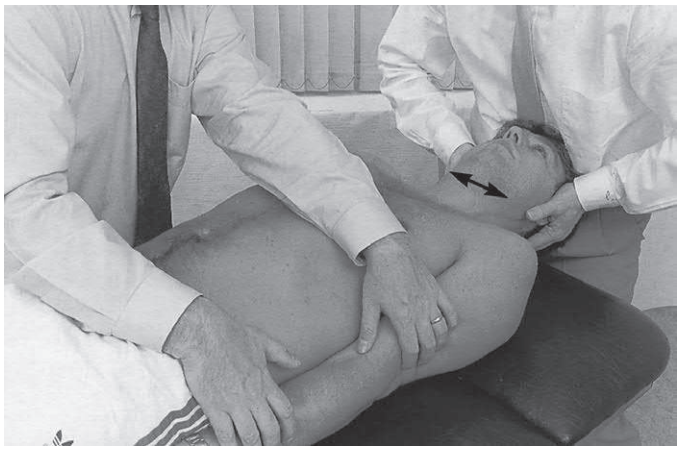


Fig 11.9 • Lateral glide.

Fig 11.10 • Traction with leverage.

via the hand under the occiput, which only steadies and is squeezed between head and couch to provide a fulcrum. The knees are now suddenly flexed, thus pulling the patient's neck with a jerk (Fig. 11.10). This results in a sudden increase of traction in the anterior spinal column from the foramen magnum downwards.

Practitioner's checklist

- Avoid flexion
- Careful positioning
- During manipulation: no movement, only traction

Manipulation procedure

Choice of technique

- *A preparative massage* to the muscles of the neck enhances relaxation and so is useful when a patient does not feel sufficiently relaxed (see p. 189).
- *Circumduction and straight pull* can be used as the first manœuvres, to accustom the patient to the traction element.
- *Rotation manipulation* is used for unilateral disc protrusions but is avoided in central displacements. Rotation is first performed in the most comfortable direction and then, if still necessary, in the least comfortable direction. It is executed to half-range first, then to three-quarters and only then to full range. When the other direction is chosen, a similar gentle start is again recommended.
- *Full rotation during traction* is only used when rotation caused improvement and only in the direction in which the result was obtained.
- *Side flexion* is mostly performed in the direction away from the painful side and very rarely towards the painful side – when, after a few sessions and after repeatedly trying the other techniques, a full result has not yet been obtained. When taking up the slack produces or increases arm pain, the manœuvre is abandoned.
- *Anteroposterior gliding* is indicated in unilateral disc displacements when the range of extension does not improve with rotation and/or lateral flexion techniques. In central protrusions it can be used in combination with straight pull and lateral flexion.
- *Lateral gliding* helps to get rid of possible post-manipulative soreness. When overcorrection is produced during a manipulation session – the unilateral pain changes sides – this manœuvre is performed.
- *Pure traction techniques* – straight pull and traction with leverage – are designed especially for the treatment of posterocentral disc protrusions. Articular movement is thus avoided.

Gentle start

Each time a new technique is chosen the manipulator starts gently. The intensity of a technique is only increased when the patient has responded satisfactorily to the previous technique.

Assessment of progress

After the use of each technique, the patient is asked to sit up and the result is assessed. A decision is then taken as to whether to continue in the same way or to change. Experience, the result of each particular manœuvre, the end-feel during exertion, the patient's age and estimation of tolerance all affect the types of manœuvre employed.

A change in symptoms or signs is interpreted as improvement when (a) intensity of pain has diminished; (b) range has increased; (c) fewer movements are painful; and (d) pain has centralized: for example, scapular pain instead of arm pain, trapezius pain instead of scapular pain, central pain instead of unilateral pain, or shortening of pain.

If one manœuvre has helped, it should be repeated until symptoms and signs no longer alter. Then another is tried.

If the manœuvre does not produce any positive results, it can be tried a second time with slightly more intensity. If improvement still does not occur, the manœuvre is abandoned and either another technique is chosen or the same technique is used in another direction. For example, if rotation to the right does not produce the expected result, either a lateral flexion technique or rotation to the left can be tried.

If a manœuvre makes the patient worse, it is not continued. The manipulator must then decide whether the worsening is the result of a wrong technique or of poor relaxation on the part of the patient, and whether the condition is in fact suitable for manipulation. If the technique is not appropriate, another can be chosen, perhaps with less movement and more traction. When two consecutive trials still increase the symptoms, manipulation is stopped. The patient is re-examined on the next occasion and a decision is taken as to whether to continue. Deciding is not always easy and great attention should therefore be paid to what the patient reports during and after each manœuvre, and in the hours that followed treatment. The moment there is the slightest doubt, manipulation is abandoned.

Manipulation strategy

Repetition of techniques

Acute conditions are best treated on a daily basis, while more chronic cases are manipulated 2–3 times a week. Manipulation is a short-term treatment, which means that, if no result is obtained after a few sessions, another approach is chosen.

Young patients can easily stand several (6–8) techniques in a session. Elderly patients receive the same treatment but only 1–3 techniques per session are used, and the interval between the treatments is longer – 1–3 times a week.

When the results of each manœuvre are only slight or minimal, manipulation is continued until the greatest possible result is obtained. When a significant improvement is suddenly noted, the session is stopped and the result reassessed on the next occasion.

The therapist should try to follow the sequence of manœuvres as recommended in the following section but should develop enough flexibility and creativity to work according to the results obtained in each individual case.

Course of the manipulative session

Posterocentral disc protrusion with unilateral cervicoscapular pain

Two types of case fall into this group.

Acute torticollis with side flexion deformity

In nuclear-type torticollis the following procedure is applied. The manœuvres are performed in a strict order, whereby manipulation in directions limited by the condition is avoided.

On the first day:

1. Traction manipulation (straight pull) in the direction of the deviation is performed, in which the head is gradually brought back to the neutral position. No other technique is used before the patient is able to maintain the head in the neutral position when seated upright.
2. Rotation manipulation under traction is then performed in the less restricted direction until this movement has become painless.
3. Lateral flexion manipulation under traction and towards the painless side should then restore a full painless range in that direction.
4. Progressive rotation, without traction, in the restricted direction, in which the head is gradually pushed to the point where pain begins and then immobilized in that position until the pain has disappeared; after this, further movement is undertaken and continued until a full range is achieved. The time taken for the pain to disappear at each stage may vary from a few minutes to 5 minutes or more, which means that up to 20 minutes may be necessary to restore the range of rotation.
5. Progressive lateral flexion, without traction, in the restricted direction is performed, in which the same slow procedure is followed until full side flexion is obtained. This movement usually improves more quickly than rotation; 5–10 minutes are required.
6. When the patient is reassessed after the whole procedure is finished, what has been achieved provides a basis for prognosis. When, after the first treatment, full painless range in all directions is attained, this indicates that by the next day the patient will be much improved or even cured.
7. The patient is then advised to repeat these progressive manœuvres every 2–3 hours and certainly before going to bed because there is a tendency to relapse. Instruction should also be given on what precautions to take to keep recurrence minimal; sleeping in the supine position is preferred. A very thin pillow should be used but support under the neck should be provided (e.g. a rolled towel with a diameter of 5–10 cm). Alternatively, if the patient sleeps on one side, a thick pillow should assure that the cervical spine lies in line with the thoracic spine. Sleeping prone should be avoided.

The patient is seen on a second day and, if considerably better, treatment then consists of manipulations for an ordinary unilateral disc protrusion (see below). When, on the contrary, a considerable relapse has taken place, the whole procedure is repeated. Full relief is usually obtained in 2–3 sessions (Fig. 11.11).

Annular-type torticollis in patients over 30 can be manipulated in the ordinary way (see below).

Unilateral cervicoscapular pain

These cases are almost always annular in nature and therefore respond very well to manipulative treatment. The following sequence is recommended:

1. Straight pull or circumduction under traction to familiarize the patient with strong traction techniques.

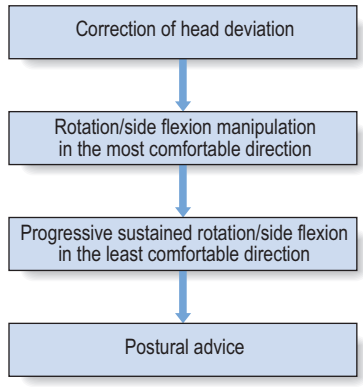

Fig 11.11 • Procedure in unilateral acute torticollis.

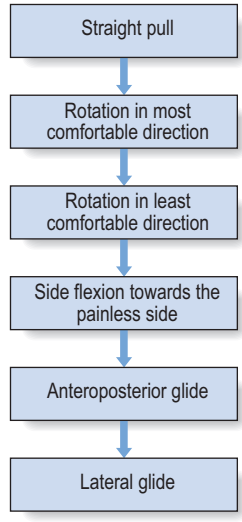

Fig 11.12 • Procedure in unilateral cervicoscapular or root pain.

2. Rotation under traction to less than full range in the less restricted or less painful direction.
3. Rotation under traction to full range in the same direction.
4. Rotation under traction to less than full range in the most restricted or most painful direction.
5. Rotation under traction to full range in the same direction.
6. Lateral flexion under traction towards the painless side.
7. Lateral glide (Fig. 11.12).

Posterocentral disc protrusion with central or bilateral cervicoscapular pain

This includes three types of case.

Acute torticollis with flexion deformity

The same procedure is used as for torticollis with deviation in lateral flexion, except that the traction in line with the deviation starts in flexion (enough time must be taken to bring the patient's head gradually back to the neutral position) and rotations are avoided. Side flexion manipulations under traction can be performed in both directions, after which the patient is put on his side and the limited extension very gradually forced to full range.

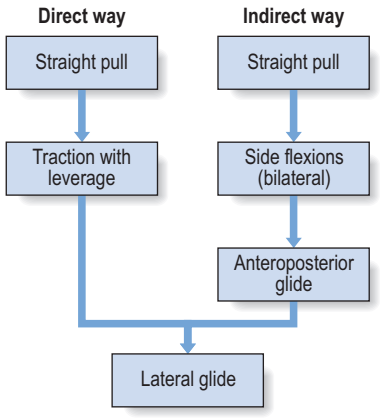

Fig 11.13 • Procedure in central or bilateral cervicoscapular pain.

Chronic neckache

A direct or an indirect approach can be taken.

Direct approach

1. Straight pull: strong traction manipulation in line with the spine.
2. Traction with leverage.
3. Lateral glide.

Indirect approach

1. Straight pull.
2. Lateral flexion under traction, which can be done bilaterally.
3. Anteroposterior glide.
4. Lateral glide.

The decision to use one approach or another depends on the severity of the clinical picture. In very mild cases it is easy to switch from one approach to the other.

The more pronounced the articular signs are and the more extension is limited, the more the manipulator will be inclined to choose the direct approach, following the principle of 'maximal traction with a minimum of articular movement'.

Signs of spinal cord involvement form an absolute bar to manipulation.

Bilateral root pain

The same procedure (Fig. 11.13) is used as in bilateral chronic neckache.

Posterolateral disc protrusion with unilateral root pain, without neurological deficit

The normal techniques are used:

1. Straight pull.
2. Rotation under traction in the less restricted or painful direction, first to less than full range and then to full range.
3. Rotation under traction in the most restricted or painful direction, first to less than full range and then to full range.
4. Lateral flexion under traction towards the painless side.
5. Lateral glide.

Before the impulses are given, the manipulator must make sure that taking up the slack does not influence the pain down the arm. If there is an effect, the technique is abandoned and another manœuvre is chosen. When two different techniques make the arm pain worse, the condition is not suitable for manipulation.

Traction

Adjuvant traction

Traction is a very important element of manipulation procedures because of its beneficial effects on the protruded fragment of disc (p. 190).

Traction as a treatment

For a long time, cervical traction has been regarded as an effective treatment for herniated cervical discs because it widens the intervertebral spaces[82] and exerts a centripetal force on the disc.[83,84] There is no doubt that traction induces pain relief and regression of herniated cervical discs.[85] A recent MRI study during 15 minutes of traction with a traction force of 18 kg also showed partial (62%) or complete regression (10%) of protruded cervical discs.[86] In spite of this, traction alone is not often used in orthopaedic medicine. The main reason is that clinical improvement is only achieved after 10 or more sessions – a result which could have been achieved much more quickly with ordinary manipulations.

However, traction is used as the primary treatment form in a small number of well-defined indications. It is most often given in the physiotherapist's room, but can – in some specific situations – be performed in bed. Usually the procedure is intermittent; on rare occasions traction is continuous.

Intermittent traction

Indications

There are four main indications for intermittent traction: in early nuclear protrusions, in minor posterocentral disc protrusions, to maintain reduction in unstable protrusions and as an alternative to manipulation.

Early nuclear disc protrusion

Differential diagnosis with an annular-type protrusion is not always easy and so it may happen that a patient is first manipulated but without success. On top of that, during manipulation an elastic rebound is felt at the end of range; when testing again after manipulation, full range cannot be obtained actively, though it was reached passively during manipulation. This type of displacement is a very good indication and responds quite well to daily traction in 3–6 sessions. However, long-standing cases do not benefit very much from this treatment and surgical removal may then be needed.

Minor posterocentral discodural interactions

Traction is a good alternative when manipulations are contraindicated (see p. 185). Even if the lesion is of the annular type,

Box 11.6

Intermittent traction: indications and contraindications

Indications

- Early nuclear disc protrusion
- Minor posterocentral disc protrusion
- To maintain reduction in unstable protrusion
- Instead of manipulation

Contraindications

- Paraesthesia induced by traction
- Brachial pain caused/increased by traction
- (*Annular disc protrusion*)

it may respond very well to traction, provided the patient is not too old and the articular signs are minor. Four to eight daily sessions usually produce good results.

To stabilize a recurrent disc

Two different situations may occur. The first is when the patient always relapses the day after manipulation. After 4–6 sessions the disc should have stabilized. If not, daily suspension at home is prescribed; 10 minutes' traction every morning may prevent the disc from protruding during the day.

Second, when the patient responds well to manipulation but continuously relapses a few weeks after the treatment, manipulation is followed by a week to 10 days' daily traction.

Instead of manipulation

Traction may be considered as an alternative for those patients who, for some reason, cannot be manipulated; 10–15 treatments may then be necessary.

Contraindications

These include the following:

Paraesthesia induced by traction

When traction provokes paraesthesia felt in the hands and/or feet, it must be stopped at once because this indicates involvement of the spinal cord.[87]

Brachial pain caused or increased by traction

When traction to the cervical spine elicits or increases root pain, the protrusion is clearly being pulled in the wrong direction – further against the nerve root.

Indications and contraindications are summarized in Box 11.6.

Technique

Traction can be applied with the patient sitting or lying supine (Figs 11.14 and 11.15). A leather collar is strapped under the patient's chin and occiput in such a way that the anterior portion clears the trachea while supporting the mandible. The collar is attached to a spreader and hangs by a cord passing over a pulley to the centre of the spreader. The therapist must make sure that the patient's ears are not squeezed. Traction is applied in the neutral position or with the head held in very slight flexion.

The physiotherapist stands by the patient and pulls gradually on the cord until the required force – usually between 8 and 15 kg – is obtained. The traction is continuous and the force maintained for 15–20 minutes.

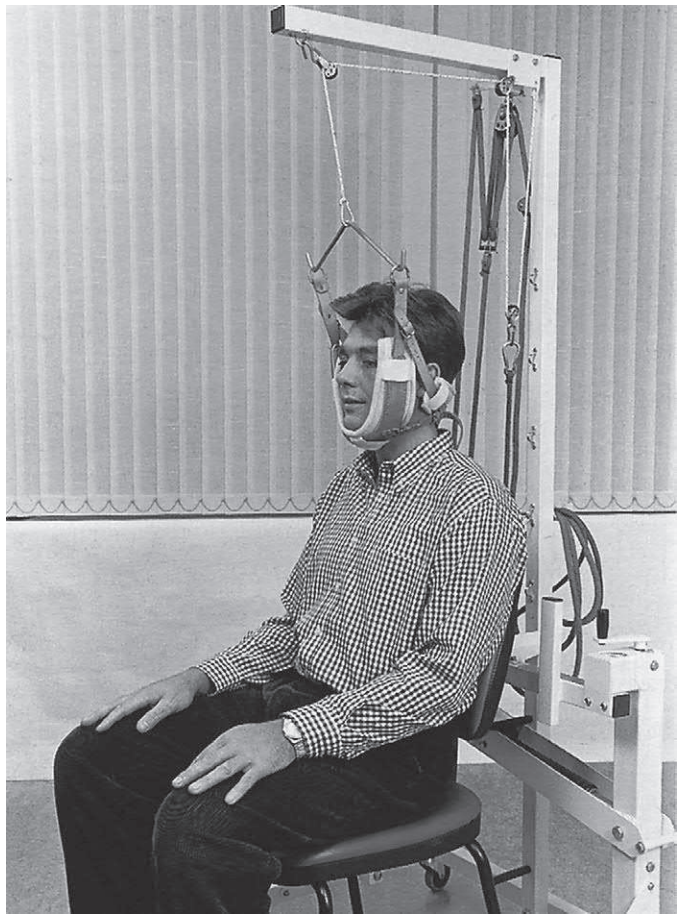

Fig 11.14 • Traction performed sitting (head suspension).

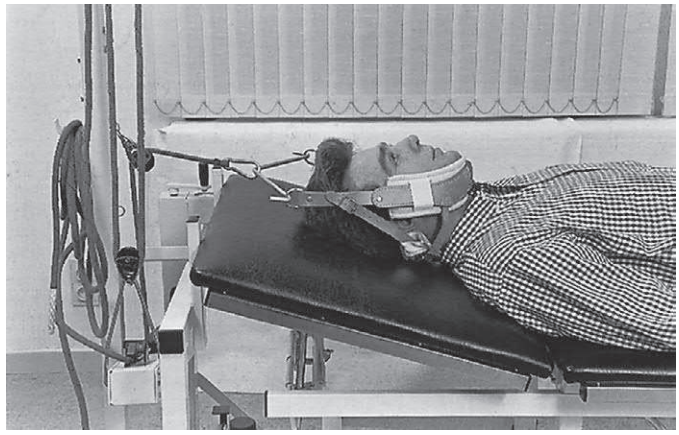

Fig 11.15 • Traction performed lying down.

Continuous traction in bed

This is used only when everything else has been tried and failed. Often it is the only alternative to surgery. The treatment has to be carried out in hospital because the patient requires full nursing care 24 hours a day. The traction (4–5 kg) is

maintained for the first 24 hours and then gradually diminished and released. The pain is expected to subside slowly and to have diminished after 7–12 days[88]; the patient may then be discharged from hospital.

Indications

There are three main indications for continuous traction.

Very severe root pain without neurological deficit

Those cases that do not respond to manipulation, head suspension or nerve block can be helped by traction in recumbency in the hope of quick diminution of the pain, which may otherwise take 3–4 months to abate.

Nuclear disc prolapse

Rarely, a young adult may be seen with a gross nuclear displacement: quite severe scapular pain is present with gross limitation of rotation in one direction. All other movements of the neck are normal. Manipulation does not work. During attempted manipulation the typical elastic recoil is felt – the head can be turned passively to full range but the active range remains very restricted. If head suspension fails, traction in bed is the only alternative.

Early posterocentral disc protrusion

Manipulation or intermittent traction is indicated and should produce good results. When these measures do not help, traction in bed is substituted.

Injection at a nerve root

Indications

The main indication for nerve root injection is root pain with neurological deficit. An injection is then the treatment of choice, especially when the root pain is too severe to await spontaneous cure.

Another indication is root pain without neurological deficit that lasts longer than 2 months, because no further improvement can be expected from manipulation. In recent root pain, nerve root infiltration is also called for if there is inadequate response to manipulation.

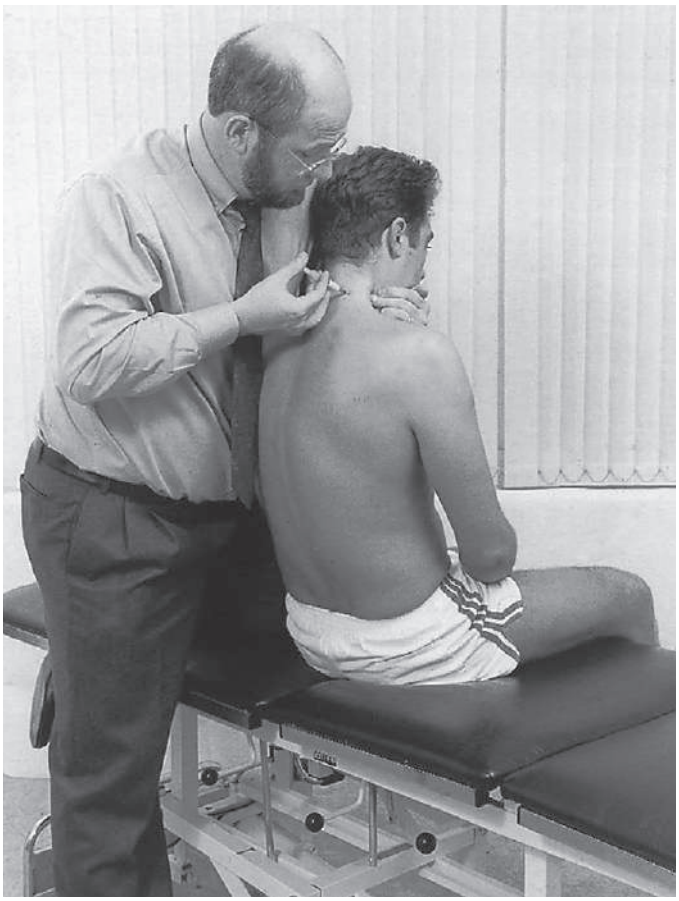
Technique

A 2 mL syringe filled with 20 mg of triamcinolone acetonide is fitted to a 4 cm needle.

The lateral edge of the corresponding transverse process is identified, just behind the posterior edge of the sternocleidomastoid muscle. The needle is inserted between the palpating finger and the midline, and aims at the identified transverse process (Fig. 11.16). It is inserted until it meets bone. Half a millilitre is injected there, and the needle is then moved laterally and slightly cranially until it slips over the edge and the rest of the injection is made here. During the injection the patient may feel radicular pain, which disappears after a few minutes. One to six injections at weekly intervals may be necessary, depending on the severity of symptoms.

Results

Radicular pain caused by a discoradicular interaction with or without neurological deficit usually benefits greatly from nerve root blocks. Most studies report a success rate of between 65 and 80% after one or two injections.[89–92] Bush *et al* performed a prospective study with independent clinical review on 68 patients presenting with cervical radiculopathy and neurological signs. The average duration of symptoms prior to presentation was 2 months (range 1–12 months). They received an



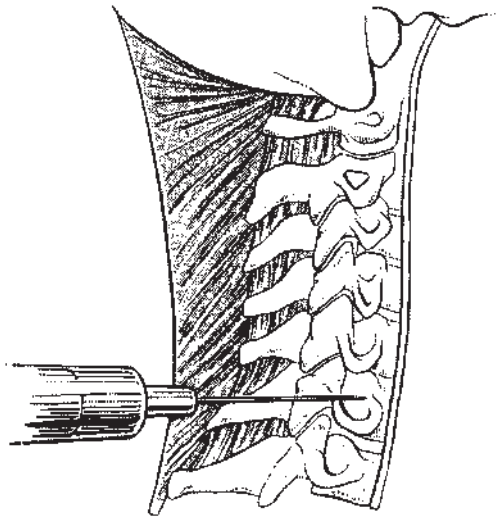


Fig 11.16 • Injection at a nerve root.

average of 2.5 periradicular corticosteroid injections per patient (range 1–6). Despite the fact that all 68 patients were potential surgical candidates, they all made a satisfactory recovery without the need for surgical intervention. Forty-eight patients (76%) did not experience any arm pain, and of the 15 patients (24%) who did, this improved from a score of 10 to an average of 2 (range 1–4) on a 10-point pain scale. The conclusion of the study was that patients with cervical radiculopathy make a satisfactory recovery with serial periradicular corticosteroid injections without the need for surgical intervention.[93]

Epidural injection

Epidural injections have been used to treat radicular pain from herniated discs, spinal stenosis, chemical discs, chronic pain secondary to post-cervical surgery syndrome, and chronic neck pain of discogenic origin. Epidural injections in the cervical spine are performed via either an interlaminar or a transforaminal approach. There are a number of studies supporting the benefit of cervical epidurals.[94,95] However, the evidence for cervical interlaminar epidural injections has been a subject of debate and at best has had only moderate success in managing cervical radiculopathy, while there is no evidence available for the management of axial neck pain, post-surgery syndrome or discogenic pain.[96–98] In our opinion, cervical epidurals are used far too often for conditions that are easily treated by simpler measures, such as manipulation and nerve root infiltrations. The injection is only called for in radicular pain that lasts longer than a year, has no tendency to spontaneous recovery and is not responding to manipulation (see p. 188).

The injection is always given in theatre conditions; access to the epidural space is obtained under sterile conditions with loss of resistance techniques under fluoroscopic visualization.[99] The epidural space is entered between C7 and T1, and 10 mL of either a steroid solution or a mixture of local anaesthetic and steroid is injected.

Collars

Partial or total immobilization of the neck should not be considered as a treatment for neck pain. It does not bring about reduction nor does it influence the normal spontaneous evolution of radicular pain. The role of a collar in non-traumatic cervical lesions is restricted to that of a prevention measure or a psychological support: it gives the patient a sense of security.[100]

Immobilizing collars are intended to prevent excessive movement that could exacerbate pain. Soft collars seem to have little effect on controlling neck movement[101,102] ; neither do hard collars (for example, the Philadelphia, NecLoc and Miami J collars) have the necessary effect, although they are more rigid.[103–105] Weight-relieving collars (for example, the Four Poster brace) diminish the weight of the head on the spine and can therefore be used in compression phenomena, such as cord compression, lateral recess stenosis or intractable neck pain.[106]

Prophylaxis

The best approach to a disc displacement is to try to reduce it, whereafter all symptoms disappear. However, because a disc is a cartilaginous structure and cannot heal, it may displace again at any time. Too many recurrences indicate that the disc is unstable and that further measures should be taken to stabilize it. First of all, the patient should avoid keeping the neck in flexion or fixed for a certain period of time. During the night a pillow should be used that enables the patient to hold the neck in physiological lordosis when lying supine, or in the neutral position when lying on the side.

When a collar is necessary, wearing it during the day (and if possible also at night) for several weeks or daily suspension at home may help to stabilize the reduced fragment.

Awaiting spontaneous recovery

Acute torticollis undergoes spontaneous cure in 1–2 weeks. The pain is constant and quite severe, and the head may be fixed in deviation, usually side flexion and occasionally flexion. After a few days the symptoms begin to diminish, but it may take 7–10 days for the pain to disappear completely.

Unilateral, central or bilateral neckache and cervicoscapular pain have no tendency to spontaneous recovery; nor has bilateral arm pain with or without paraesthesia in the hands.

Unilateral radicular pain recovers spontaneously in the course of several months, reckoned from the onset of radicular pain, not of scapular discomfort. When muscular paresis is not present, recovery may take 3–4 months. When a palsy is present, the pain disappears more speedily, usually in 2–3 months. Muscular power is restored within 3–6 months after symptoms have ceased. The only exception is a C8 root palsy, which may take up to 6 months to disappear and may occasionally leave a patient with a permanently weak thumb.

Time and patience should be employed to explain the mechanism of spontaneous recovery to the patient and to give a good prognosis (see p. 157). A continued interest should be taken, with regular review until symptoms have largely subsided so as to discourage the patient from seeking futile and expensive treatments elsewhere.

Surgery

Surgical intervention for neck pain and/or radicular pain is seldom required.[107] In the absence of neurological deficit, it has no better prognosis than the natural history of the process.[108] If the neurological deficit is caused by a posterolateral disc protrusion, natural history usually provides just as good long-term results as surgical interventions.[109,110] However, if the neurological deficit is caused by a bony outcrop in the lateral foramen, surgery will become inevitable. Surgery is also the treatment of choice in cervical canal stenosis, leading to myelopathy.

Technique

Currently, anterior cervical discectomy with fusion is the gold standard in the surgical treatment of cervical disc herniations.[111–113] Since the introduction of the technique in 1958 various anterior fusion methods have been developed.[114–116] The anterior approach has several advantages over posterior decompression, i.e. direct decompression of the spinal cord and roots, better alignment and a lower degree of invasiveness. Several modifications have been developed, but there is currently no consensus regarding the optimal technique.[117] Microsurgery, known as the posterior keyhole laminotomy-foraminotomy, is used mainly for single-level radiculopathy caused by osteophytic compression in the lateral recess.[118,119]

Treatment of non-discogenic lesions

The treatment techniques discussed here are: manipulation and capsular stretching, deep transverse friction and injection/infiltration.

Manipulation/capsular stretching

Indications

Migraine

Sometimes an incipient attack of migraine can be aborted with 30 seconds of strong traction on the neck. Although it is not clear what mechanism is responsible, Cyriax thought that stretching the carotid artery might come into play.

In middle-aged or elderly people, and especially in those who have had migraine from adolescence, manipulation can also be preventative. The techniques that are used are the same as for reduction of disc displacements: straight pull, rotation and side flexion under traction (see p. 189). When neck movements do not cause pain, one session – consisting of one manœuvre in all four directions – may suffice. Painful movements indicate that 2–3 treatments may be necessary before all discomfort ceases. This is a purely empirical finding, which Cyriax identified when patients treated for an ordinary disc lesion reported that, subsequent to manipulation, their attacks of migraine diminished or even disappeared.[120]

Capsuloligamentous disorders

Simple mobilizations without traction can be used to treat some soft tissue lesions in the neck.

Generalized arthrosis

Early arthrosis of the upper cervical joints which presents with upper neck pain, a moderate full articular pattern and a ligamentous end-feel responds well to a few sessions of *quick stretching* in rotation and side flexion to both sides.

In more advanced cases with gross symmetrical limitation and a hard end-feel, the treatment will consist of gradual *slow stretching* in all four directions. Up to four sessions may be necessary.

Facet arthrosis

Manipulation of the facet joint by gradual *capsular stretching* produces reasonable results. The range of movement will probably remain unchanged but the discomfort is largely abolished after 2–4 sessions, perhaps in combination with deep transverse friction (see p. 202) or with facet injection (see p. 203).

Ankylosing spondylitis

Painful stiffness of the neck can be temporarily offset by *slow stretching* in all directions. The manœuvre can be repeated as often as seems necessary – not during a flare-up of the condition – and such mobilizations are effective as long as bone-to-bone end-feel has not been reached.

Postconcussional syndrome

When diffuse capsular adhesions have formed about the occipitoatlantoaxial joints they can easily be ruptured by *quick stretch* manipulation in the direction that has been found to be painful at its extreme. Two to three treatments may be required.

Morning headache in the elderly

Symptoms can be lastingly eliminated by 1–2 sessions of *slow stretching*. There is no upper age limit to this approach. In very old patients only one movement is forced at a time, which means that the patient may have to attend several times before full recovery is obtained.

Indications and types of manipulation for non-disc lesions are listed Boxes 11.7 and 11.8.

Mobilization techniques without traction

Forced rotation

The patient lies supine on the couch.

The manipulator stands at the patient's head. If the neck is to be rotated to the right or left, the right or left thenar

Summary of types of manipulation for non-disc lesions

Under traction

- Migraine

Without traction

Quick stretch

- Early arthrosis
- Diffuse capsular adhesions after trauma

Slow stretch

- Advanced arthrosis
- Ankylosing spondylitis
- Arthrosis of a facet joint
- Morning headache

eminence is placed against the patient's left or right maxilla at the temporomandibular joint and the fingers are hooked around the chin. The other hand grasps the occiput and the head is held in slight extension. The head is turned to the end of range and movement is then forced by a simultaneous action of both hands in opposite directions.

Quick stretch results from a manipulative thrust over a very small amplitude at high velocity. Ligamentous adhesions may be felt (and heard) to break. This manœuvre is carried out once and a painless range ensues.

Slow stretch is obtained by maintaining a steady push at the extreme of range for as long as the patient can tolerate, usually between 30 and 40 seconds. Pressure is then very slowly released and the head gradually brought back to the neutral position (Fig. 11.17). The movement is then repeated once or twice, depending on the patient's age.

Forced side flexion

The patient lies supine on the couch and the manipulator stands at the patient's head. When side flexion is to be to the right, the head is supported under the occiput with the fingers of the left hand and the thenar eminence lies against the side of the head above the ear. The metacarpophalangeal joint of the index finger of the right hand is placed against the transverse process of the sixth cervical vertebra and the thumb is kept extended to avoid the patient's trachea. This hand serves as a fulcrum and helps to keep the movement localized to the cervical spine only.

The quick stretch manœuvre is a short manipulative thrust, the result of a simultaneous scissor movement of both hands in opposite directions.

During slow stretch, sustained procedure keeps the head side-flexed at the extreme of range (Fig. 11.18). Because the force has to be maintained for some time, this technique is quite tiring for the operator and therefore extra pressure can be applied with the knee against the elbow. The foot is therefore placed on a stool.

Deep transverse friction

Deep transverse friction can be given to the occipital muscular insertions and to the capsules of the facet joints.

Post-traumatic muscular lesions

Post-traumatic lesions at the occipital insertion of the semispinalis capitis and, rarely, the splenius capitis muscles give rise to occipital pain on resisted extension and resisted side flexion towards the affected side. These features can be treated with deep transverse massage performed 2–3 times a week. Chronic cases may need up to 20 sessions for recovery.

Technique

The patient lies prone on a couch with an opening near the head through which he can breathe. The physiotherapist sits on the painless side, level with the patient's neck. The head is steadied with one hand and the other imparts the massage. This is done with the index finger, reinforced by the middle

Fig 11.19 • Deep transverse friction to the occipital insertions of semispinalis or splenius capitis muscles.

finger, and counterpressure is taken with the thumb at the painless side. Tenderness is sought in the attachment of the semispinalis capitis between the superior and inferior nuchal lines. If the lesion lies in the splenius capitis, tenderness is found more laterally at the mastoid process.

The working forearm is held in slight supination, which enables the therapist to exert upwards pressure against the occipital bone, at the exact point of the lesion. The thumb is used as a fulcrum and massage imparted by a to-and-fro movement over the tender area (Fig. 11.19).

Facet arthrosis

Early arthrosis, usually localized at the C2–C3 or C3–C4 interapophyseal joint, can be treated with deep transverse friction. If the result is poor, either capsular stretching or infiltration of a steroid suspension is substituted.

Technique

The patient sits at the couch with the elbows resting on it and the chin supported by cupped hands. The physiotherapist, standing by the patient's painful side, palpates the area where the lesion is expected to lie. If the most tender spot corresponds to the facet joint considered to be responsible for the pain, massage is applied there. The articulation is found quite laterally, just behind the posterior border of the sternocleidomastoid muscle. Massage is performed with the flexed thumb and counterpressure with the fingers. The direction is oblique, so that, parallel to the joint line, the thumb passes downwards as it is drawn backwards by internally rotating and abducting the shoulder and flexing the wrist[121] (Fig. 11.20).

After 5 minutes' treatment, movements are tested again. When the correct spot has been located, there should be some improvement, in which case massage is continued for another 5–10 minutes. Lack of improvement indicates that the chosen level is not right and reassessment is carried out. The patient is treated 2–3 times a week, and 3–6 weeks of treatment may be required.

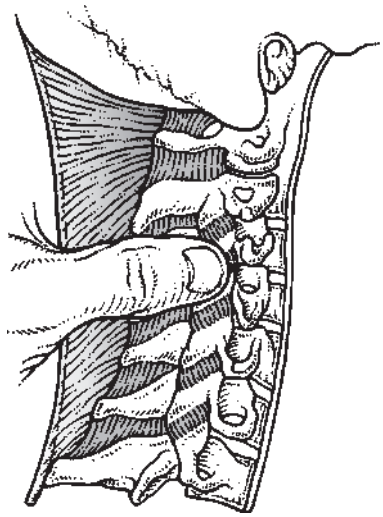

Fig 11.20 • Deep transverse massage (Troisier and Elroy technique).

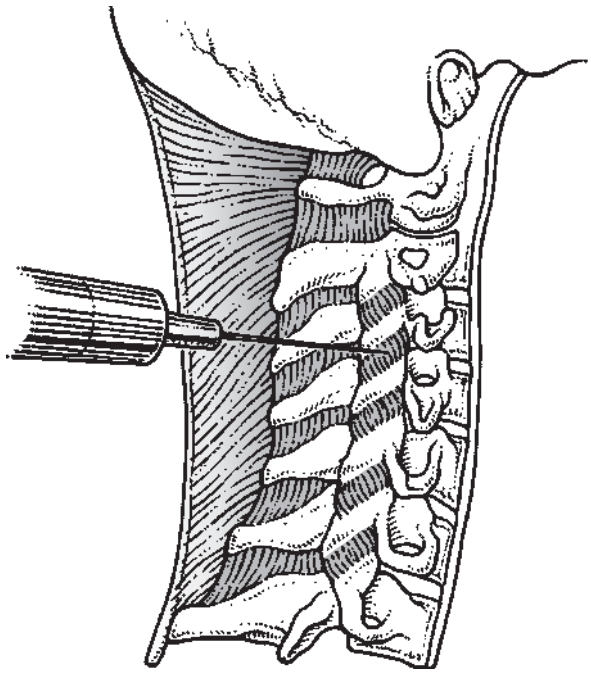

Fig 11.21 • Infiltration of a facet joint capsule.

Injection/infiltration

Early and more advanced arthrosis of an interapophyseal joint may respond to a steroid injection in the facet joint capsule. Unilateral localized pain at the mid-neck, which does not respond to manipulation, must be considered to originate from a facet joint and is most frequent at the C2–C3 and C3–C4 levels.

Intra-articular steroid is called for when ankylosing spondylitis or rheumatoid arthritis has affected the cervical spine and one or two particular facet joints only are painful.

Technique

The patient sits at the couch with the elbows resting on it and the chin supported by cupped hands. The operator stands behind the patient and palpates for the tender facet joint, which lies 2–2.5 cm from the midline. A 1 mL tuberculin syringe is filled with 10 mg of triamcinolone acetonide suspension and fitted with a thin needle 3 cm long. The needle is inserted until it strikes the lamina and is then moved until it traverses a tough ligamentous structure, the capsule, before it abuts against cartilage. This feeling assures the operator that he has reached the joint. A few drops are then infiltrated at several adjacent points, some intracapsular, some intra-articular. If the needle is thrust in too close to the midline it is possible to traverse the interlaminar space and enter the spinal canal. One to two infiltrations will render the patient pain-free for a considerable period (Fig. 11.21).

When a nerve root becomes compressed by an osteophytic outcrop and symptoms occur which are severe enough to concern the patient, infiltration with triamcinolone acetonide around the nerve root is tried. The technique for this is described on p. 199.

Pain in the shoulder is, after low back pain, the most frequent complaint of orthopaedic patients. Despite the frequency of shoulder lesions – and the consequent pain and disability – much confusion still exists as to aetiology, terminology and treatment,[1] in contrast to the statement made by Cyriax:[2,3]

> The shoulder is the most rewarding joint in the whole body. As a rule, one can always come to a clear diagnosis, and, if treated in the proper way, most shoulder lesions seem to be curable. Moreover, it is the most suitable joint for the general practitioner, since almost no technical aids are required. A good history and full clinical examination, together with a detailed knowledge of the anatomy, suffices to solve the majority of the shoulder problems.

Complicated cases that are difficult to diagnose exactly are encountered. If clinical findings are difficult to interpret, the following general points should be of help.

First, it should be realized that double lesions do exist, clouding the diagnosis. For example, it is not uncommon to find supraspinatus tendinosis together with infraspinatus tendinosis or in association with subdeltoid bursitis. In these doubtful cases, a diagnostic infiltration of a local anaesthetic can be most helpful in isolating the second lesion.

On other occasions, patients present with a painful limitation of passive movement together with pain on resisted movements, and the question arises as to whether the problem is in an inert or a contractile structure. If there is capsular limitation on examination, the joint should be treated first. If resisted movements remain painful after the joint has been managed appropriately, then the tendons should be treated. This approach is the best one, because resisted movements very often become negative after arthritis has disappeared. The only explanation for the phenomenon is the close relationship between the capsule of the shoulder and the surrounding tendons.[4] It can easily be understood how tension on the contractile structures may influence the pain originating in arthritis. Therefore pain on resisted movement(s) in association with an articular pattern should not be interpreted as being caused by a simple tendinosis. Of course, a severe tendinosis can limit active movement, because of the pain. But passive movements are of full range with a normal end-feel, even though there might be severe pain at the end of movement.

An arthritis is an arthritis, a tendinosis is a tendinosis and both have to be treated as such. It is a common misbelief that, as long as steroid is injected somewhere in the shoulder area, it will spread and cure the lesion, no matter where the lesion lies or where it was injected.[5] In fact, if there is one region in the body which ought to be diagnosed and treated very specifically it is the shoulder. It is necessary to replace a vague diagnosis such as 'rotator cuff disease' or frozen shoulder by a precise one indicating exactly what is wrong.[6–8]

Referred pain

Pain referred to the shoulder

Pain referred to the shoulder, and possibly further down the arm, can be caused by nerve root compression, mainly as the consequence of a posterolateral cervical disc protrusion. A good history is important; the pain has usually started in the neck, probably interscapularly, and has shifted laterally into the arm and hand. Very often the pain is worst at night and is accompanied by pins and needles and numbness. Most frequently the C7 nerve root is compressed, causing pain at the posterior aspect of the whole arm to the second, third and fourth fingers. Other nerve roots can also be involved in a cervical disc lesion but this is far less frequent. Referral to the appropriate dermatome is usual.

In a posterocentral cervical disc lesion with compression of the dura mater, the pain does not spread beyond the deltoid area. Therefore arm pain is not present.

One rare disorder causing pain down the arm is a cervical neuroma. The condition starts with pain in the arm, which progressively spreads proximally as the tumour increases in size.

Other possible causes of referred pain at the shoulder are visceral disorders. The diaphragm is largely developed from the third and fourth cervical segment, the heart from the eighth cervical to the fourth thoracic. Therefore both can give rise to pain in the shoulder and arm. Irritation of the diaphragm and of the phrenic nerve, for example by blood or air under the diaphragm, is another well-known source of acute shoulder pain.[9,10]

A pulmonary neoplasm at the base of the lung with involvement of the diaphragm can provoke pain in the shoulder area. The same may also happen with a tumour of the superior sulcus (Pancoast's tumour). The majority of these patients complain of shoulder pain and are often mistakenly thought to be suffering from a musculoskeletal lesion.[11,12]

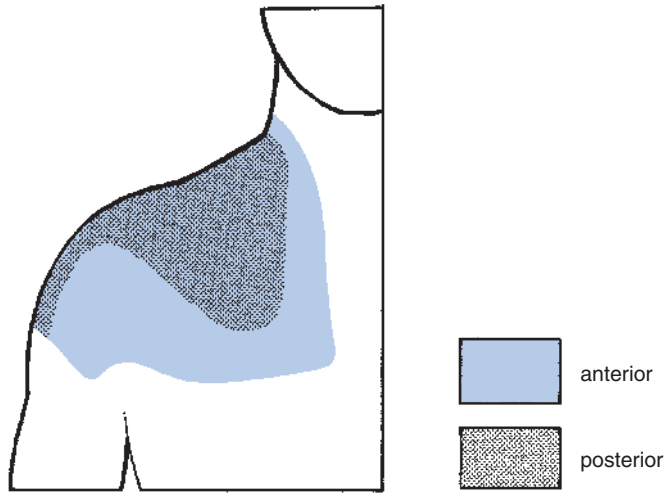

Fig 12.1 • The C4 dermatome.

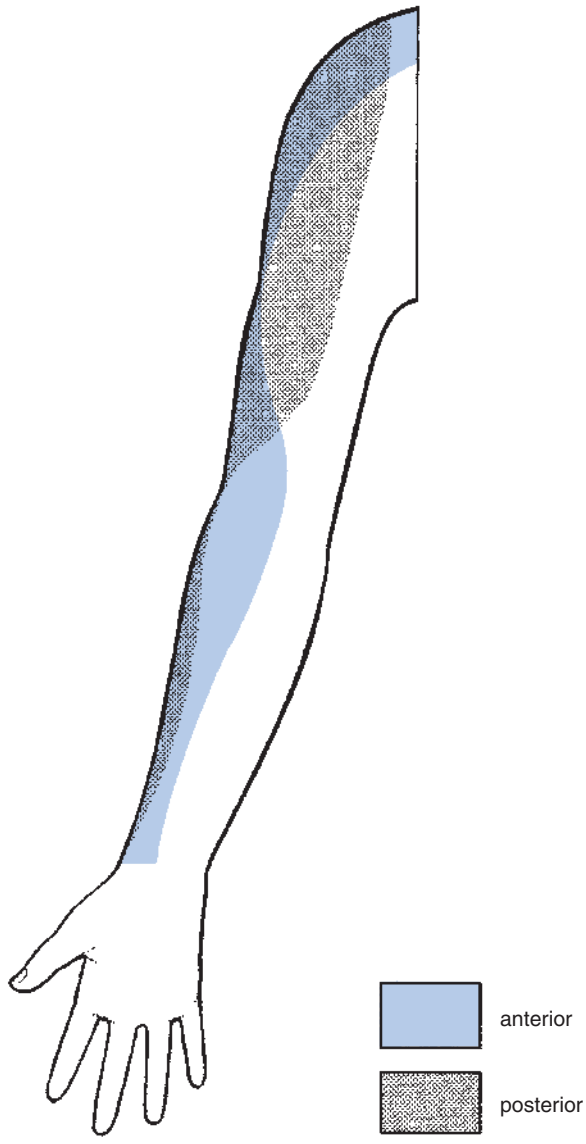

Fig 12.2 • The C5 dermatome.

Pain referred from the shoulder

Most structures around the shoulder are derived from the C5 segment. There is one important exception: the acromioclavicular joint, which is of C4 origin (Fig. 12.1). In acromioclavicular joint problems the pain is felt at the tip of the shoulder, with little spread. Exceptionally, when the lesion lies at the inferior acromioclavicular ligament, the pain can spread into the upper arm.

In a lesion of one of the other shoulder structures, such as in all types of tendinosis, arthritis and subdeltoid bursitis, the pain is not so much felt at the tip of the shoulder but rather starts in the deltoid region and may spread further down the radial aspect of the arm to the base of the thumb (C5 dermatome; Fig. 12.2). How far down the arm the pain is referred depends on the severity of the lesion: the more severe the inflammation, the further the pain will spread. In glenohumeral arthritis, the degree of pain reference is of particular interest

in following the healing process: as the patient improves, the inflammation decreases and the pain spreads less far.

History

The first question to be elucidated by the history is whether the pain in the arm is genuinely from a shoulder lesion or whether it is the consequence of a more proximal lesion, arising perhaps from the cervical spine. If the answer to this is not clear from the history, a preliminary examination, including tests of the cervical spine, shoulder and elbow, is necessary.

In arthritis of the shoulder, the history will be important to establish the stage (see Ch. 13). In other disorders it is of less significance.

The answers to a number of questions (summarized in Box 12.1) will be needed.

- *What is your age?* Age can be relevant in several disorders. It can be helpful in defining the exact type of arthritis. Traumatic arthritis will only be met after 40 years of age, arthritis from immobilization after the age of 60. Subdeltoid bursitis might be present between 15 and 65 years of age. Tendinosis can occur at any adult age.
- *What is the pain and does it radiate?* Pain starting in the deltoid area and spreading towards the wrist, along the radial aspect of the arm, is caused by a lesion that originates in C5. Such pain may be felt in the whole dermatome or only in part of it. The majority of the shoulder structures belong to the C5 segment. The acromioclavicular joint, a C4 structure, is the main exception. A patient who indicates the tip of the shoulder only as the site of pain suggests strongly that there is a lesion of the acromioclavicular joint. Whether the pain is caused by arthritis, bursitis or simple tendinosis will make no difference to where or how far distally the pain is felt. The distal spread of referred pain depends only on the degree of inflammation. It is routine to ask if the pain remains above the elbow or radiates below it – a matter of particular importance in arthritis.
- *Is there any pain in the arm at rest?* This gives information about the severity of the lesion: if spontaneous pain is present, there is a greater degree of inflammation than if pain is felt only on movement. Again, the answer to this question is one of the criteria for judging the stage of arthritis.
- *Can you lie on the affected side at night?* Pain when lying on the shoulder indicates more severe inflammation than just pain on exercise. Bursitis, tendinosis or arthritis may make it impossible for the patient to lie on the affected side at night. Consequently, this question is not of much help in defining the exact nature of the structure at fault. However, it is rather important in following the resolution of the disorder: as the condition improves, the pain at night diminishes and finally disappears.
- *Did the pain come on spontaneously or was there any particular reason for it, such as overactivity or an injury?* It is clear that overactivity may provoke tendinosis. In a ruptured tendon, however, one should not necessarily expect recent overuse. Overactivity can also cause arthritis in a joint that is already osteoarthrotic; this is just as true for the acromioclavicular joint as it is for the glenohumeral joint. In haemophilia, haemarthrosis usually comes on spontaneously; it is more common at the knee but may occur at the shoulder as well.
- *For how long have you had the pain?* If the pain has already been present for some months, an acute subdeltoid bursitis can be excluded because the full course of this condition is 6 weeks. In addition, onset is abrupt over a few days, sometimes only hours, as in an attack of gouty arthritis. Arm pain because of root compression by a cervical disc protrusion wears off in about 4 months. Long-standing pain can be the outcome of a chronic subdeltoid bursitis or a simple tendinosis. Both can last for years. Monoarticular steroid-sensitive arthritis can take up to 2 years to disappear spontaneously.
- *Are any other joints affected?* A more generalized inflammatory disorder is expected if other joints have been previously involved or are attacked at the same time. Indeed, the shoulder joint can be the seat of rheumatoid arthritis, lupus erythematosus and ankylosing spondylitis.
- *How is your general condition? Have you had any operations?* Recent unexplained loss of weight can be the first sign of a carcinoma. A primary tumour at the shoulder or metastases can be a local source of shoulder pain. A Pancoast's tumour of the lung often provokes pain in the shoulder area.

Box 12.1

Summary of history taking

- Age?
- Where is the pain? Does it radiate?
- Pain at rest or only on use?
- Can you lie on that side at night?
- How did the pain come on: spontaneously/overuse/injury?
- For how long have you had the pain?
- Are other joints affected?
- General condition? Any operations?

Inspection

The inspection starts with checking what position the head is held in and whether both shoulders are level. It is important to check for redness, swelling, muscular wasting or any deformity such as scapular winging. A step deformity at the upper lateral aspect of the shoulder is caused by an acromioclavicular dislocation, with the distal end of the clavicle lying superior to the acromion. Atrophy of the upper trapezius may indicate spinal accessory nerve palsy.[13] Atrophy of supraspinatus and/or infraspinatus is caused by either a supraspinous nerve palsy or long-standing rotator cuff lesions.[14] Effusion of more than 10–15 mL arising from the glenohumeral joint is normally

visible on inspection at the anterior centre of the humeral head. Local swelling may also be found in acute, haemorrhagic or chronic subdeltoid bursitis and in acromioclavicular joint cysts,[15] as well as in tumours.

Functional examination

The shoulder is an easy joint to examine. The intention is to obtain the maximum information from a minimum number of tests. Recent studies have shown high inter-rater and intra-rater reliability of the examination scheme presented.[16–18]

Preliminary examination

In most cases of shoulder–arm pain the history will reveal whether the pain originates from the shoulder itself or is of cervical origin. Sometimes, however, the examiner is not quite sure and will then use a quick survey of all structures between C1 and T2 to exclude other sources of pain in the upper quadrant. It is good practice to perform a preliminary examination of the upper quadrant in the following situations:

- There is or was neck pain
- There is or was trapezius pain
- The pain is only at the top of the shoulder and/or at the clavipectoral area
- The pain is in the arm but remains quite localized
- The pain in the arm is influenced by movements of the neck
- Coughing, sneezing or taking a deep breath increases the pain
- There is paraesthesia.

The preliminary examination of the upper quadrant is comprised of the following tests (Box 12.2):

1. Six active movements of the cervical spine – range of movement and/or painfulness; quick survey of the cervical spine
2. Active elevation of the shoulder girdle – range of movement and/or painfulness; quick survey of all the structures of the shoulder girdle
3. Resisted rotations of the cervical spine and resisted elevation of the scapulae; quick survey of nerve roots C1–C2–C3–C4
4. Active elevation of both arms – range and pain; quick survey of shoulder and shoulder girdle
5. Resisted movements of the upper limb – strength and pain; this is both a quick test for peripheral lesions at the elbow–arm–wrist and a neurological examination of roots C5–C6–C7–C8–T1 and of the peripheral nerves of the upper limb
6. Passive examination of the elbow; quick test of the elbow joint.

Any influence on the pain or any weakness will guide the examiner approximately towards the affected area, which is then examined thoroughly.

Thumb

19. Resisted extension (C8)

Finger

20. Resisted adduction of the little finger (T1)

If the examination reveals that the lesion lies in the shoulder, the examiner will try to define in which particular structure the lesion is situated by carrying out a detailed shoulder examination; this is comprised of 12 basic tests (summarized in Box 12.3).

Basic functional examination of the shoulder

Clinical examination should not begin by palpation for local tenderness. This widespread habit is a common cause of misdiagnosis.

The basic shoulder examination consists of 12 tests. It is important always to perform every basic test and not to stop, even if the diagnosis appears clear after a limited number of tests. Stopping too soon can easily lead to an incomplete diagnosis. It is important to realize that, in mixed patterns of pain

on both passive and resisted movement(s), pain on resisted movements does not exclude a disorder in an inert structure, nor pain on passive movements a disorder in a contractile structure. These results may sometimes lead to diagnostic difficulties (see Ch. 4).

Accessory tests may be called for. They will only be performed if, after the basic functional examination, the diagnosis still remains unclear. After the basic examination is complete, at least a differential diagnosis should be in mind. To arrive at the final diagnosis, one or more accessory tests may be useful.

Box 12.3

Summary of the basic functional examination of the shoulder

Elevation

1. Active elevation of both arms
2. Passive elevation
3. Painful arc

Glenohumeral joint

4. Passive scapulohumeral abduction
5. Passive lateral rotation
6. Passive medial rotation

Resisted movements

7. Adduction
8. Abduction
9. Lateral rotation
10. Medial rotation
11. Flexion of the elbow
12. Extension of the elbow

Elevation of the arm

Active elevation

The patient is asked to raise both arms sideways above the head, as far as possible (Fig. 12.3a). The range of movement and the influences, if any, on pain are noted.

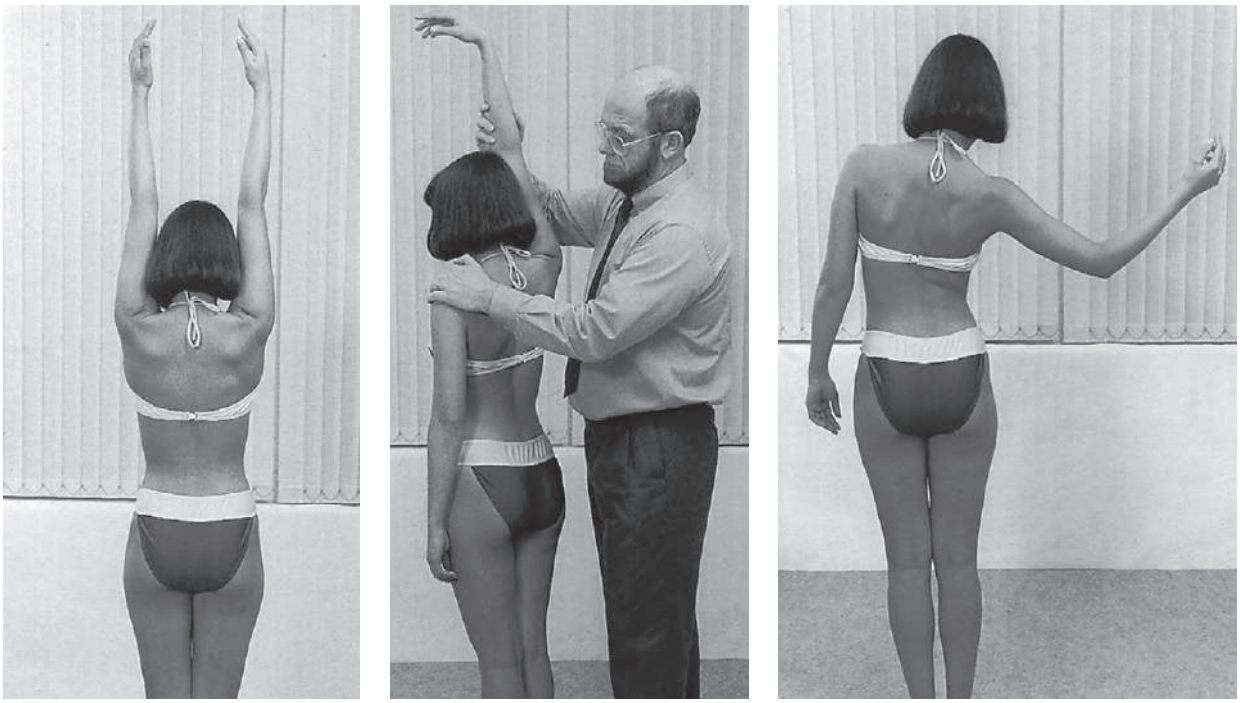
This very unselective and broad test investigates both inert and contractile structures, not only of one single joint, but also of all five 'joints' of the shoulder girdle (see online chapter *Clinical examination of the shoulder girdle*). Therefore, the result should always be interpreted in light of the other tests. As it gives a good idea of the patient's willingness to cooperate, it will also help in identifying a person who has no genuine lesion but is feigning illness.

Passive elevation

The examiner takes the patient's arm just proximal to the elbow, brings it upwards from the side and pushes it as far as it will go towards the head. At the same time counterpressure is applied over the contralateral shoulder, preventing the patient from side-flexing to the other side (Fig. 12.3b). Pain, range of motion and end-feel are noted. Because this movement comes to a halt when the axillary portion of the capsule is stretched, the normal end-feel is elastic.

Painful arc

The patient raises the arm, actively, in a frontal plane and concentrates on pain likely to occur at mid-range, being asked



(a) (b) (c)

Fig 12.3 • Elevation of the arm: (a) active elevation; (b) passive elevation; (c) painful arc.

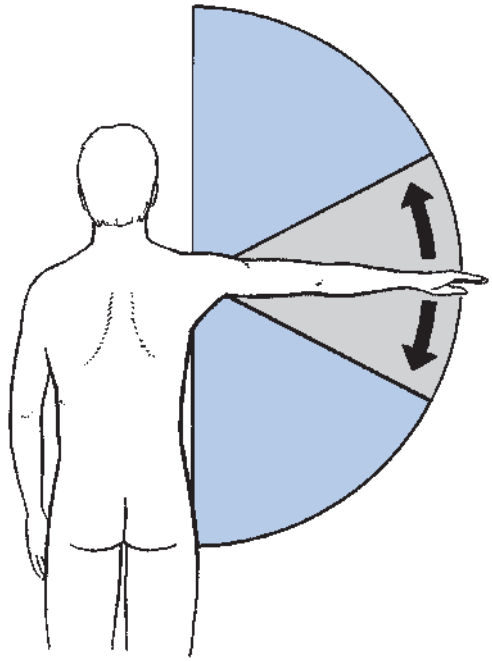


Fig 12.4 • Painful arc.

to indicate where pain starts and where it stops on further elevation (Fig. 12.3c).

A painful arc is defined as the symptom appearing somewhere around the halfway mark, with the arm near the horizontal and disappearing before the end of the movement (Fig. 12.4). This description holds even if pain is again present at the end-point. Some patients have an ascending arc, others a descending one; both are regarded as a real painful arc and no diagnostic distinction is made between them. Sometimes an arc becomes visible to the examiner, i.e. when the patient avoids the painful movement by bringing the arm towards the front of the body during elevation.

A painful arc is more likely to occur during active elevation rather than during passive movement because contraction of the abductor muscles pulls humerus and acromion closer to each other. It always implies a lesion in the subacromial area or its neighbourhood. Because of their localization between acromion and greater or lesser humeral tuberosity, the affected structures can be painfully pinched.

Three tests for the glenohumeral joint

Passive scapulohumeral abduction

The lower angle of the scapula is immobilized by the thumb and index. With the other hand, the examiner takes the patient's arm just above the elbow and lifts it up until the scapula starts to move (Fig. 12.5a). It is important for the patient not to assist this movement actively because then the scapula immediately starts to rotate, so making the movement a compound one involving several joints.

The normal range of scapulohumeral abduction is about 90°. Performed in the way described, only movement between humerus and scapula takes place. If the movement is impaired, the glenohumeral or the subacromial joint is at fault.

Passive lateral rotation

The examiner takes the patient's arm above the wrist, flexes the elbow to a right angle and pulls the arm with gentle pressure into full lateral rotation, meanwhile avoiding extension by holding the patient's elbow against the side of the abdomen. The trunk is immobilized by bringing the other hand around the patient's contralateral shoulder (Fig. 12.5b).

This movement comes to a stop by stretching the anterior portion of the capsule. Therefore the end-feel is elastic. The normal range is about 90°. Since individual differences exist, both sides should always be compared.

Besides the anterior portion of the joint capsule, other structures, such as the subcoracoid bursa, the acromioclavicular joint and the subscapularis tendon, are tested as well. Limitation of the movement is mainly found if something is wrong with the scapulohumeral joint itself; in this event, a harder end-feel is usually present.[19,20] A simple tendinosis of the subscapularis does not cause limitation of the movement but may render it very painful.

Passive medial rotation

With one hand still just above the patient's wrist and flexing the patient's elbow to 90°, the arm is brought into full medial rotation, without extension. The examiner's other hand is placed dorsally between the scapulae (Fig. 12.5c). The normal amplitude is about 90°. As before, this movement should be compared on both sides.

Occasionally a painful arc can be present on medial rotation. This has the same diagnostic value as a painful arc on elevation and bears the practical consequence that in order to test for real limitation of movement the examiner must persist to get beyond the painful arc.

Resisted movements

Resisted adduction

The patient is asked to pull the right arm towards the body as hard as possible. The examiner puts one hand around the elbow, and the other at the patient's ipsilateral side (Fig. 12.6a).

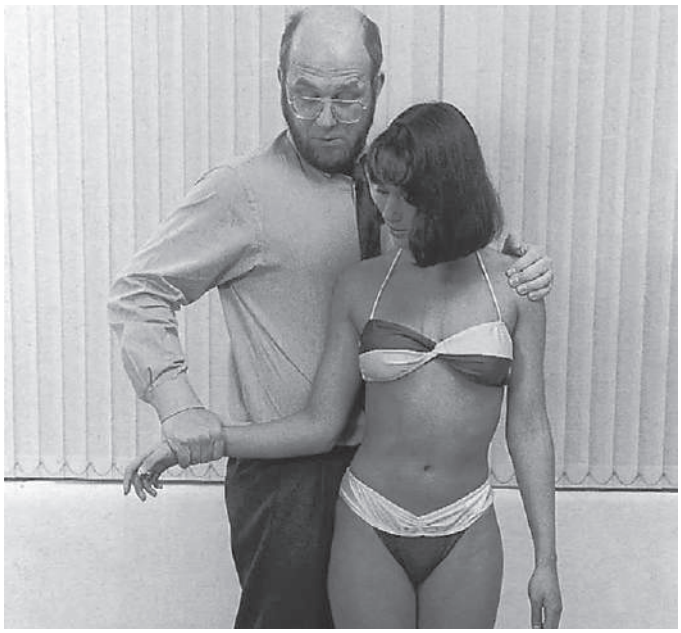
Resisted abduction

The test is performed with the arm hanging down, a few degrees of abduction being permitted. The examiner asks the patient to push his or her arm to the side, meanwhile applying counterpressure at the elbow. The examiner's other hand stabilizes the patient on the contralateral side (Fig. 12.6b).

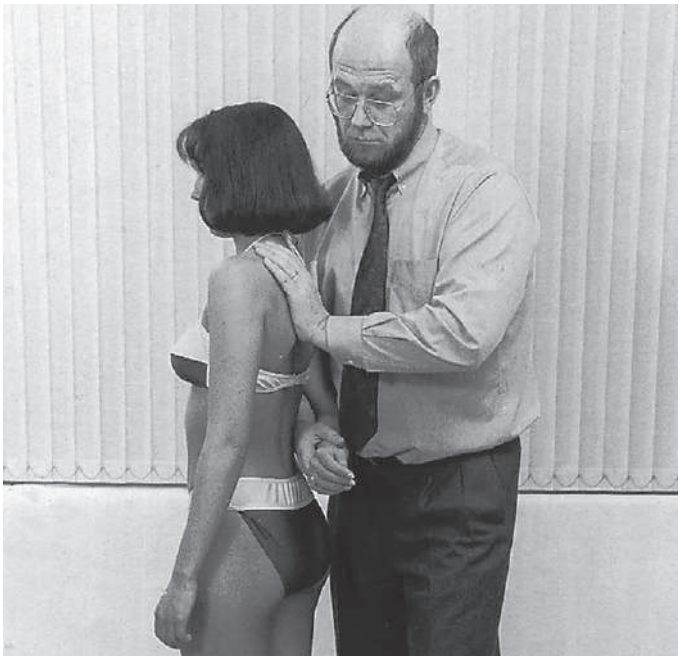
Resisted lateral rotation

The patient is asked to bend the elbow to a right angle and to push the forearm away from the body. To avoid any movement of the trunk, the other hand is put on the patient's contralateral shoulder (Fig. 12.7a). Counterpressure is applied just above the wrist and care must be taken to get two details right. First, the patient should keep the elbow against the body, so that there is no element of abduction. Second, extension of the elbow during lateral rotation is avoided. This is easily checked

(a)



(b)



(c)

Fig 12.5 • Three tests for the glenohumeral joint: (a) passive scapulohumeral abduction; (b) passive lateral rotation; (c) passive medial rotation.

if the examiner puts the little finger underneath the patient's wrist: extension at the elbow causes the digit to move down.

Resisted medial rotation

This is tested in the same position as resisted lateral rotation, but the patient's arm is held at the inner part of the wrist and the forearm is pulled towards the body (Fig. 12.7b).

Resisted elbow flexion

With the elbow still bent at a right angle and the forearm supinated, the forearm is pulled up. Counterpressure is applied to the distal part of the forearm just above the wrist. The other hand is placed on the patient's ipsilateral shoulder (Fig. 12.8a).

Resisted elbow extension

In the same position as for flexion, the patient attempts to extend the elbow. To be able to hold the patient's elbow at 90° of flexion, the examiner puts his or her own elbow on the iliac crest, the arm in an almost vertical position underneath the patient's wrist. The other hand rests on the patient's ipsilateral shoulder (Fig. 12.8b).

(a)

(b)

Fig 12.8 • Resisted flexion (a) and extension (b) of the elbow.

Palpation

General palpation for heat and swelling is done after the functional examination. These may be present in bacterial arthritis and in primary and secondary tumours of the humeral head, glenoid and acromion, and in acute and chronic subdeltoid bursitis.

Palpation for pain is only performed when the basic examination proves that the lesion lies within the reach of a finger. As already indicated, it always follows the clinical examination and never precedes it. Comparison between the two sides is essential. Palpation for tenderness is mainly done in acute and chronic subdeltoid bursitis and in a sprained superior ligament of the acromioclavicular joint.

Accessory tests

Sometimes the diagnosis is still not clear after the basic examination and a differential diagnosis has to be undertaken. At other times, the exact structure at fault has been identified by this stage of the examination but the precise localization of the lesion within that particular structure remains uncertain. In both cases, one or more accessory tests may be required (Box 12.4). Passive horizontal adduction is the only one which is explained here. The other tests are discussed, together with the corresponding disorders, in the following chapters.

Box 12.4

Summary of accessory tests of the shoulder

- Passive horizontal adduction
- Passive horizontal lateral rotation
- Apprehension test for anterior instability
- Apprehension test for posterior instability
- Load and shift manœuvre
- Sulcus sign
- Yergason's test
- Resisted horizontal adduction
- Resisted horizontal extension
- Resisted horizontal adduction with the arm forwards
- Resisted flexion
- Resisted extension
- Pressure against a wall
- Scapular adduction against resistance

Passive horizontal adduction

The patient's arm is brought horizontally in front of the body. At the end of the movement the elbow is pressed gently further towards the contralateral shoulder (Fig. 12.9). Twisting of the patient's trunk is prevented by the examiner bringing the other hand behind this shoulder.

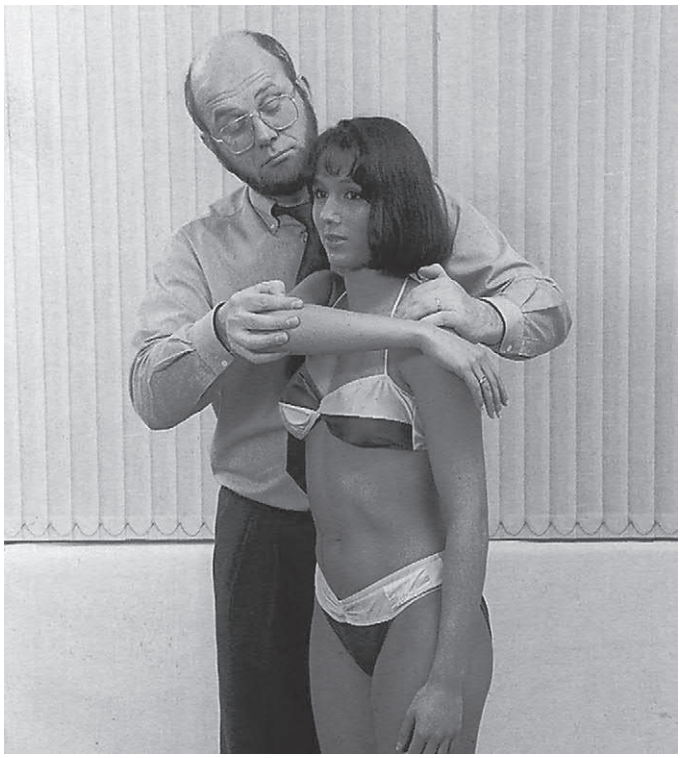

Fig 12.9 • Passive horizontal adduction.

The indications for this test are:

- Sprain of the acromioclavicular joint[21]
- Subcoracoid bursitis
- Subscapularis tendinosis.

Technical investigations

All technical investigations of the shoulder have in common the fact that they are performed to search for anatomical changes. This is in contrast with the objective of a clinical examination, which aims to detect functional deficiencies and/or pain. Anatomical changes that are not causing functional disturbances (remain asymptomatic) are very common in the shoulder region and their frequency increases with age.[22–24] Therefore, one should always interpret technical diagnoses with care and even reluctance, for it is perfectly possible that the lesion seen on imaging is in fact asymptomatic and another lesion that is not shown is at the root of the disability. A common mistake is the combination of a symptomatic glenohumeral arthritis that remains undiagnosed with sonography and an asymptomatic rotator cuff tear that is easily detected with the same technique. We therefore fully agree with Kessel, who states: 'An X- ray is best used to check a hypothesis which has been formed by history and clinical examination. One should eschew the temptation of a shortcut to the X-ray room or scanner.'[25]

Plain radiography

The main indications for radiography of the shoulder are evaluation of fractures and dislocations, imaging of bony disorders such as tumours and metastases, and identification of calcifications in or around tendons. Plain radiographs may also be helpful in the evaluation of anterior and posterior instability. Although ultrasonography is nowadays the most frequently used method to evaluate rotator cuff lesions, plain X-ray examination can be of use in the detection of accompanying appearances, such as changes in the coracoacromial arch, an unusual form or a spur off the acromion.[26] Radiography is also still advocated in long-standing massive cuff tears.[27,28]

Ultrasound scanning

Ultrasound scanning is mainly advocated for the detection of full or partial rotator cuff lesions. In experienced hands it can reveal not only the integrity of the rotator cuff but also the thickness of its various component tendons. Through careful positioning and through knowledge of the dynamic anatomy of the cuff, the experienced ultrasonographer can image selectively the upper and lower subscapularis, the biceps tendon, the anterior and the posterior supraspinatus, the infraspinatus and the teres minor. Ultrasonography has further advantages: it is non-invasive and safe, bilateral examinations are quickly performed, the shoulder can be examined dynamically and, above all, the procedure is inexpensive.[29]

One important disadvantage, however, is that the method has a long learning curve. The results are examiner-dependent and a good outcome can only be expected in experienced hands.[30] Specificity and sensitivity of as high as 98% and 91% respectively in comparison with surgical findings were claimed by Mack *et al*.[31] Others have found an overall sensitivity of 97% in diagnosing full cuff tears and of 91% in partial thickness tears.[32]

Arthrography

Single-contrast arthrography can be helpful in diagnosing complete tears of the rotator cuff, incomplete deep surface tears and instability problems.[33] It will show loss of axillary-fold space and diminished joint capacity in adhesive capsulitis, but because this disorder is so easy to detect clinically, arthrography should never be required. It is of no assistance in clarifying the differential diagnosis in cases of impingement, in the absence of a rotator cuff tear.

Arthroscopy

Arthroscopy is useful for both diagnosis and treatment.[34–39] It should be regarded as an adjuvant in those cases where the normal diagnostic aids are insufficient.[35] As it offers an excellent view of the glenoid, labrum and capsule, it is an excellent technique in repair of shoulder instability.[36]

However, confronted with the almost perfect results obtained through examination technique, the physician should never forget that full and partial tears of the rotator cuff exist in a substantial part of a normal asymptomatic population. Both cadaveric studies[37,38] and imaging studies[39,40] on asymptomatic individuals have demonstrated that cuff defects become increasingly common after the age of 40 and that most occur without substantial clinical manifestations.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has rapidly become a commonly used technique for shoulder evaluation, proving its utility in the evaluation of muscle, tendons, hyaline and fibrous cartilage, joint capsule, fat, bursae and bone marrow.[41] Today it is the most accurate non-invasive method available for imaging the rotator cuff.[42] The major advantages of this modality include its non-invasive nature, lack of ionizing radiation, excellent contrast and anatomic resolution, multiplanar imaging capability, and ability as a single imaging modality to evaluate simultaneously for a wide variety of pathologic processes.[43] One disadvantage is that small foci of soft tissue calcification may be missed on MRI.[44] As with all techniques that provide optimal visualization, one should always take into account the high rate of asymptomatic lesions and never rely simply on the outcome of the technique to make a diagnosis and start a treatment.[45–48]

Computed tomography

Computed tomography (CT) is equally as accurate as MRI for evaluation of the glenoid rim and labrum, the humeral head and the glenohumeral capsule. Nevertheless, MRI is to be preferred because it is more accurate in tendinopathies and no X-ray exposure occurs.[49] In shoulder instability, CT-arthrography seems to be the best diagnostic method.[50]

Bursoscopy

Bursoscopy can be performed under general or local anaesthesia. Although there are almost no indications for bursoscopy,[51] it may be of help in diagnosing lesions of the bursal part of the rotator cuff. At the same time, it offers visualization of the acromial roof.

Limited range of movement

Capsular pattern

Introduction

The capsular pattern at the shoulder joint is a proportional limitation of the three passive scapulohumeral movements. There is some limitation of abduction, more limitation of external rotation and less limitation of internal rotation.[1,2]

A capsular pattern always indicates a lesion of the capsule of the joint, whatever its nature may be.[3] It may be either an acute synovitis or a chronic organized reaction of the fibrous capsule.

In an acute inflammation of the synovia, the selective limitation of movement is caused by involuntary muscle spasm that protects the inflamed joint from further overstretching. In long-standing inflammation of the capsule, structural changes have set in. Intracapsular fibrosis and thickening of the capsule now cause mechanical obstruction of the movements. Several arthrographic[4,5] and magnetic resonance imaging (MRI) studies[6–9] have demonstrated that these adhesions form mainly at the axilla and the anterior portion of the capsule. This greater loss of inferior and anterior capsular elasticity explains the greater restriction of lateral rotation and abduction (the capsular pattern) (Fig. 14.1).

Staging

Although only one capsular pattern at the shoulder exists, it can present in many ways. A clear distinction must be made between the *degree of limitation*, the *stage* and the *phase*. Limitation of movement and stage do not always match.

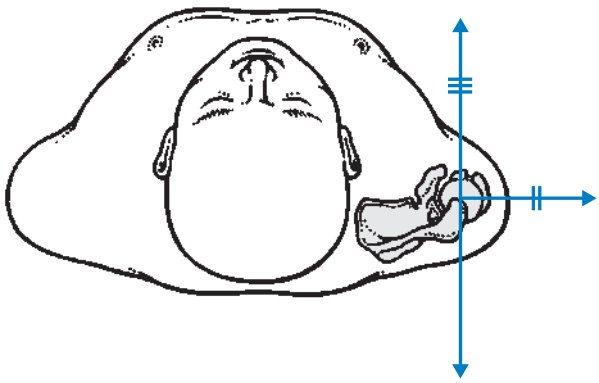

Fig 14.1 • The capsular pattern: for some limitation of abduction, there is more limitation of external rotation and less limitation of internal rotation.

Table 14.1 Capsular pattern: different degrees of limitation*

Severity of limitation	Lateral rotation	Scapulohumeral abduction	Medial rotation
Slight	30°	10°	Full range but painful
Medium	60–70°	45°	10–15°
Severe	90–100°	70–80°	15–25°

*From Cyriax[1]: p. 135.

The degree of the limitation is expressed in its magnitude; limitation can be slight, medium or gross, although it is always in the same (articular) proportion (Table 14.1).

The stage is a clinical estimation of the severity of synovial inflammation. The staging is based on four clinical criteria: pain at rest, nocturnal pain, the distal reference of the pain and the end-feel (Box 14.1). Three stages are considered. Stage I corresponds to a minor degree of inflammation: there is no pain at rest and no nocturnal pain, the pain does not spread beyond the elbow and the end-feel shows no protective muscle contraction. Stage III is the worst: the highly inflamed synovia leads to pain at rest and at night, the pain spreads beyond the elbow, and the end-feel shows protective muscle spasm. From a therapeutic point of view, stage is more important than degree of limitation, especially in post-traumatic arthritis and immobilizational arthritis.

The phase situates the arthritis on the timeline of the natural history. Classically three phases are considered: the painful phase, the progressive stiffening phase and the thawing phase (see p. 223).

During the initial phase of arthritis, when limitation has not yet set in, making a diagnosis can be very difficult. The only finding is pain at the end of all passive movements. It may then be helpful to remember that passive lateral rotation is the most painful movement, accompanied by a slightly abnormal end-feel. It is only after some time that an increasing limitation of lateral rotation sets in, subsequently followed by a diminishing range of both abduction and medial rotation.

Box 14.1

Staging

Stage I: minor inflammation

- No pain at rest
- No pain at night
- Pain remains above the elbow
- Normal or slightly hardened end-feel

Stage III: gross inflammation

- Pain at rest
- Pain at night
- Pain spreads below the elbow
- End-feel indicates muscle spasm

Stage II

- Shows a mixed result on the four clinical criteria (one or more of the criteria are slightly positive and the other ones negative). Example: a patient having pain below the elbow, but no pain at rest, who can lie on that side at night and has a more or less elastic end-feel. This is only one example of a stage II arthritis; all other combinations of the four criteria are possible

Conditions

Stiffness of the glenohumeral joint has classically been called 'frozen shoulder'.[10] Several investigators have attempted to propose a nomenclature to separate different types of shoulder stiffness.[11–13] The subgroup typing was based on both the severity of stiffness and the presence or absence of an associated cause. The group without an apparent background was further subdivided into either 'post-traumatic frozen shoulder', where an injury or a surgical intervention was at the root of the disorder, and 'primary frozen shoulder', where no causative precursor could be found.[14]

Cyriax[1] listed 13 different disorders leading to 'shoulder stiffness' with a capsular pattern (Box 14.2).

Whenever a capsular pattern is found, an attempt is made to categorize the lesion. Differentiation between the subgroups is achieved by history, clinical presentation and paraclinical investigations as follows:

- Try to detect an intrinsic aetiology, which may be either a general disease (rheumatoid type of arthritis) or a local condition: infection, gout, haemarthrosis or tumour.
- In the remaining subgroup where no intrinsic aetiology can be found and the only finding is of a progressive stiffening of the capsule, history will indicate whether the arthritis should be called post-traumatic, post-immobilization or primary.

Categorizing capsulitis of the shoulder in this manner is extremely important because different lesions have a different development and prognosis. Furthermore, categorization is of great use in deciding the course of treatment.

Box 14.2

Classification of 'frozen shoulder'/shoulder arthritis

Classification of 'frozen shoulder'	Cyriax's classification of shoulder arthritis
With apparent aetiology • Rheumatoid/infectious/crystalline • Osteoarthrosis Without apparent aetiology • Post-traumatic frozen shoulder • Primary frozen shoulder	• Traumatic arthritis • Immobilizational arthritis • Monoarticular 'steroid-sensitive' arthritis • Shoulder–hand syndrome • Rheumatoid-type arthritis • Haemarthrosis • Crystal synovitis • Septic arthritis • Primary tumours • Metastases • Aseptic necrosis • Osteoarthrosis • Neuropathic destructive arthropathy

Traumatic arthritis

This condition is almost never encountered in patients younger than 40 years. Because the risk of traumatic arthritis in youth is virtually zero, preventive measures after injury are unnecessary for the young.

Natural history

A capsular pattern may develop after glenohumeral (sub)luxations, contusions or surgical procedures to the shoulder.[15] Most often, however, injury need not have been severe and a traumatic arthritis may precipitate some days after the shoulder capsule sustained an indirect and sudden traction or, for example, after the joint bumped against a wall. Because it can take some weeks for the pain to become bad enough to force the patient to consult a physician, it is quite possible that such a minor accident may have been forgotten.

The evolution and natural history of traumatic arthritis are quite typical. It takes about a year for the lesion to heal spontaneously. During this process, three stages of about 4 months each are observed (Fig. 14.2).[16] In the first, 'painful phase', both pain and limitation of movement increase. In the second, 'progressive stiffness phase', pain diminishes but limitation remains the same. It is not until the beginning of the last 4 months that limitation begins to decrease (the resolution or 'thawing' phase), so that by one year movement is back to normal.[17] Several authors, however, have demonstrated a significant number of patients with a delayed thawing phase and one instance showed persistent stiffness for 6 years.[18–20] Sometimes elevation and lateral rotation may remain slightly restricted permanently.[21]

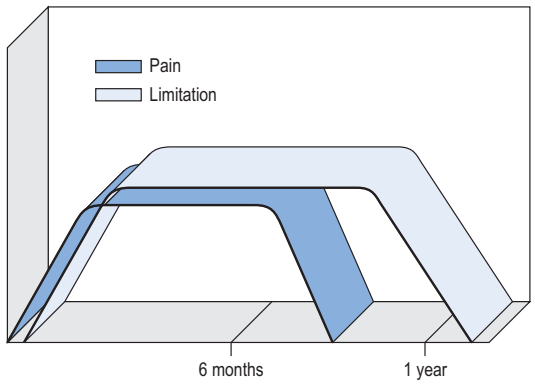

Fig 14.2 • Natural history of traumatic arthritis.

Painful phase

The onset of the arthritis is very characteristic. Immediately after the injury an ache develops that may wear off in 2 days or so but which re-appears a few days later, increasing progressively over the next few months. During the painful phase, the intensity of the arthritis typically evolves from stage I, through stage II to stage III.

In the first 2 weeks after onset, the patient complains of an ache mainly on activity. During this period, pain does not spread beyond the elbow and sleep on the affected side is possible. A subtle capsular pattern can be detected on functional examination: for example, limitation of some 20° on lateral rotation and 5° on abduction, together with a normal (but slightly painful) range on medial rotation. All these movements are also painful at the end of the achievable range. The end-feel may be slightly altered but not definitively abnormal. A clear stage I arthritis is present.

As the arthritis increases, stage II will be found at 2–6 weeks from the onset: pain may interfere with sleep, it spreads below the elbow or a spastic end-feel may be apparent on passive testing. After 2 months, the inflammation is at its worst. Now, with the features of stage III, the patient suffers from continuous pain, day and night, which spreads below the elbow. A limitation of about 80° on lateral rotation, 60° on abduction and 20° on medial rotation may be present. The end-feel is abrupt (hard or muscle spasm).

Progressive stiffness phase

Although the severity of the synovial inflammation may progressively diminish from the fourth month, the limitation in range remains the same for a few more months. With decreasing inflammation, pain at night and at rest gradually disappears but remains above the elbow. The end-feel changes from spastic to hard ligamentous (but still painful). The arthritis gradually returns to stage II and finally, after about 8 months, stage I.

Thawing phase

The final stage of the natural evolution is the resolution or the thawing phase, characterized by a slow and gradual gain in mobility. Usually a few months (4–6) may be required to achieve full functional motion. The joint is in stage III with moderate pain and a hard ligamentous end-feel.[22]

Treatment

The choice of treatment for post-traumatic arthritis should always be adjusted according to the duration and severity of symptoms. Treatment techniques should also be applied in the context of the patient's needs, risk factors and tolerance. Finally, the outcome of the treatment must always be related to the expected natural history of the disease, and treatment is only begun when it is expected to change the course of this natural history positively.[23,24]

Prophylaxis

The primary management for post-traumatic arthritis in the shoulder is prevention: to suppress the natural tendency of most patients to immobilize the painful joint until comfort returns. Therefore, a patient older than 40, seen shortly after a shoulder injury, should be encouraged to use the arm as normally as possible with movement to full range at least twice daily. When the patient has excessive pain, a therapist can undertake mobilization just to maintain normal movement at the glenohumeral joint. The joint should be only gently forced actively and passively, using the capsular stretching technique. In this way, arthritis with secondary limitation of movement will not have an opportunity to develop and the pain disappears. Once pain has ceased, treatment can be stopped.

Passive movements

If arthritis has set in, it is too late for prevention and treatment to the capsule should be given. Gentle but firm passive stretching exercises have proven effective in the relief of pain and recovery of range in motion in up to 90% of patients with capsular stiffness.[25–30] However, some studies report inadequate results with stretching and even exacerbation of the condition.[31,32]

Two main types of passive mobilization are used, depending on the degree of inflammation. As a consequence, clinical staging is the guide. Stages I and II with non-spastic end-feel (stage IIa) are cured by mobilization using the capsular stretching technique. Stages IIb (spastic end-feel) and III are treated by either capsular distraction, which is a less irritating type of mobilization, or by intra-articular injections with corticosteroid. Preference is for the steroid injections but, if the patient refuses injections or if use of steroid is contraindicated, distraction can be very useful.

Warning

Stretching manœuvres on a highly inflamed capsule exacerbate the condition. The following indications of a high degree of inflammation are therefore considered as contraindications:

- Arthritis in stage III or in stage II with a spastic end-feel.
- Wrong end-feel on first distraction attempt: when the therapist brings the patient's arm up and starts the manœuvre, attention should be paid to pain and end-feel. If it is possible to bring the elbow slightly further towards the couch without increasing pain too much or without provoking muscle spasm, it is a good sign that capsular stretching will succeed. In the opposite case, stretching should not be undertaken and intra-articular injections or the distraction technique should be used instead.
- After-pain lasting for more than 2 hours.

Capsular stretching

Technique

Before capsular stretching is begun, analgesic short-wave diathermy can be given for 10 minutes.

The patient lies supine and brings the ipsilateral hand on to the forehead. The therapist stands on the same side, facing the patient, and puts one hand on the sternum and the other on the elbow of the affected side. By pushing the elbow backwards towards the couch, the capsule of the joint is stretched (Fig. 14.3). In this way the inferior recess of the capsule, where

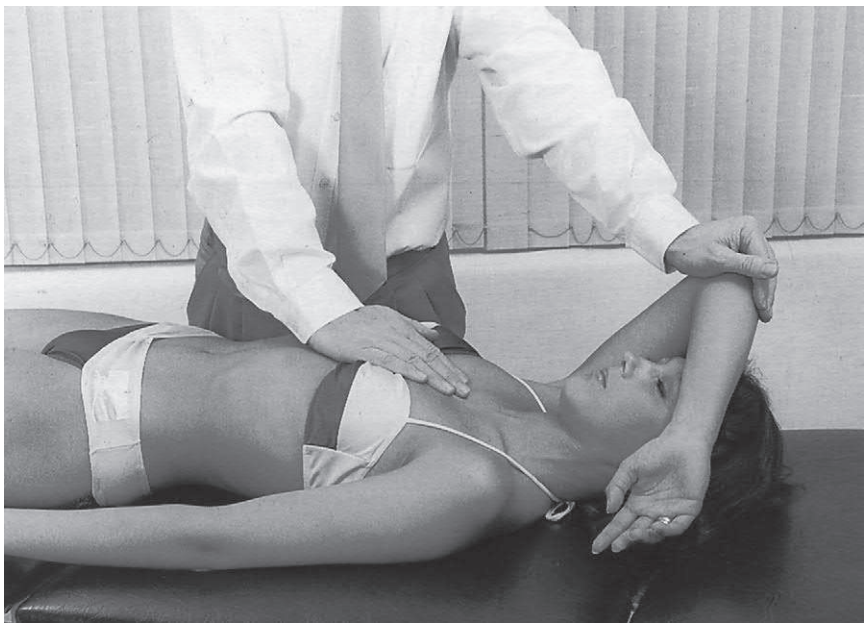

Fig 14.3 • Capsular stretching.

most of the adhesions lie, is elongated. The hand on the sternum prevents the patient from curving the trunk to avoid the stretch. The capsular stretching is done in elevation. As this is a combined movement, the rotations improve simultaneously with the increase in abduction range. If this does not happen, the shoulder must be stretched in lateral rotation as well.

Stretching is not manipulation and any tendency to 'jerk' should be avoided. Rather the manœuvre is carried out by exerting continuous pressure that is gently intensified for a few seconds, then slackened off slightly for a little while and increased again. This is repeated for as long as the patient can bear it and is followed by a full rest, in which the arm is brought down, avoiding pain by axial traction. Stretching should be repeated several times during one session and can be combined with hold–relax techniques.

The therapist should teach the patient which mobilizing exercises can be done at home in order to maintain the mobility that has been regained. These should be performed several times daily.

Force used during stretching

The stretching itself is applied with a reasonable amount of force, sufficient to provoke some discomfort at the time. But more important than the patient's sensation during the treatment is what is felt afterwards, which provides the information about the amount of force to be used.

If there is increased pain for the first 2 hours after the procedure, the correct amount of power has been used and future treatment must be identical. If pain is not increased, the stretch power has been insufficient and, at the next session, must be increased.

If the patient returns after 2 days still having increased pain attributable to the procedure the implication is not – as one might logically assume – that the stretching was too aggressive. Rather it indicates this shoulder cannot accept capsular stretching at all. Even if only stage I or IIa arthritis is present, and although all indications for stretching seem to be fulfilled, distraction or injections should be substituted.

Sequence and duration

These sessions are held three times a week for about 15–20 minutes each. Improvement is expected after 5–15 sessions, depending on the severity of the lesion.

Stretching is continued until the shoulder is back to normal (pain and range) or no further gain is achieved. The results are good, and passive capsular stretching has been proven to be a fast and safe mode of treatment for 'adhesive capsulitis' in stage I or IIa arthritis.[33–35]

Long-standing cases

Sometimes, in long-standing cases, it is possible to hear and feel adhesions rupture on stretching. Immediately afterwards, pain diminishes and mobility increases. Two or three of these ruptures may be necessary to restore a full range of movement.

Distraction

This technique consists of very gentle elongation of the joint capsule performed in such a way that the fibres are stretched longitudinally. It has been suggested that this inhibits nociceptive reflexes which result from long-standing stimulation of the nocisensors. These reflexes would be responsible for increased sympathetic activity giving rise to vasoconstriction of the vessels around the joint.[36]

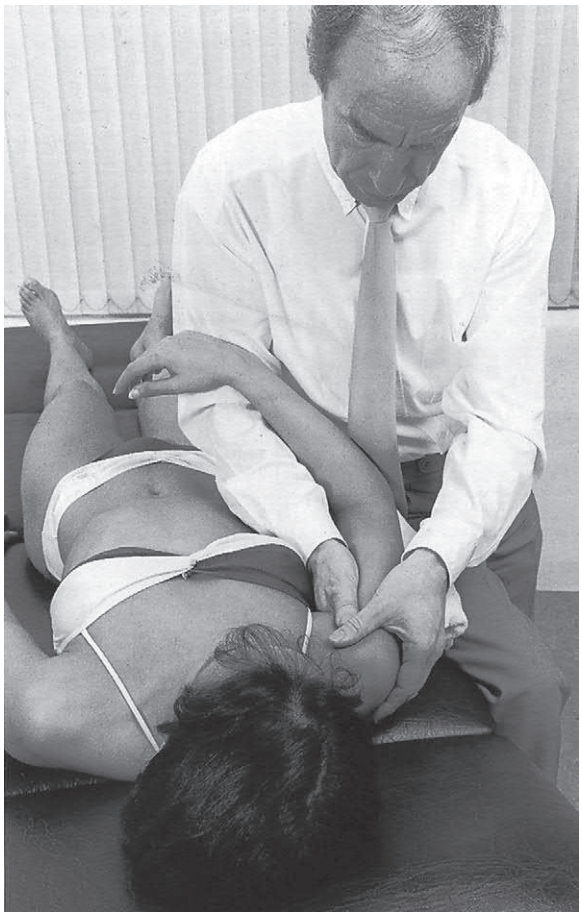

Fig 14.4 • Capsular distraction.

Indications

Patients with stage I or IIa arthritis in whom capsular stretching is contraindicated have an open choice between steroid or distraction.

Distraction may be used in patients with traumatic arthritis in stage IIb or III for whom steroids are refused, have been used without success or are contraindicated.

Technique

The patient lies supine, the arm along the side, with a small cushion beneath it for maximum comfort. The therapist sits at the patient's painful side and brings the ipsilateral hand deep into the axilla, the other one partially on the outer aspect of the shoulder, partially reinforcing the one in the axilla (Fig. 14.4). The ipsilateral hand will try to pull the head of the humerus out of the glenoid fossa. The direction of the pull is mainly lateral and slightly cranial and anterior.

Initially the manœuvre is done with the patient's arm in the most comfortable position. Once mobility has increased, some degree of lateral rotation and abduction can be added, so that the distraction is performed at the end of the possible range. At first, when there is a lot of pain, fine vibration can be additionally incorporated so as to stimulate the mechanoreceptors and inhibit the nocisensors, resulting in pain relief.

During the first sessions not much happens. It is only after a few sessions that the therapist feels a loosening of the patient's shoulder such that the humeral head is felt to leave the glenoid fossa.

This technique is performed with so little force that it is not at all painful during the session and is not followed by any after-pain.

Sequence

As with stretching, this technique is done three times a week for about 15–20 minutes each. Distraction is continued until the arthritis has regressed to stage II or IIa. Then normal capsular stretching can be performed.

Manipulation under anaesthesia

Manipulation under anaesthesia has been used for over a century. Some believe in its effectiveness,[36–38] while others have denounced its use because they think there is no change in the time course of the disease after the manipulation or they have seen too many complications. Ruptures of the subscapularis tendon, damage to the neurovascular structures, and fractures and dislocations have been reported after manipulation under anaesthesia.[39–43] That the method can cause iatrogenic damage was recently demonstrated by an arthroscopic study.[44] After manipulation, the anterior portion of the capsule was seen to be ruptured in 75% of the patients. Iatrogenic superior labrum lesions were observed in 15%, fresh partial tears of the subscapularis tendon in 10% and anterior labral detachments in 15%.

Manipulation should be considered only if all other treatment methods fail. In fact this type of treatment is very seldom needed as almost all capsular limitations can be resolved by either mobilization techniques or a sequence of intra-articular injections with triamcinolone.

Intra-articular injections

In an attempt to suppress the painful inflammatory response in post-traumatic capsulitis of the shoulder, intra-articular injections with corticosteroids have been used for decades. Studies that evaluate the response to intra-articular injections generally combine the injection with other treatment methods and rarely compare the efficacy of the injection alone. However, some studies could demonstrate improvement in pain scores and increase in range of motion after steroid injections alone.[45–49] Other investigators are very sceptical about the injections as their studies failed to demonstrate the benefit of the treatment.[50]

Cyriax could not initially find benefit in intra-articular hydrocortisone injections[51] but after he detected the advantages of a sequence of consecutive intra-articular injections with triamcinolone, he became a very enthusiastic advocate of intra-articular injections for capsulitis of the shoulder.[52]

Our experience is that traumatic arthritis responds very well to injections of 20 mg of triamcinolone, provided the treatment is given in stage III or IIb and the correct sequence is followed (see below).

Technique

The patient lies prone, the arm under the abdomen and the elbow flexed at a right angle. This position has two advantages: first, it brings the articular surface of the humeral head to point straight backwards, so creating a large target for the needle; second, the patient cannot move the arm.

The coracoid process is palpated in the infraclavicular fossa. The examiner puts the index finger here and places the thumb dorsally on the posterior angle where the scapular spine meets the acromion. A 4 cm needle is fitted on a 2 mL syringe filled with 20 mg of triamcinolone. It is inserted just below the thumb and aimed at the coracoid process. The same approach is used nowadays for arthroscopy via the posterior portal.[53,54] After about 2–3 cm the needle is stopped by the articular surface of the head of the humerus and there is a typical cartilaginous sensation. At this point, the needle lies intra-articularly. Just before the needle is arrested, tough resistance is felt on passing through the capsule (Fig. 14.5).

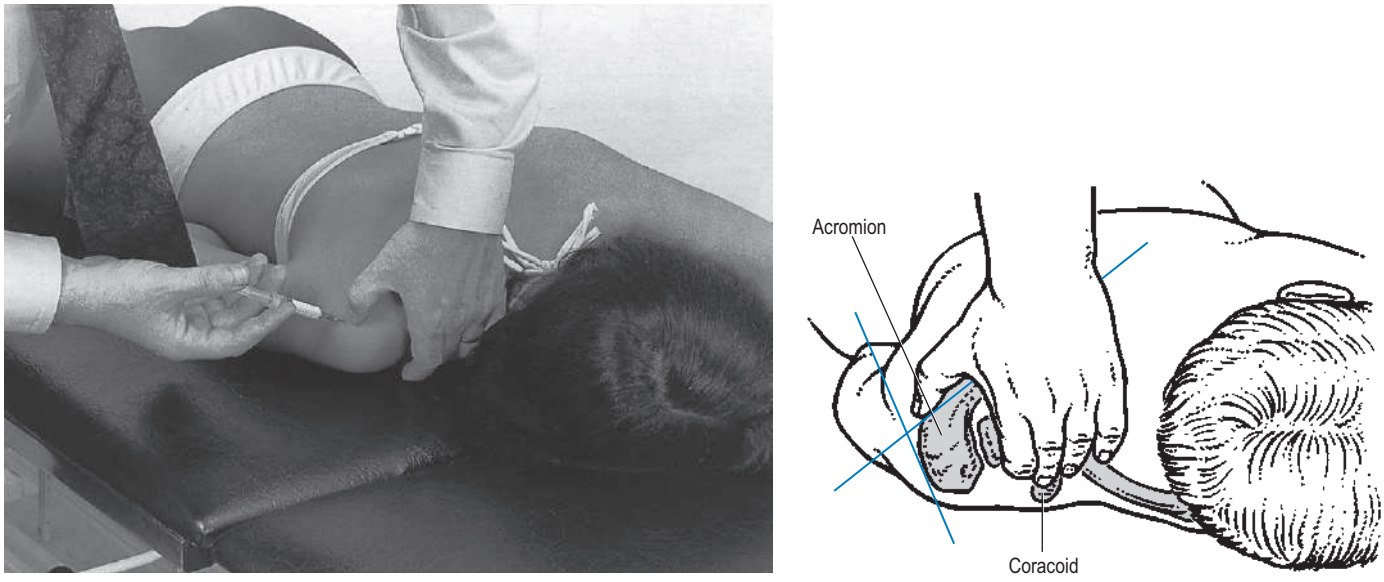

Fig 14.5 • Intra-articular injection.

With the needle in cartilaginous contact, 2 mL of triamcinolone are injected. A reasonable amount of resistance is encountered. Exceptionally, not even a single droplet can be injected, in which case the point of the needle is fully within the articular cartilage. Should this be the case, the needle should be withdrawn by about 2 mm while injection pressure is maintained. Once the tip of the needle leaves the cartilage, the steroid floats in. The injection is given in this position and is minimally painful.

Sequence

The aim is to keep the capsule continuously under anti-inflammatory influence until the inflammation has almost fully disappeared. Therefore the next injection must be given just before the effect of the previous one has worn off.

A practical scheme, with increasing intervals between the injections, is as follows:

- First injection: day 0.
- Second: after 1 week: day 7.
- Third: 10 days after the second injection: day 17.
- Fourth: 2 weeks after the third one: day 31.
- Fifth: 3 weeks later: day 52.
- Sixth: 4 weeks later: day 80.
- Seventh: 5 weeks later: day 115.
- Eighth: 6 weeks later: day 157.
- Ninth: 6 weeks later: day 199.

The usual sequence is that, after the first injection, the patient will have less pain, and from the third injection onwards the limitation of movement starts to decrease.

The injections are given until the arthritis reverts to stage I. Treatment can then be stopped and the arthritis will continue to resolve spontaneously. In general, about five injections are needed.

Exceptionally it happens that, even if the scheme is followed, a patient who is temporarily better after the last injection complains of increasing pain during the days before the next appointment. This means that the interval between injections was too long and should be reduced.

Sometimes the pain subsides progressively as expected but limitation of movement does not alter. In this event, capsular stretching should be tried and is started once the arthritis is at stage I. If stretching makes the pain relapse, it must be postponed for a few weeks and another injection given.

A summary of the treatment of traumatic arthritis is shown in Figure 14.6.

Complications and side-effects

Because there is a small but real risk of infection via intra-articular injections, it behoves the practitioner to prepare the skin and handle the procedure under surgical conditions.

It is also important to remember that steroid injections in diabetic patients, even given intra-articularly and in quite small doses, may cause blood glucose to fluctuate and also may incur a greater risk of infection.

Further side effects may include some flushing on the following day and perhaps some interference with the menstrual cycle because of hormonal effects.

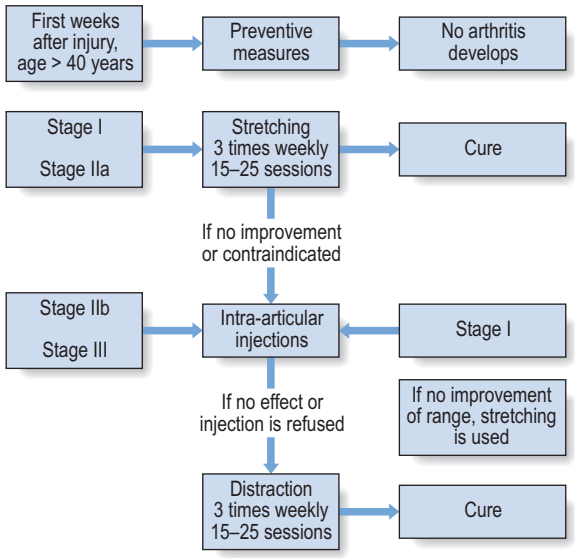

Fig 14.6 • Treatment of traumatic arthritis.

Other treatments

Hydraulic distension

Hydrodilatation, sometimes referred to as distension arthrography, has been proposed as a therapeutic procedure for glenohumeral joint contracture.[55] It is proposed that its benefits are derived from a combination of the anti-inflammatory effect of cortisone with the mechanical effect of joint distension, thereby reducing the stretch on pain receptors in the glenohumeral joint capsule and its periosteal attachments.[56] Hydrodilatation was first used in 1965 by Andren and Lundberg,[57] who reported variable results ranging from extremely effective to extremely painful. More recent studies have also cited variable results.[58–60] Several double-blind, prospective studies could not detect any significant differences between a regimen of hydrodilatation that included steroids compared with steroid injections alone.[61–64] As with manipulation under anaesthesia, this technique should be reserved for those few cases that do not respond to passive mobilization and injection with corticosteroids.

Arthroscopic release

Recent studies have demonstrated that arthroscopic capsulotomy may be an effective technique in the management of the frozen shoulder that does not respond to physiotherapy.[65–68] During standard shoulder arthroscopy, intra-articular cautery is used for complete division of the anterior–inferior capsule, the intra-articular portion of the subscapularis tendon and the middle glenohumeral, the superior glenohumeral and the coracohumeral ligaments.[69]

Immobilizational arthritis

In patients over 60, when the shoulder is immobilized, it is at risk of becoming stiff. The reasons for the initial immobilization may be multiple. Immobilizational arthritis is a well-known complication in hemiplegics.[70–73] During a prospective study, conducted by Bruckner and Nye, 25% of patients with

subarachnoid bleeding developed a frozen shoulder over an observation period of 6 months.[74] Other neurological conditions such as Parkinson's disease may precipitate capsular stiffening.[75,76] Immobilization of the arm for disorders such as a fracture of the elbow or the humerus is also reason enough to develop a post-traumatic arthritis.[77] For many years clinicians have associated ischaemic heart disease and shoulder arthritis,[78] which eventually develops as the result of immobilization after an infarction or surgery.

Natural history

The development and natural history of immobilizational arthritis cannot be distinguished from those of traumatic arthritis. Again, there are three phases in the progress of the disease. In the painful phase, both pain and limitation of movement increase. In the subsequent progressive stiffness phase, the pain diminishes but the limitation remains the same. Lastly limitation decreases during the final 'thawing' phase. Altogether, it takes about a year for the lesion to recover spontaneously and movement to return to normal.

Treatment

This condition should never be encountered. It is very important for primary care physicians and physiotherapists to realize that immobilized shoulders should be given gentle movements at least once a day, in order to prevent the development of an immobilizational shoulder arthritis. This simple advice was already given by Neviaser, who in 1945 wrote: 'I believe we can accept the fact that disuse and inactivity play a very important role in the etiology.'[79] In prevention, it is sufficient to maintain the normal range of movement from the very beginning of immobilization. If arthritis has set in by the time the patient is first seen, it should be managed in the same way as traumatic arthritis: stage I is treated with capsular stretching, stage III with a series of intra-articular injections of 20 mg of triamcinolone. Stage IIa can also be treated with stretching if the end-feel is right. If this is not the case, the patient should receive intra-articular injections.

Monoarticular 'steroid-sensitive' arthritis

A monoarticular arthritis that develops without apparent cause – neither trauma nor immobilization can be traced in the history – is called 'idiopathic frozen shoulder'[80] or monoarticular 'steroid-sensitive' arthritis. The latter term comes from Cyriax, who discovered that most cases of 'freezing arthritis' could be successfully treated with a series of intra-articular steroid injections.[81]

Pathophysiology

Although the exact cause of the capsular inflammation and the subsequent capsular fibrosis is not exactly known, recent investigators have focused on the inflammatory cellular changes and immunological response in the synovium and the capsule. Currently it is not known exactly what triggers the initial synovial inflammation. Some point to specific cytokines which may be involved in the early inflammatory stages of the disease.[82] Several references in the literature assume frozen shoulder to be an algoneurodystrophic process.[83,84] Others suggest that a proteinase may be involved in the pathogenesis of both a Dupuytren's contracture and a frozen shoulder.[85,86] Others have suggested that an area of focal necrosis in a degenerative tendon is the earliest lesion, followed later by a generalized chronic inflammatory reaction of the whole capsule and of the rotator cuff.[87]

Hannafin and colleagues have studied the histopathologic evolution of monoarticular shoulder arthritis. They found an initial hypervascular synovitis, provoking a progressive fibroblastic response in the adjacent capsule, finally leading to diffuse capsular fibroplasia, thickening and contracture.[88]

Incidence

The bulk of patients who present with primary monoarticular arthritis of the shoulder are between 45 and 60 years of age,[77,89] although the disease can be encountered at any age.[90] Approximately 70% of patients presenting with adhesive capsulitis are women.[91] The overall prevalence of the disorder is about 2%. In diabetics the figure is almost 11%.[92,93] Other studies show diabetes to be present in 25–38% of the patients suffering from adhesive capsulitis.[94,95] Some connection with hyper- or hypothyroidism has also been suggested, although the link between the disorders remains obscure.[96] Recently adhesive capsulitis has also been described in patients treated with highly active antiretroviral drugs.[97,98]

Natural history

The onset is spontaneous and involves only one shoulder at a time; sometimes the other shoulder may become involved within 5 years.[99]

In the spontaneous evolution of a monoarticular steroid-sensitive arthritis, four periods of about 6–9 months each are distinguished (Fig. 14.7).[100] Initially, the patient starts to feel pain at the shoulder for no apparent reason. This increases progressively, becomes continuous (although often worst at night) and starts to spread beyond the elbow. It causes many months of sleepless nights, a more than sufficient reason to start treatment at once. At the same time movement becomes

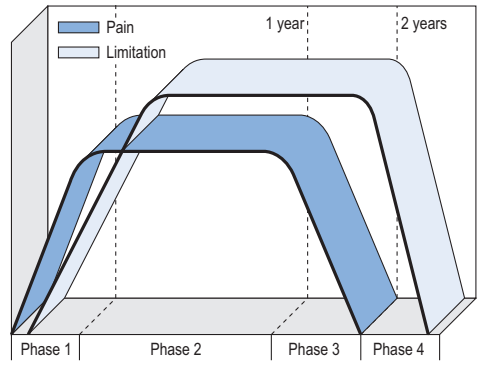

Fig 14.7 • The four phases of monoarticular steroid-sensitive arthritis.

progressively limited. During the second phase, the pain gets no worse but remains maximal for another 6 months. Limitation does not change for about 12 months. One year (sometimes even more) after the onset, the pain starts to diminish and it disappears almost fully at the end of this third phase. Restriction of movement, however, does not alter. Finally, in the fourth period, the limitation of movement gradually decreases. At this time, only some slight discomfort and a certain degree of stiffness remain, which usually disappear fully at the end of the 2 years. Exceptionally, a few degrees of restriction of elevation will be permanent.[101,102]

These clinical phases in the natural history of idiopathic capsulitis of the shoulder correspond roughly with the histopathologic phases identified by Hannafin:[88,103] first hypervascularization and inflammation of the synovia (first period), then progressive fibroblastic response of the capsule (second and third periods), and finally the remodelling of the capsule (fourth period).

Functional examination

The first phase is initially characterized only by pain, which occurs at the extreme of all passive movements. Almost no limitation will be present during the first few weeks. Arriving at a diagnosis may be difficult at this stage. As in traumatic arthritis, it is of help to know that the pain is referred in the C5 dermatome and that full passive lateral rotation is the most painful test. Also, the changing end-feel may be of clinical importance in making an early diagnosis. Later, as the pain increases, limitation of movements sets in. From now on, a clear capsular pattern is found that will have its maximum limitation by the end of the first period (6–9 months from the onset of the disorder). By then the end-feel will certainly be that of muscle spasm.

Both pain and limitation remain maximal during the entire second phase.

The third phase is characterized by a gradual decrease in pain. The end-feel progressively changes towards a hard one, indicating the loss of capsular elasticity. Limitation of movement, however, does not change yet.

During the final ('thawing') phase, the range of movement progressively increases to return to normal about 2 years after the onset. Some authors have stated, however, that it may take longer for the stiffness to disappear completely or that some degree of stiffness may remain.[104] In general, the duration of the recovery stage is related to the duration of the stiffness phase: the longer the stiffness phase, the longer the recovery phase.[105]

Staging

As in traumatic arthritis, three stages are distinguished in relation to the degree of inflammation (see p. 222): stage I is the slightest, while stage III is the worst (Table 14.2).

The stages are based on the following criteria:

- Does the pain spread beyond the elbow?
- Is there spontaneous pain?
- Can the patient lie on the affected side at night?
- What is the end-feel?

Table 14.2 Stages of monoarticular steroid-sensitive arthritis

	Stage I	Stage II	Stage III
Pain beyond elbow?	No	Yes	
Spontaneous pain?	No	Yes	
Can lie on the affected side at night?	Yes	Mixed pattern	No
End-feel?	Normal		Abrupt: hard or muscle spasm

Although the treatment is the same for stages I, II and III, the classification helps in following the natural development, gives an idea of the effect of the treatment, and indicates when to stop treatment.

Treatment

Because spontaneous recovery takes about 2 years and the patient suffers severely in the meantime, treatment is absolutely necessary.[106,107] As a rule, a series of intra-articular injections with triamcinolone are given, whatever the stage of the arthritis. Exceptionally, capsular distraction is used for those patients who do not want injections or when steroids are contraindicated. If distraction is used, it should be performed in the same way, frequency and duration as for traumatic arthritis (see p. 225). Injections for monoarticular steroid-sensitive arthritis are given in the same way (technique and interval) as for traumatic arthritis (see p. 226). They can be stopped once the patient can use the arm freely, the end-feel is back to normal and no relapse of pain occurs by 6 weeks after the previous injection. If some limitation of movement still exists by then, it usually disappears spontaneously during the following months.

It is rare for patients not to respond to injection therapy or to remain with a painless stiff shoulder.[108] In 1989 we did a prospective study on 54 patients with idiopathic arthritis of the shoulder. The youngest patient was 40, the oldest 71. On clinical examination all showed a clear capsular pattern and none had pain on any resisted movement. Laboratory tests were performed to exclude other rheumatoid types of arthritis and to check for a possible association with diabetes (only one diabetic patient was identified). Over 90% of the cases presented initially with stage II or stage III arthritis. All were treated by a series of intra-articular injections given at increasing intervals. The total number of injections given was between four and nine with an average of six (Fig. 14.8). After the first injection half the patients were less troubled at night. This figure increased to more than 90% after the third injection. Spontaneous pain decreased in the same way as the nocturnal pain but with some delay, being less severe and progressively less distantly referred. After eight injections, 98% of all patients had no pain (Fig. 14.9).

The range of movement of rotation and elevations began to increase after the first injection, though this was not very obvious clinically. An increased amplitude usually became clear after the third injection. The final conclusion of the study was that 98% of all patients recovered fully from their pain – only

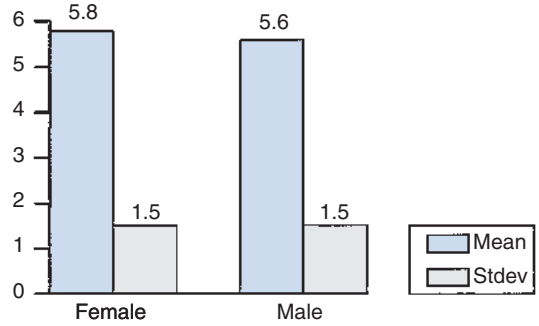

Fig 14.8 • Mean numbers of steroid injections given in a study of monoarticular steroid-sensitive arthritis (grey error bars are standard deviations (Stdev)).

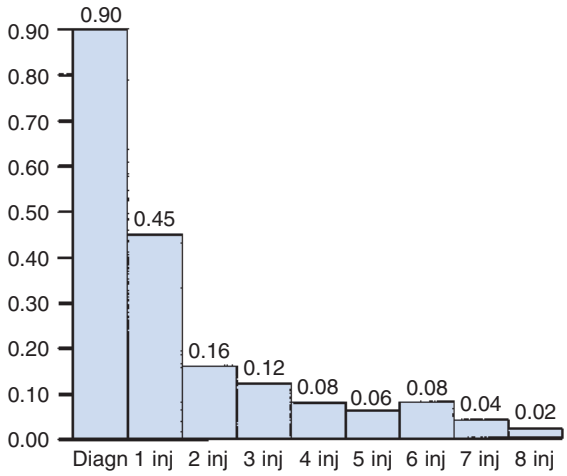

Fig 14.9 • Decay of nocturnal pain (% of total) in relation to the given number of injections.

one patient continued to have a painful shoulder. There was an 80% increase in range of movement after the seventh injection. The results of this study correspond roughly with what was found by others.[87,109]

Shoulder–hand syndrome

Shoulder–hand syndrome, first described in the 1950s, is a relatively rare clinical entity classified as a complex regional pain syndrome type 1 (CRPS1), or 'reflex sympathetic dystrophy'.[110] The condition consists essentially of a painful 'frozen shoulder' in combination with disability, swelling, and vasomotor or dystrophic changes in the ipsilateral hand. At onset, the hand is bluish and diffusely swollen. Later the wrist and fingers become stiffened (flexion contracture with limitation of extension) and the skin shiny and atrophic.[111] The shoulder involvement usually precedes, sometimes accompanies or rarely follows the changes in the hand. The pathophysiology is not completely clear but a predominant 'sympathetic' factor affecting the neural and vascular supply to the affected parts seems to be involved.[112,113] Cyriax considered the syndrome to be a type of monoarticular steroid-sensitive arthritis.[114] So far the exact cause has not been clarified, although some assume that emotional instability could be an important factor. The arthritis is treated in the same way as any other steroid-sensitive arthritis

Rheumatoid-type arthritis

Rheumatoid arthritis (RA) is an autoimmune disorder of unknown aetiology characterized by symmetric, erosive synovitis and sometimes multisystem involvement. Any joint can be involved, but the proximal interphalangeal and metacarpophalangeal joints of the hand and the wrist are preferential sites, as well as the metatarsophalangeal joints of the foot, the knee joint and the joints of the shoulder, ankle and hip. Symmetry is the hallmark of joint involvement. The synovium of bursae and tendon sheaths can also be affected. It gives rise to pain and stiffness, usually greatest in the morning. There is a marked capsular pattern with a spastic end-feel. Warmth and tenderness can be palpated over the joint.

Conventional radiography remains the standard imaging technique for joint studies in patients with suspected RA. The first radiological signs are osteoporosis and joint space narrowing. Later chondral erosions and small bone erosions at the joint margin are seen. Marginal and central erosions follow in advanced stages. Fibrous ankylosis, joint deformities (subluxations and dislocations), fractures and fragmentations are typical findings of more advanced RA.[115–117] RA is best treated systemically; local intra-articular injections are used only as a secondary aid.

Sometimes the shoulder is the seat of a *reactive type of arthritis* in which the inflammation is caused by an infection but in which no bacterial or viral agent can be isolated from the synovial fluid.[118]

Ankylosing spondylitis rarely starts in the peripheral joints but cases have been described with initial localization at shoulder or hip.[119,120] Particularly in the paediatric form of the disease (juvenile ankylosing spondylitis), peripheral joint involvement is more frequent and can precede, by many years, the onset of back features.[121] In its later course, signs and symptoms will be more localized in the spine and the sacroiliac joints. Arthritis at the shoulder from this disorder responds well to intra-articular steroids. The pain disappears fully but very often movement remains limited.

Reiter's disease seldom afflicts the shoulder joint. It is usually polyarticular in nature. Classically the triad urethritis–arthritis–conjunctivitis is present. Arthritis as a manifestation of psoriasis or lupus responds well to steroids, although a slight limitation of movement may remain.

Haemarthrosis

A patient complaining of severe pain immediately after an injury and showing a capsular pattern should always be suspected of having a haemarthrosis. In haemophilia, the haemarthrosis can develop spontaneously. It is more common at knee, elbow and ankle joints than in the shoulder.[122] Blood is very irritant to articular cartilage and so should be aspirated at once. If it is not, it will lead to full destruction of the joint over a the course of a few years.[123]

Crystal synovitis

Crystal synovitis at the shoulder from urate crystals (gout) is very rare.[124] This disorder should be considered when a capsular pattern comes on spontaneously in a few hours. It normally remains monoarticular but has often been preceded by earlier attacks in smaller joints (particularly in the metatarsophalangeal joint of the big toe). It disappears spontaneously in the course of a week and responds very well to colchicines or phenylbutazone. Diagnosis is mainly based on the presence of urate crystals in the synovial fluid.[125]

Pseudogout is the result of the presence of pyrophosphate crystals in the joint. The term 'chondrocalcinosis' is used if calcification in the hyaline cartilage of the joint is visible on radiography.[126] The knee is much more commonly affected than the shoulder.[127] Clinically, the presentation is spontaneous but is less acute in onset than gout. Crystals are also present in the synovial fluid and can be detected by high-resolution sonography.[128] Pseudogout resolves spontaneously in about 3–4 weeks.

Septic arthritis

Septic non-tuberculous arthritis

Septic arthritis can be provoked by direct inoculation of a bacterium into the joint, by haematogenous dissemination or from adjacent osteomyelitis. It is mainly seen in elderly people, often in connection with other predisposing factors such as diabetes, immune deficiency, malnutrition and alcoholism.[129,130] Some cases occur after mastectomy and radiotherapy for breast cancer.[131] A joint affected by a chronic arthritis, such as rheumatoid arthritis, is more likely to develop septic arthritis. It rarely occurs in the healthy elderly or in young adults. In children it may be a sequel to adjacent osteomyelitis. Acute septic arthritis may also present as an iatrogenic infection following joint arthroscopy, joint aspiration or local corticosteroid joint injection.[132–134] In many cases *Staphylococcus aureus* is the causative agent.[135] Sometimes a streptococcus or *Escherichia coli* is present, and even a gonococcal infection may be found.

The history is that of an acute and very painful shoulder, which after a few days becomes warm and red. A previous injection is sometimes mentioned. Usually the patient is very ill with high temperature, nausea and toxaemia. In rare cases, fever may be absent.

Inspection may show a swelling, which is often due to a subcutaneous abscess that communicates with the joint. On testing the shoulder, a very pronounced capsular pattern is found. In the initial stage, radiology is diagnostically irrelevant. As the condition develops further, periarticular osteoporosis, diminution of the joint space and finally joint destruction are found. Biological features, such as raised erythrocyte sedimentation rate and increased leukocyte counts, are suggestive but not confirmative. A diagnostic (and evacuating) aspiration of the joint, with a wide-bore needle (>20 gauge), usually shows over 100 000 leukocytes/mm^3, more than 90% being of the polymorphonuclear type. Sometimes the bacterial agent can be isolated.[136]

Treatment and prognosis

Septic arthritis of the shoulder is more difficult to treat than septic arthritis at any other joint. It is a very severe disorder and death is not uncommon.[137] The condition is normally managed with systemic antibiotics and daily evacuation of the pus. Also the combination of arthroscopic irrigation debridement and systemic antibiotic therapy is often used.[138] Sometimes open surgical drainage is necessary.

The erythrocyte sedimentation rate is a useful monitor of adequate treatment.[139] Very often the long-term result is significant limitation of movement at the glenohumeral joint because of bone destruction.

Tuberculosis of the glenohumeral joint

In tuberculosis of the shoulder joint, the clinical picture is far less pronounced than in septic arthritis and is slower in progression. Clinical diagnosis can be very difficult and is made only late in the course of the disease. A capsular pattern is found, often in association with severe muscle atrophy. Aspiration of the joint, followed by direct microscopic examination and culture, together with radiology (severe osteoporosis, narrowing of the joint space and erosions), are of help in diagnosis. The treatment is the same as for septic arthritis but specific antitubercular agents are administered.

Primary tumours

Primary tumours at the shoulder are mainly encountered in the young and may occur in acute leukaemia[140] or be due to sarcoma.[141] The tumour often presents insidiously. In the beginning it is characterized by localized, non-mechanical pain. From the moment that the tumour incites a synovial response, a painful capsular pattern at the shoulder will gradually develop.[142,143] In a younger patient, this should always arouse the suspicion of a primary tumour. Even the slightest limitation in a young patient is a formal indication for further careful exploration of this area by techniques such as radiography, computed tomography (CT) or MRI.

Warning

Spontaneously developing limitation of shoulder movement in a young patient should prompt suspicion of a primary tumour.

Metastases

Metastases can be localized either in the humeral head or at the glenoid. Rapidly increasing pain around the shoulder, radiating into the arm, and increasingly restricted shoulder movements in a patient with deteriorating general health are strongly suggestive of a secondary neoplasm. Sometimes a previous operation for a primary tumour is mentioned.

Localized warmth is usually the first sign, later followed by a very pronounced capsular pattern, with much pain and

limitation because both joint and muscles are affected.[144] Moreover, the resisted movements are extremely weak and painful. Visible muscular wasting is present. A radiograph or a bone scan can help confirm the diagnosis.

Warning

A gross capsular pattern, together with painful muscular weakness and wasting coming on over a short period of time, should prompt suspicion of metastases.

Aseptic necrosis

The humeral head remains the second most common site of osteonecrosis after the femoral head. While similarities in aetiology and pathogenesis exist, the anatomy and function of the glenohumeral joint are vastly different, which, consequently, results in delayed diagnosis and treatment. First of all, the glenohumeral joint is not exposed to the same weight-bearing forces as the hip joint. Additionally, the glenohumeral articulation is less conforming than the hip joint, and restricted shoulder motion can be compensated by surrounding joints. This allows for maintenance of shoulder function, even with advanced disease. Finally, the proximal humerus has an extensive anastomotic arterial supply, mitigating the effect of a loss of any single arterial inflow.

As in the hip, osteonecrosis of the shoulder results from disruption of the osseous arterial inflow or the venous outflow. The cause is either traumatic (fractures of the proximal humerus have been associated with an osteonecrosis rate ranging from 15 to 30%),[145] non-traumatic or idiopathic. Non-traumatic cases may be the result of haemoglobinopathies,[146] radiation of the joint or diving accidents.[147] High doses of systemic corticosteroids represent the most commonly reported iatrogenic cause of osteonecrosis.[148,149]

Often, the initial signs and symptoms are subtle and may include vague diffuse shoulder pain and difficulty sleeping. This pain deteriorates with disease progression and may be tolerable until the later stages. Determining the presence of risk factors for osteonecrosis, including prior steroid exposure, other medical conditions or alcohol abuse, may sometimes provide the only clue to the disease. Also, the patient's age at presentation may offer a hint, as these patients are generally younger than those with primary osteoarthritis.[150] The clinical picture, particularly early in the disease process, may be that of a slight capsular pattern. Also symptoms of locking, popping or a painful click may indicate the presence of loose osteochondral fragments.[151] With disease progression, significant limitations in motion of a non-capsular type – secondary to joint incongruity – and an increase in pain will become more evident.

Technetium bone scanning and MRI can detect aseptic necrosis in the early stage.[152,153] Later on, the whole joint is destroyed and the disease can be visualized on plain radiography.

Treatment consists of core decompression in the early cases.[154,155] In very severe cases, shoulder arthroplasty may be indicated.[156]

Osteoarthrosis

A number of different processes can destroy the glenohumeral joint surface. If no apparent reason for the development of osteoarthrosis can be found, it is termed *primary degenerative joint disease*. This is characterized by a triad of anterior capsular contracture, posterior wear of glenoid and subchondral bone, and posterior humeral subluxation.[157] Primary arthrosis does not usually evoke much pain. Indeed, a patient with an arthrotic shoulder, in the absence of any capsular inflammation, complains merely of painless crepitus on movement. During and after exertion there may be a vague ache, which usually disappears after a few hours. There is a capsular pattern with a hard but almost painless end-feel. With shoulder movement, crepitus may be detected on palpation. However, an osteoarthrotic joint is much more liable to develop arthritis, which can be the result of only a slight injury or some unusual activity. Once arthritis has set in, the limited movements also become painful. The diagnosis of primary arthrosis at the shoulder should be made on clinical grounds and should not be based solely on the radiograph, as it is quite possible to have no arthrosis on clinical examination but signs of it present on the radiograph.

In contrast, *secondary degenerative joint disease* may be much more painful and disabling. It occurs when previous injury, surgery or another condition affects the joint surface and causes degeneration. Chronic glenohumeral subluxations often lead to severe osteoarthrosis. The condition also develops when a chronic and massive tear of the rotator cuff subjects the uncovered humeral articular cartilage to compression against the undersurface of the coracoacromial arch. The resulting arthrosis is then called 'cuff arthropathy'.[158] In this case, clinical examination will reveal total rupture of the supraspinatus in combination with limited movement in a capsular way. Also, in the end-stage of avascular necrosis of the shoulder, the irregular head destroys glenoid articular cartilage, which results in secondary degenerative joint disease.[159]

Treatment

For the primary arthrosis, not very much need be done. Limitation of movement cannot be altered either by capsular mobilization or by intra-articular injections. If a traumatic arthritis or an immobilizational arthritis supervenes, intra-articular injections have no effect. The only remaining treatment is capsular stretching, which can only be executed if the arthritis is in stage I or stage II.

In secondary degenerative joint disease of the shoulder, considerable pain and functional impairment can result, for which there is no option other than surgery.

Neuropathic destructive arthropathy

Neuropathic osteoarthropathy, also known as Charcot neuroarthropathy, is a chronic, degenerative arthropathy and is associated with decreased sensory innervation.[160] There are numerous causes of neuropathic osteoarthropathy, the three most common being diabetes, syphilis and syringomyelia. Diabetic patients tend to have involvement of the joints of the

foot and ankle, whereas larger joints such as the knee are commonly affected in patients with syphilis. Patients with syringomyelia tend toward involvement of the shoulder and elbow.[161] Syringomyelia is a disorder involving a fluid-containing cavity (syrinx) within the spinal cord. These cavities commonly occur in the lower cervical and upper thoracic segments, and the distension may propagate proximally. Syringomyelia may have congenital, traumatic, infectious, degenerative, vascular or tumour-related causes.[162,163] The joint and the subchondral bone are destroyed because of the loss of the trophic and protective effects of its nerve supply. In neuropathic destructive arthropathy, a gross but painless capsular pattern with a very hard bone-to-bone end-feel is found. The complete clinical picture is slow to develop. By the time the painless capsular pattern and bony end-feel are found, the underlying condition is usually already known from other neurological signs, such as muscular weakness and atrophy in the upper limbs occurring over a short period. Radiography provides the key to the diagnosis.[164]

Table 14.3 summarizes shoulder lesions that present with a capsular pattern.

Table 14.3 Shoulder lesions presenting with a capsular pattern

Type	Disorder	Signs/symptoms
Monoarticular arthritis		
Acute onset	Gout	Urate crystals in aspirate
	Pseudogout	Calcium pyrophosphate crystals Radiographic signs
	Septic arthritis	Severely ill Shoulder very painful, warm, red and swollen
	Haemarthrosis	Haemophilia Injury
Slow onset	Traumatic arthritis	Patients over 40 Trauma
	Immobilization arthritis	Patients over 60 Immobilization of the arm
	Monoarticular steroid-sensitive arthritis	Spontaneous onset Negative blood tests
	Osteoarthrosis	Hard end-feel Painless crepitus
	Shoulder–hand syndrome	Hand bluish and diffusely swollen Distal dystrophy and stiffness
	Neuropathic destructive arthropathies	Painless, sometimes bilateral Bony-block end-feel Neurological signs
	Metastases	Local warmth Muscular wasting Extreme pain and weakness on all resisted movements
	Primary tumour	Young person developing a painful stiff shoulder in a short period of time
	Aseptic necrosis	Moderate or severe pain Only a few signs
Polyarticular arthritis		
Symmetrical distribution	Rheumatoid arthritis	
	Arthritis due to systemic lupus erythematosus	
Asymmetrical distribution	Ankylosing spondylitis	
Unspecified distribution	Psoriatic arthritis	

Non-capsular patterns

Three main groups are distinguished: limitation of active elevation, limitation of passive lateral rotation and limitation of passive medial rotation.

Limitation of active elevation

To recall: the term 'elevation' is used to indicate the upward movement of the arm in a sagittal plane. Full elevation assumes a normal range of movement of the shoulder girdle and a normal range of 'abduction' at the glenohumeral joint. The latter is the upward movement in a sagittal plane of the humerus in relation to a fixed scapula.

A limitation of active elevation may result from either inert or contractile structures of both shoulder and shoulder girdle. If there is a full range of passive movement, together with pain and/or weakness during resisted movements of neck, shoulder girdle or humerus, the lesion belongs to a contractile structure. If both active and passive elevation is limited, the problem must lie in the inert structures. Passive scapulohumeral abduction will then differentiate between a lesion of the shoulder joint and a disorder that causes limitation of scapular movement (Fig. 14.10).

Both passive elevation and passive scapulohumeral abduction limited

Acute subdeltoid bursitis

This is one of the most painful disorders in orthopaedic medicine. It has a swift onset and, untreated, recovers spontaneously in about 6 weeks. According to Cyriax,[1] there is some tendency for recurrence within 5 years at one or both shoulders.

For no apparent reason, pain starts and increases progressively to reach a maximum in about 3 days (Fig. 14.11), by which time it is very severe and may radiate throughout the entire C5 dermatome. The slightest movement of the shoulder is unbearable and, even if the arm is kept totally immobile, the pain is very pronounced, leading to sleepless nights.

On presentation, the patient typically supports the arm with the other hand. Lack of sleep and the severe suffering can show clearly on the patient's face. The pain can be so excruciating that the patient refuses to move the elbow away from the body.

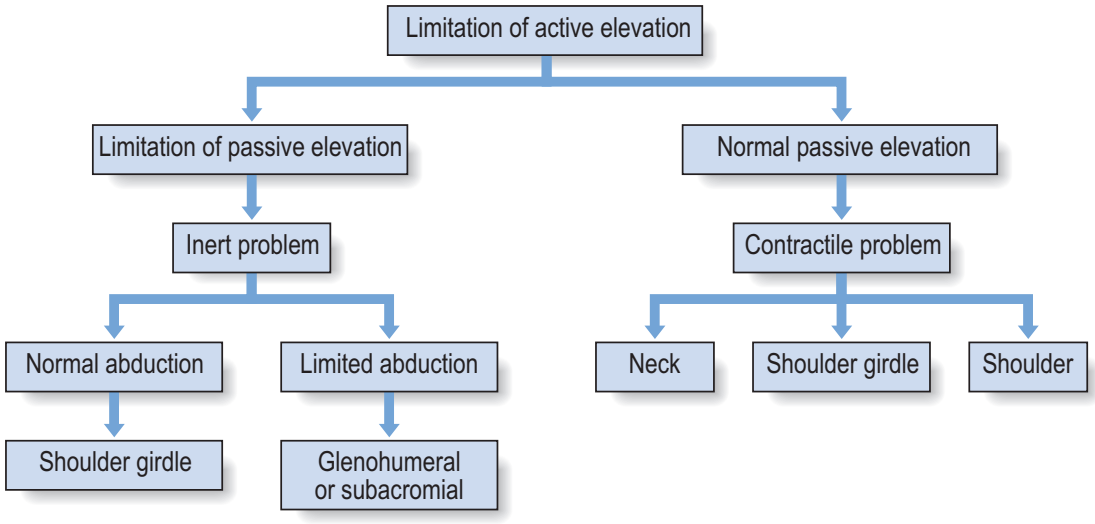

Fig 14.10 • Differential diagnosis of limitation of active elevation of the shoulder.

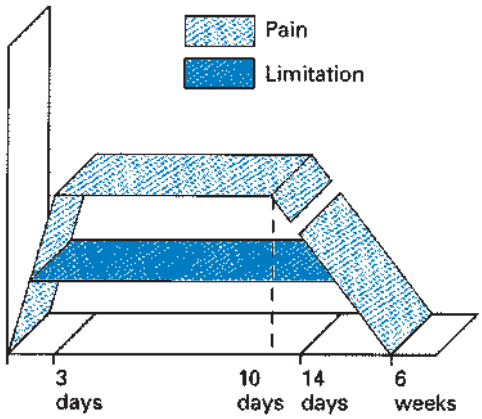

Fig 14.11 • Natural history of acute subdeltoid bursitis.

Active and passive elevation are therefore hardly possible and an 'empty end-feel' is found on passive elevation; the movement is stopped by the patient, who begs the examiner not to proceed, despite being possible as tissue resistance is not encountered. Marked limitation of passive scapulohumeral abduction is also present.

Other passive movements are also painful, sometimes only slightly limited but in a clearly non-capsular way; in acute subdeltoid bursitis, passive elevation and abduction are most restricted, whereas in arthritis it is passive lateral rotation that is most reduced. It is quite natural in such a painful disorder for some resisted movements, such as abduction and lateral rotation, to be painful too.

If the patient presents at the very beginning (first day after the onset), a painful arc on elevation may be found. However, once the inflammation has become severe, this disappears because it is no longer possible to go beyond the point of painful impingement. After 7–10 days of severe pain, it starts progressively to wear off so that at the end of 3–4 weeks only an ache remains. At this point, active elevation is still limited to about half-range. After 4–6 weeks the pain has disappeared totally and range of movement has returned to normal. During the last week, when full recovery is almost complete, a painful arc may reappear.

The clinical examination is followed by palpation of the superficial part of the bursa, which is very tender and sometimes even swollen. It should be noted that in acute bursitis not only the palpable (subdeltoid part) but also the subacromial bursa are involved.

Differential diagnosis

The clinical presence of this type of bursitis, in which a striking non-capsular pattern emerges, is so typical that differential diagnosis should not offer much in the way of difficulty. The only condition that has similar symptoms and signs is a septic bursitis. Subacromial septic bursitis also presents with acute shoulder pain and a gross non-capsular pattern of limitation. Signs that arouse suspicion are: swelling, redness, warmth and systemic signs such as fever and an elevated white blood cell count.[165] Septic bursitis should be suspected in patients with disease states associated with immunosuppression, patients with systemic infection, and patients who have received a corticosteroid injection.[166]

Other conditions with a swift onset can also be taken into consideration:

- Gouty arthritis: this has a very abrupt onset but lasts only 3–7 days. On clinical examination a capsular pattern is found.
- Septic arthritis: although very similar to acute bursitis – swift onset and very painful – this is easily differentiated by the accompanying symptoms of fever, general illness and local warmth and by the presence of a pronounced capsular pattern.
- Pathological fracture: mainly as a result of metastases, a pathological fracture is usually preceded by severe pain of weeks' or months' duration, together with limitation of capsular movement. Severe exacerbation of pain comes on immediately when fracture occurs.
- Dislocation of the shoulder: a history of an injury or of previous attacks is present. Deformation on inspection and radiography provides the key.

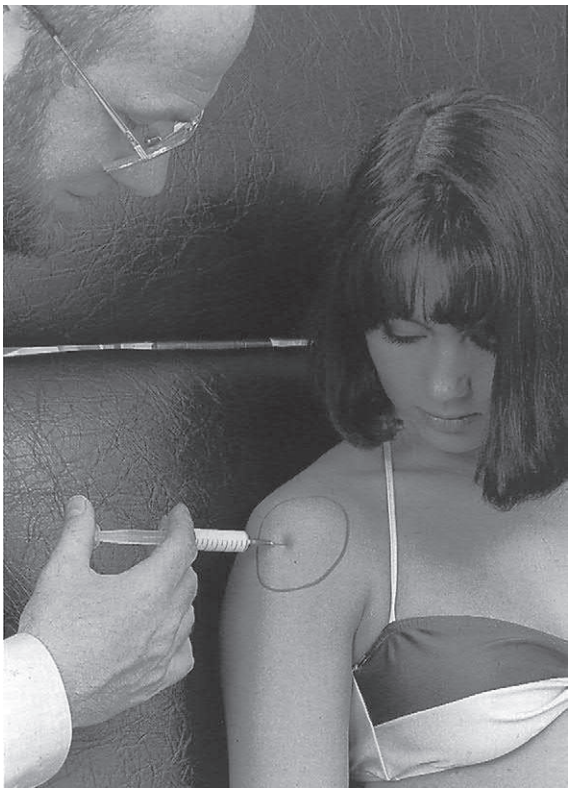

Fig 14.12 • Infiltration of the superficial part of the subdeltoid bursa.

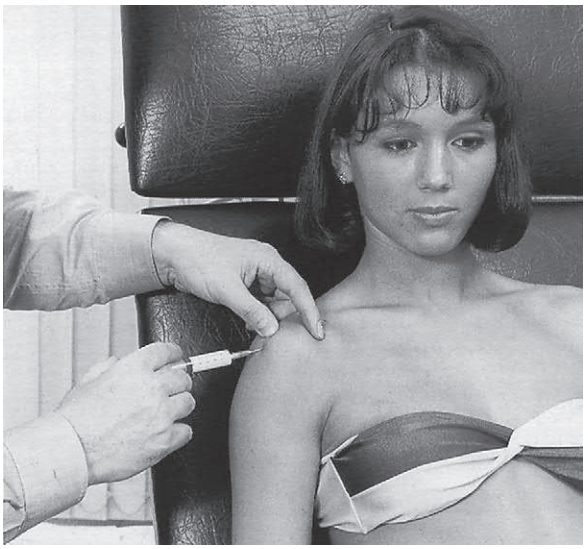

Fig 14.13 • Infiltration of the deep part of the subdeltoid bursa.

Treatment

During the first 10 days after onset, infiltration of the entire bursa with triamcinolone is most helpful. If done correctly, this is one of the most successful treatments in orthopaedic medicine; in almost all patients, full cure is achieved in less than 5 days. In patients who have not presented within 10 days or those who refuse steroids, a 'figure-of-eight' bandage at night, fixing the arm to the body, avoids any involuntary movement during sleep. In the day, the arm is carried in a sling for as long as the pain so warrants.

Giving an infiltration into such a severely inflamed bursa is extremely painful unless a strong local anaesthetic is added. Two syringes are used: one with a needle of about 3 cm, used for the superficial part of the bursa, and one with a 5 cm needle, used for the deep part of the bursa. Both syringes contain 1 mL of triamcinolone, 40 mg/mL mixed with 4 mL of prilocaine 2%. The technique used is the same as for chronic subdeltoid bursitis, but in acute bursitis, both subacromial and subdeltoid parts of the bursa must be treated (Figs 14.12 and 14.13). Gentle palpation of the entire subdeltoid part determines the area of tenderness, which is usually much larger than in chronic subdeltoid bursitis. The subdeltoid area is mapped and infiltrated thoroughly. The second infiltration is then given via a lateral approach under the acromial arch. Special care must be taken to deposit some of the product all over the tender part of the subdeltoid bursa and the entire subacromial bursa.

Immediately after the infiltrations, the pain is somewhat relieved and thereafter the patient improves gradually with time. Usually after-pain is not felt.

The patient should rest the arm and return 2 days later to be re-examined. If some pain still remains and elevation is not full and painless by then, some part of the bursa must have been missed. The remaining inflammation – either at the subdeltoid or the subacromial section of the bursa – is again localized and thoroughly infiltrated. Maximally, half the amount if infiltrate used at the first attempt is now used. Recurrences are not usually seen.

Special cases

There are two special types of subdeltoid bursitis:

- *Acute bursitis with calcified deposit*: The clinical picture is almost the same as in ordinary acute bursitis but spontaneous recovery does not take so long, although the tendency for recurrence is higher.[167] The treatment is the same. In order to diminish the tendency of recurrence, it is worth trying to dissolve the calcification by repeated infiltrations of procaine, after the acute attack has been dealt with. For this purpose, 5 mL of procaine 2% is infiltrated at weekly intervals for 3 or 4 weeks, each time infiltrating the part of the bursa where the calcification lies (Fig. 14.14).[168,169]
- *Haemorrhagic subdeltoid bursitis*: This occurs only in elderly patients. It usually comes on spontaneously or may accompany a tendinous rupture. The patient complains of moderate pain and swelling. On clinical examination, some limitation of movement is found which is mainly the result of fluid and not of pain. As in acute subdeltoid bursitis, a non-capsular pattern is present. On palpation, pain can be elicited and fluctuation detected. Treatment consists of repeated aspirations at weekly intervals. Infiltrations are not required. If blood keeps reaccumulating, a haemangioma has to be considered.

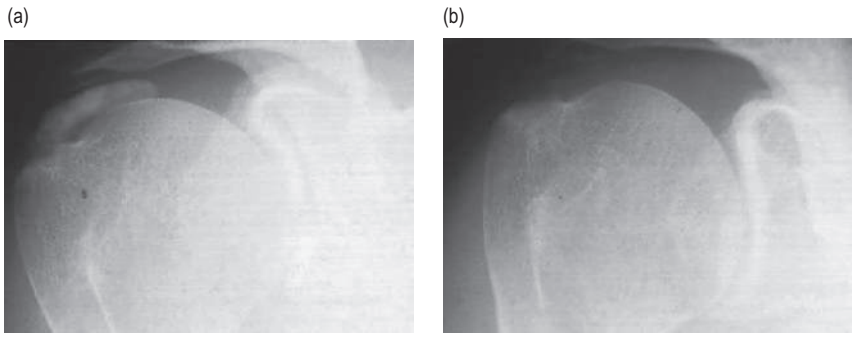

Fig 14.14 • Acute bursitis with calcified deposit before (a) and after (b) treatment.

Psychogenic limitation

Mental problems may sometimes be expressed in terms of physical behaviour. It should not be a surprise that psychogenic symptoms are often localized at the shoulder because the shoulder joint is closely connected with emotional tone: the outstretched arm is a symbol of pleasure and welcome; the arm held into the side expresses rejection.

The diagnosis 'functional' limitation of elevation is quite simple to make: there is a marked limitation of both active and passive elevation, the end-feel being that of an active, voluntary muscular contraction. However, active and passive elevation of the shoulder girdle (shrugging of the shoulders) is completely normal and the passive, scapulohumeral abduction is as limited as is passive elevation of the arm.

The patient does not realize that, even if the shoulder joint is ankylosed, mobility of the scapula permits 60° tilting and the arm must be capable of this amount of elevation unless the scapula has also become fixed. Hence, detection of a non-physical problem is simple if, in a patient with normal scapular mobility and normal elasticity of the pectoralis major muscle (see below), the range of voluntary and passive elevation is contrasted with the range of passive abduction at the scapulohumeral joint.

Passive elevation limited and passive scapulohumeral abduction normal

This indicates that the glenohumeral joint is intact but that the disorder is due to a malfunction of structures belonging to the shoulder girdle. These lesions are discussed more extensively in the online chapter *Interpretation of the clinical examination of the shoulder girdle*.

Contracture after breast surgery

Breast-conserving therapy has become a safe option for the primary surgical treatment of early breast cancer. Nevertheless, there are cases where this type of treatment is impossible. In these cases, mastectomy followed by immediate reconstruction is one type of alternative treatment. Another step in breast cancer surgery is management of the axilla, which may involve complete axillary lymph node dissection. After such a major operation, a limitation of about 30–60° on both active and passive elevation of the arm can occur, from loss of elasticity of the pectoralis minor muscle as a consequence of scarring tissues.[170,171] The scapula–humeral range remains normal. Pain is absent.

Pulmonary tumour

An apical tumour of the lung (Pancoast tumour) is often initially misdiagnosed as a shoulder problem.[172,173] Tumours of the base of the lung may also give rise to pain referred to the base of the shoulder (C4) in that they may irritate the diaphragm. Once a neoplasm of the lung involves the thoracic cage, muscle spasm of the pectorales muscles ensues and causes a limitation of both passive and active elevation: the arm cannot be raised beyond the horizontal. Trying to go any further is very painful and is stopped by muscular spasm. Pain and/or limitation are not found at the glenohumeral joint and the scapula is fully mobile. In addition, there is pain on resisted adduction and medial rotation of the arm. Care should be taken not to misinterpret these signs as being a psychogenic limitation.

Warning

The end-feel of muscle spasm always means that a serious disorder is present and should alert the examiner. A plain radiograph of the lungs must be taken at once.

Contracture of the costocoracoid fascia

This disorder often causes diagnostic difficulties. Initially there is only pectoroscapular pain on full elevation of the arm. Later on, when the pain becomes more or less constant, a slight limitation of about 5–10% of elevation can be detected. Passive movement at the glenohumeral joint is normal. The possibility of a shortened costocoracoid fascia is brought to mind when a small but painful limitation of active and passive scapular elevation is detected but resisted movements of the scapula prove painless. Forward movement of the scapula is slightly painful; backward movement is negative.

A shortening of the costocoracoid fascia may be caused by a neoplastic invasion, healed apical tuberculosis or an injury. The contracture may also develop without apparent reason. It should be differentiated from other subclavicular disorders, such as a lesion of the subclavius muscle, sprain of the conoid and trapezoid ligaments, or subcoracoid bursitis (see online chapter *Interpretation of the clinical examination of the shoulder girdle*).

Ankylosed acromioclavicular or sternoclavicular joint

This is encountered in advanced cases of ankylosing spondylitis, in arthrosis or in rheumatoid arthritis. It leads to a severe

limitation of elevation of the arm, which cannot be raised actively or passively beyond the horizontal because scapular rotation is limited. Clinical examination reveals full scapulohumeral abduction but total absence of scapular elevation and rotation.

Active elevation limited and passive elevation normal

Fracture of the first rib

A stress fracture rather than trauma is usually the cause. In that a fractured rib heals spontaneously in about 2 months, the condition is considered only with pain of recent onset. The patient complains of unilateral pain located under the scapula, behind the clavicle or at the root of the neck.[174] The lesion is characterized by neck, scapular and arm signs. Typically, both active and passive side flexion of the neck to the painless side increase the pain because this pulls on the fractured rib via the scalene muscles. As a consequence, resisted side flexion towards the pain is also painful. All scapular movements – active, passive and resisted – are also more or less painful. When the patient is asked to raise the arm actively beyond the horizontal, he or she cannot do so, whereas passive elevation is of full range but only slightly painful.[175] Radiography confirms the diagnosis.

Clay-shoveller's fracture

This rare condition is a traction fracture of a spinous process in the lower cervical or upper thoracic area.[176,177] At this level, the trapezius, rhomboid and posterior serratus superior muscles are attached to the spinous processes. A fracture is usually the result of heavy work. Less commonly it is encountered in athletes. The patient normally feels a sudden sharp pain followed by local tenderness. Although neck movements are almost painless, the patient can hardly move either arm actively into slight elevation. A very pronounced limitation of active elevation of about 150° is found but passive elevation remains normal. Both active scapular elevation and resisted scapular elevation are also painful. There is local tenderness and, on the radiograph, avulsion of the seventh cervical or first thoracic spinous process is seen. The lesion heals spontaneously in 5–6 weeks. Immobilization is unnecessary.

Long thoracic nerve palsy

A lesion of the long thoracic nerve resulting in a palsy of the serratus anterior muscle may follow local invasive procedures on the anterolateral aspect of the thorax,[178] local trauma or a traction injury to the nerve.[179,180] However, in the majority of cases no cause can be established. The usual onset is with unilateral scapular pain which continues day and night for about 3 weeks. During this period the arm becomes weak and heavy. In rare cases pain is totally absent, the patient complaining only of fatigue of the arm.[181]

The clinical examination is more specific and provides the key to the exact diagnosis. On inspection, winging of the scapula may be present. Clinical examination shows a painless limitation of active arm elevation of about 45–90°.[182] Passive movements are of full range. Neck, scapular or arm movements have no influence on the pain. Weakness is present within

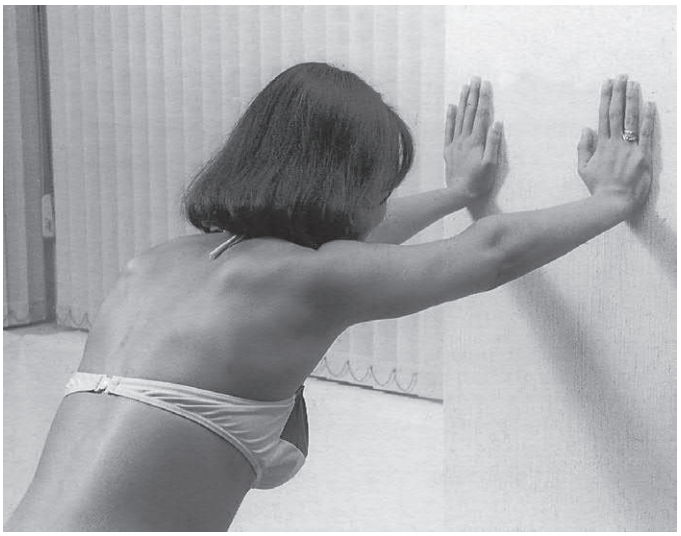

Fig 14.15 • Test for mononeuritis of the long thoracic nerve.

the serratus anterior muscle and can easily be detected by the following test: the patient is asked to push against a wall with the arms stretched out horizontally in front of the body (Fig. 14.15). This pushes the medial border of the scapula further away from the thoracic cage when the movement is not countered by a contraction of the serratus anterior muscle. The abnormal movement is seen as a considerable winging of the scapula.

The natural history is spontaneous recovery from the pain in about 3 weeks, and full recovery of normal muscle function usually occurs in an average of 9 months.[183]

Accessory nerve palsy

The spinal accessory nerve is the sole motor nerve of the trapezius. A palsy may result from a crush injury to the nerve[184,185] after a forceful blow to the neck. Often the lesion is posttraumatic, after cervical lymph node biopsy or other surgical procedures.[186,187] Sometimes no clear cause for the neuritis can be detected and in such a case the diagnosis may be quite difficult.

There is a severe and continuous unilateral scapular ache with spontaneous onset, lasting for about 3 weeks. The patient then starts to complain of weakness in the arm, which may last for months.

Inspection elicits an asymmetrical neckline with drooping of the affected shoulder. This may be accompanied with slight lateral displacement and winging of the scapula.[188] Elevation is between 15° and 30° limited. Winging is accentuated during arm elevation and disappears during forward flexion of the arm due to the action of the serratus anterior muscle.[189] Again, passive elevation is full-range and painless. Passive and resisted movements of the shoulder are completely normal. During resisted external rotation, winging of the scapula once again becomes visible.[190]

The diagnosis can be confirmed by testing the strength of the trapezius muscle. The patient is asked to pull both scapulae together while counterpressure is given at the medial side of

Fig 14.16 • Test for mononeuritis of the accessory nerve.

the inferior angle (Fig. 14.16). In accessory nerve neuritis, the scapula can be pushed away easily.

In an idiopathic mononeuritis the pain disappears after about 3 weeks but spontaneous recovery of motor function may take about 4–8 months.[191]

C5 full root palsy

This is usually the result of slowly but progressively increasing compression of the C5 nerve root by an osteophyte in the fourth intervertebral foramen. It may finally result in a painless inability to raise the arm actively because of pronounced weakness of the supraspinatus and the deltoid muscles. Other C5 muscles, such as the infraspinatus and the biceps, are, of course, also weak. A C5 palsy may also result from a traction injury, which is usually caused by a sudden depression of the entire shoulder girdle, in combination with a simultaneous and forceful side flexion of the neck in the opposite direction (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

C7 full root palsy

A severe C7 palsy may cause weakness of shoulder adduction. Often, a slight limitation of active elevation is also noticed. The diagnosis is obvious when a palsy of the triceps and/or the flexors of the wrist is also found.

Total rupture of the supraspinatus

In full rupture of the supraspinatus tendon the patient is unable to elevate the arm actively. Passive elevation is of full range with a severe painful arc. Resisted abduction is weak and painless (see p. 257).

Limitation of passive lateral rotation

Only a few lesions cause an isolated limitation of lateral rotation of the arm. History, end-feel and accessory tests differentiate between an anterior capsular contracture and a subcoracoid bursitis.

Anterior capsular contracture

An isolated contracture of the anterior capsule results from trauma or develops gradually after rupture of the infraspinatus tendon.

Previous shoulder injury such as subluxation is one cause. Usually the whole joint suffers from the traumatic impact and a traumatic arthritis results. Exceptionally, only the anterior portion of the capsule bears the impact of the injury. A localized synovitis and subsequent capsular contracture follow.

An anterior capsular contracture may also result from complete rupture of the infraspinatus tendon. Because the teres minor muscle is a weak and incomplete lateral rotator, it does not, on its own, bring the arm in full lateral rotation, which finally leads to a loss of the normal elasticity of the anterior portion of the capsule.

The condition is characterized by a painful limitation of passive lateral rotation together with an abnormal end-feel. In the beginning the end-feel is that of muscle spasm; later, it changes to typically hard.

Treatment

It is important for all patients with a rupture of the infraspinatus tendon to exercise on a regular basis to keep the shoulder mobile, as a means of prevention. This can be achieved through sporting activities or through passive mobilizations which bring the shoulder into full lateral rotation. Patients who have already developed a contracture of the anterior capsule are best treated by capsular stretching. This can be done in the same way as for shoulder arthritis but stretching in lateral rotation must also be included (Fig. 14.17).

Technique: capsular stretching in lateral rotation

The patient lies supine, the arm abducted to about 45°, and the elbow bent to 90°. The therapist stands at the affected side and takes the arm in both hands, just proximal to the elbow; the contralateral forearm pushes the patient's forearm down just above the wrist. This results in stretching of the anterior part of the joint capsule into lateral rotation. The amount of force used, the duration and the sequence are the same as for stretching in arthritis.

Subcoracoid bursitis

This rare condition comes on for no apparent reason and provokes unilateral pectoral pain. On clinical examination, a painful limitation of lateral rotation is the main finding. The limitation is due to passive stretching of the pectoralis major muscle over the inflamed bursa. If the lateral rotation is performed again, this time disregarding the patient's pain, the range of lateral rotation will be found to have increased. The limitation will even completely disappear during a lateral rotation with the upper arm abducted to the horizontal

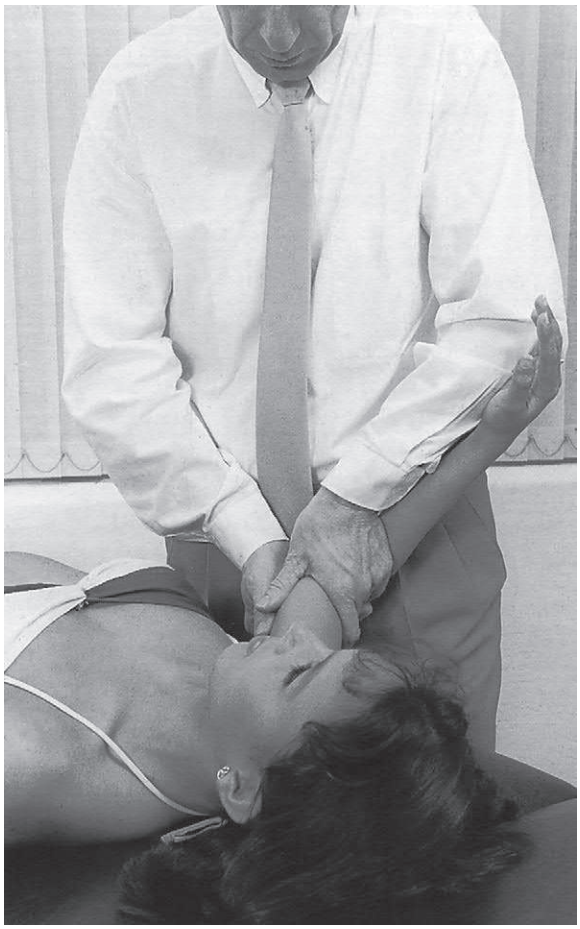

Fig 14.17 • Capsular stretching in lateral rotation.

Fig 14.18 • Passive horizontal lateral rotation.

(Fig. 14.18). Although still painful, it is no longer limited since, in this position, the pectoralis major compresses the inflamed bursa less.[192]

The main *differential diagnosis* is an anterior capsular contracture. Here, the limitation does not depend on the position of the upper arm and the movement always comes to a stop at the same point in the range. Another accessory test that differentiates between a capsular contracture and a subcoracoid bursitis is passive horizontal adduction in front of the chest, which pinches the subcoracoid bursa painfully between scapula and upper arm (see p. 217).

Other differential diagnoses that must be considered are subscapularis tendinitis, a lesion of the pectoralis major, sprain of the trapezoid–conoid ligament and early glenohumeral arthritis. In the former two conditions, passive lateral rotation, although painful, is not limited and resisted medial rotation causes pain. For a lesion of the pectoralis major, resisted adduction is also painful. A sprain of the trapezoid–conoid ligament does not give rise to limitation of movement; only pain at the extremes of all passive tests is present and passive horizontal adduction is painless.

At the very beginning of a glenohumeral arthritis (idiopathic or traumatic), it is possible to find only a slight painful limitation on passive lateral rotation, together with some pain on full passive elevation and medial rotation. The end-feel may be more or less normal. On passive lateral rotation with the arm abducted to the horizontal, the same limitation is found.

Treatment

The condition can be treated only by infiltration with steroid.

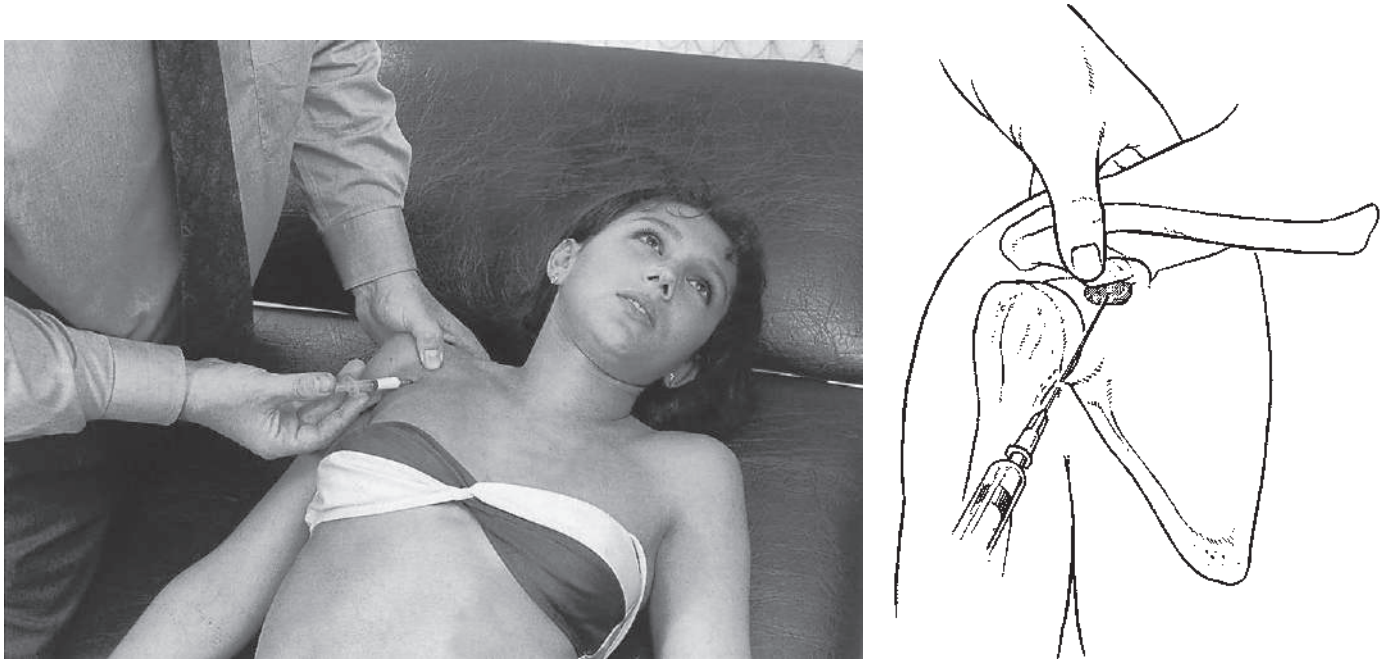
Technique

The patient is put in the half-lying position, and asked to adduct the scapula and shrug the shoulders. Adduction brings the coracoid process into prominence and shrugging the shoulders takes it away from the top of the lung. Next the tip of the coracoid process is palpated and a point chosen about 2 cm below it. A 5 cm needle is inserted here, pointing in a cranial–medial–dorsal direction and aiming at the base of the coracoid bone (Fig. 14.19a). After it hits the bone, it is withdrawn by about 1 cm and 2 mL of triamcinolone is infiltrated here over several withdrawals and reinsertions (Fig. 14.19b). The infiltration is repeated at weekly intervals until full relief is obtained. Three infiltrations usually suffice.

Limitation of passive medial rotation

Isolated limitation of the medial rotation is very rare. A discrete painful loss of internal rotation is sometimes seen in combination with a lesion of the upper/posterior rotator cuff (supraspinatus–infraspinatus). This limitation is most prominent if the internal rotation is performed in 90° of abduction and is thought to be caused by a thickened posterior capsule.[193] The limitation usually disappears spontaneously after the tendinous lesion has been healed.

A summary of the non-capsular limitation patterns at the shoulder is shown in Figure 14.20.



(a) (b)

Fig 14.19 • Infiltration of the subcoracoid bursa.

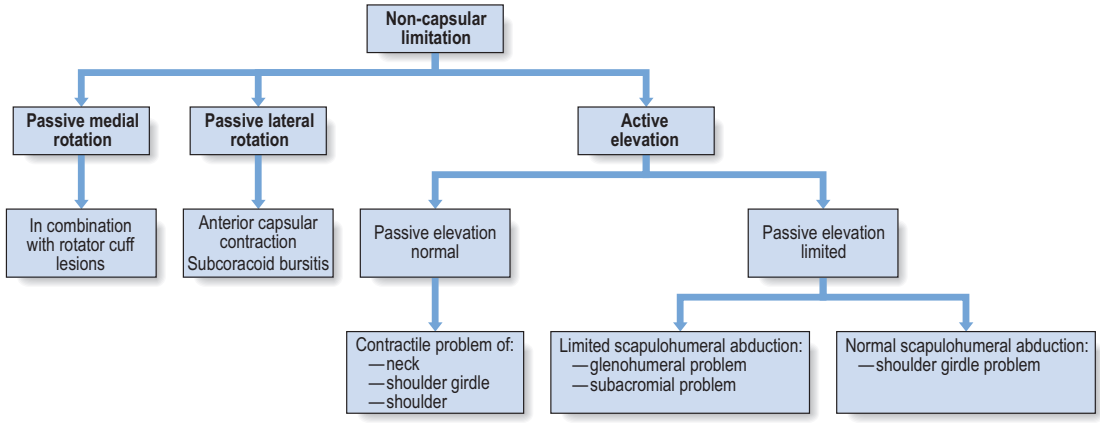


Fig 14.20 • Summary of the non-capsular limitation patterns at the shoulder.

Full range of movement

Disorders of inert structures may be characterized by a full range of passive movements and a normal end-feel. However, passive movements are painful at the end of range or at half-range (painful arc). Resisted movements from the basic functional examination are, of course, negative – painless and strong. Only a few potential lesions correspond to this pattern. They are: a sprain of the acromioclavicular ligaments, a sprain of the coracoclavicular ligaments and chronic subacromial bursitis.

Acromioclavicular sprain

The acromioclavicular joint is stabilized by capsular ligaments which reinforce the thin capsule all around, and by extracapsular (coracoclavicular) ligaments. Vertical stability of the joint is controlled mainly by the coracoclavicular ligaments, whereas horizontal stability is controlled by the acromioclavicular ligaments.[194]

An acromioclavicular injury is most commonly the result of a fall on to the point of the shoulder with the arm at the side, as often occurs in football, hockey, alpine skiing[195] or judo.[196,197] In this position, the acromion is driven medially and

downwards in relation to the distal end of the clavicle, the latter being fixed through interlocking of the sternoclavicular ligaments.[198] Less often the trauma is a fall on the elbow or on the outstretched arm. In this event, a cranial force is exerted on the acromion.

Finally, on occasion, the sprain is the result of too much tension on the acromioclavicular ligaments from overuse, as can be seen in swimmers, weightlifters and bodybuilders.[199] In an osteoarthrotic joint, ordinary daily work may cause acromioclavicular sprain.

Symptoms

Pain is felt at the shoulder during and after activity. Lying on the affected side is usually painful. In that the acromioclavicular joint is derived from the C4 segment, and the C4 dermatome is rather small, little referred pain is to be expected. As a rule, when the patient is asked to point out the exact site of the pain, he or she generally puts a finger right on the acromioclavicular joint. Exceptionally the pain spreads beyond the lateral acromial rim or upwards to the trapezius, which usually indicates involvement of the inferior capsular ligament. In this event, differentiation from a case of chronic subdeltoid bursitis may be difficult and often necessitates a diagnostic infiltration with local anaesthetic.

Functional examination

There is pain at full range on passive elevation and passive lateral and medial rotation. Limitation of movement is not found. Resisted movements are usually painless, although exceptionally pain may be present on resisted adduction or abduction as a result of transmitted stress on the acromioclavicular ligaments.

Logically one would expect all scapular movements to hurt as well, because they all put strain on the acromioclavicular joint. Strangely enough, these tests are mostly negative in that far less stress is put on the acromioclavicular joint during active and passive scapular movements than on using the arm as a lever on passive arm movements. Sometimes a painful arc is present, locating the lesion in the inferior acromioclavicular ligament.

With this type of clinical pattern, an accessory and useful differential diagnostic test should be done: passive horizontal adduction across the front of the chest (see p. 217). This is the most painful movement when the acromioclavicular joint is affected and may even be limited in a severe sprain of the posterior part of the acromioclavicular ligaments. After the diagnosis has been established clinically, the joint line is palpated for local tenderness. When palpation is painful, it establishes the superior ligament at the site of the lesion. The inferior ligament is obviously beyond the reach of the fingers and cannot be palpated but, as previously described, if it is involved, a painful arc is usually present. Sometimes there is a combined lesion of both superior and inferior ligaments. In this event, palpation of the joint line is positive and a painful arc is also found.

Most commonly, a sprain to the joint occurs without ligamentous damage and no displacement can be palpated. If the traumatic force had sufficient magnitude to disrupt the acromioclavicular ligaments, (sub)luxation of the acromioclavicular joint becomes visible. Acromioclavicular sprains and dislocations are classified on the integrity of the acromioclavicular and coracoclavicular ligaments. Classically there are three grades of acromioclavicular dislocation (Fig. 14.21).[200–202] Recently grades IV, V and VI acromioclavicular dislocations have been added to the classification system.[203] In type IV injuries, the clavicle is grossly displaced posteriorly into the trapezius muscle; type V is a severe vertical separation of the clavicle; and in type VI the clavicle is dislocated inferiorly into either a subacromial or a subcoracoid position.

Differential diagnosis

An uncomplicated (grade I) sprain of the acromioclavicular joint is sometimes difficult to differentiate from chronic subdeltoid bursitis and early glenohumeral arthritis.

In chronic subdeltoid bursitis, a very similar clinical picture (all passive movements are painful at full range, together with a painful arc) may be seen. The pain in bursitis is usually

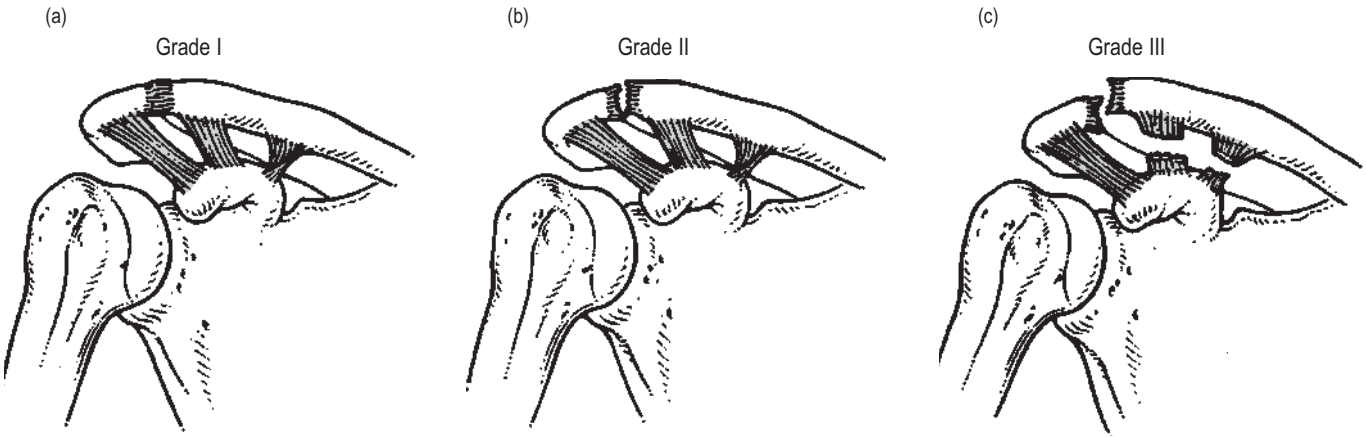

Fig 14.21 • Acromioclavicular joint lesions: (a) grade I: a small lesion of the acromioclavicular ligament without displacement; (b) grade II: rupture of the acromioclavicular ligament with cranial displacement of the clavicle, of less than half its width; (c) grade III: a a rupture of the coracoclavicular ligaments and a full dislocation of the clavicle.

felt in the deltoid area and spreads further down the arm in the C5 dermatome. There is usually no history of trauma. Painful passive horizontal adduction is less pronounced than in acromioclavicular sprain. If the superficial part of the bursa is at fault, palpation is positive; if the deep part is affected, certainty can only be obtained by a diagnostic infiltration of local anaesthetic.

The differential diagnosis from early arthritis of the shoulder is difficult when no notable limitation of movement is present. The patient complains of pain at the shoulder, radiating down the arm. On functional examination, pain is present at the end of all passive movements. The most painful movement is full passive lateral rotation, whereas in a sprain of the acromioclavicular joint it is passive horizontal adduction. In arthritis the end-feel on lateral rotation is slightly harder than normal.

Treatment

Sprain without displacement (grade I)

As adhesions do not form in a sprain of the acromioclavicular joint, it is best treated by relative rest. The only additional measure needed is to stop the inflammation. This can be achieved by deep friction (superior ligament) or by a local infiltration of steroid (superior and inferior ligaments). No matter how long the lesion has existed, the treatment remains the same.

Rest on its own is usually not enough. It gives the patient a false impression of healing. The pain disappears only temporarily until normal activity is restarted, when it recurs.

When sprain is the result of repeated stress on the acromioclavicular ligaments caused by specific activities, the lesion may recur. In this event the patient must avoid these activities in the future.

Technique: palpation

The patient sits with the arm in the neutral position and the back resting against the couch. The posterior angle of the scapular spine is palpated first. The finger is then brought to the lateral edge of the acromion and more medially on the flat upper surface of the acromion. A hard bony rim is felt, sticking out at approximately 2 cm medial to the lateral acromial border. This is the outer end of the clavicle, which is always slightly elevated. The joint line lies just lateral to it.

Palpation may be difficult in stout patients, or in elderly people in whom a rim of osteophytes at the acromial part of the acromioclavicular joint can be mistaken for the outer clavicular end. In these cases, some extra landmarks can be used. When the anterior edge of the acromion and clavicle is palpated, a depression is felt at the level of the acromioclavicular joint line. The anterior depression can be slightly opened if an assistant pulls the arm into full lateral rotation. If traction is applied to the arm in a distal direction, the palpating fingers on the acromioclavicular joint can usually feel the movement between clavicle and acromion.

Technique: infiltration of the superficial ligament

After exact delineation of the painful spot, a 2.5 cm needle is fitted to a syringe containing 1 mL of triamcinolone. If the deep ligament is also affected (painful arc), 2 mL is used.

The patient sits in the same position as previously described for palpation. The needle is obliquely inserted at the centre of the painful area (Fig. 14.22a). The aim is to infiltrate the whole of the tender area, at both sides of the joint line, via a series of partial withdrawals and reinsertions of the needle while depositing a few droplets into the ligament each time. A typical ligamentous resistance is encountered. It should be noted that the ligament lies superficial to the osseous structures and therefore the needle should not be inserted deeply but must have its tip in bony contact.

Technique: infiltration of the deep ligament

The same type of needle and amount of steroid are used. After the joint line has been identified, the needle is inserted from above, halfway between the anterior and posterior margins of the acromioclavicular joint. It may be useful to have an

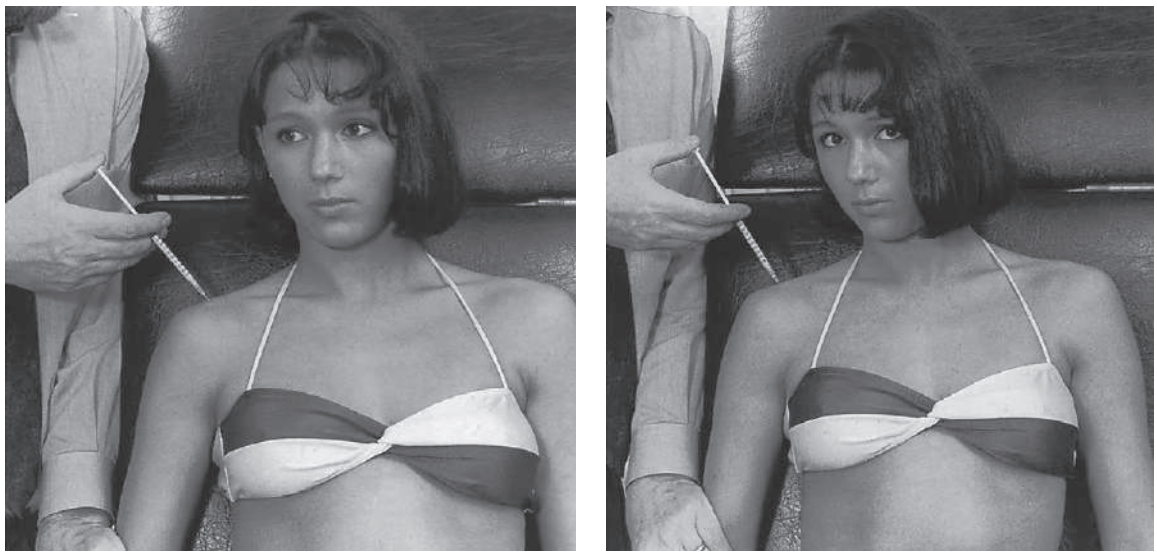

Fig 14.22 • Infiltration of the (a) superficial and (b) deep (lower) ligament of the acromioclavicular joint.

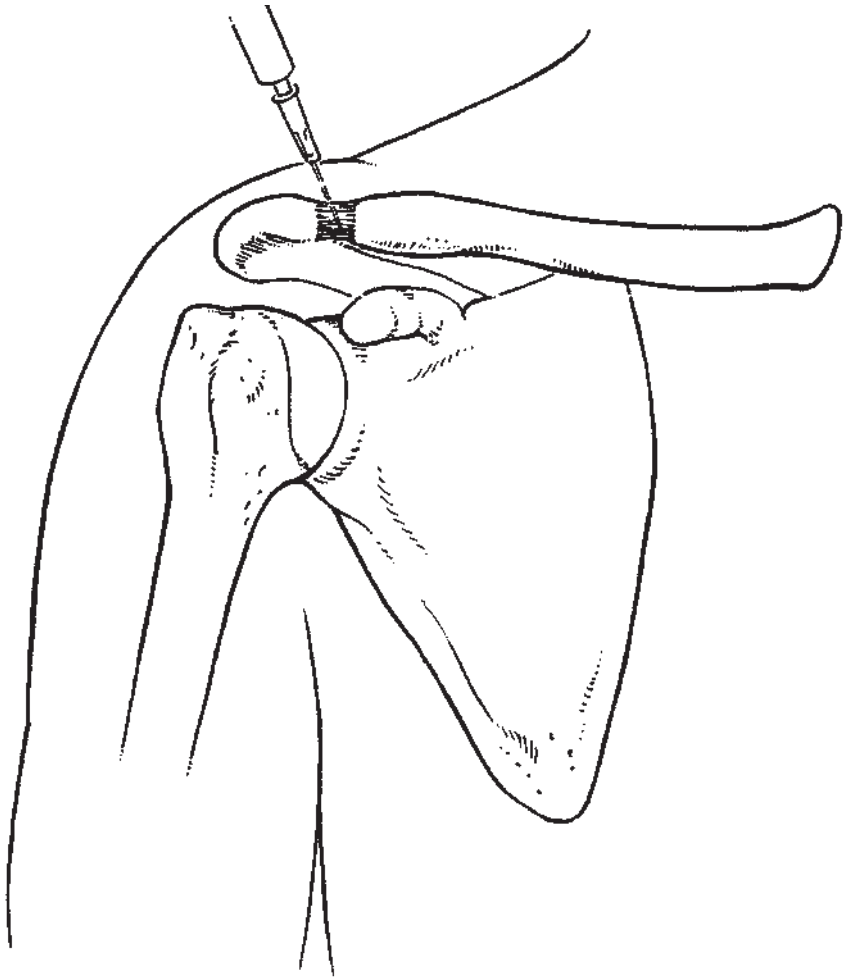

Fig 14.23 • Infiltration of the acromioclavicular joint: deep ligament.

assistant who brings the arm of the patient into full lateral rotation, so as to open the acromioclavicular joint space as widely as possible. The needle is normally inserted in a craniolateral to caudomedial direction (Figs 14.22b and 14.23). First the superficial ligament is encountered, next the meniscus and finally the deep ligament. They all offer the same resistance. The deep ligament lies about 2 cm from the surface. The needle must be inserted almost to its full length until ligamentous resistance is felt. The structure is then infiltrated fanwise over its full length.

Follow-up

The patient rests the arm for 1 week and is reassessed. If the tests are still positive, a further infiltration is done. One or two infiltrations usually suffice.

Technique: friction

This applies only to the superficial ligament. The patient adopts the same position as for palpation. The therapist stands behind, level with the affected shoulder. Friction is given with the index finger of the ipsilateral hand reinforced by the middle finger (Fig. 14.24). The fingers are placed exactly on the tender fibres of the superficial ligament at the joint line. Counterpressure is applied with the thumb at the back of the shoulder (see Fig. 14.24), placed vertically under the fingers. It is best to keep the index finger rather flat in order to treat the whole lesion at once. Because of the orientation of the fibres, friction is applied in an anteroposterior direction. As usual, the therapist alternates active and passive phases: the active moment is when the finger is pulled backwards towards the body, starting with the fingertip at the anterior portion of the ligament.

Friction is carried out three times a week for 20 minutes each session. Cure is normally obtained after 10–15 sessions.

Treatment of recurrences

Some cases tend to recur. In this event, sclerosant infiltrations may be useful. The technique used is the same as for steroid infiltration: 0.75 mL of P2G (phenol solution) mixed with 0.25 mL of xylocaine 2% is used per ligament and repeated twice at weekly intervals. The patient should be warned to expect severe after-pain for about 4 days.

Sprain with moderate displacement (grades II and III)

In all but the most severe dislocations, treatment consists of a short period of standard sling immobilization and early functional rehabilitation. Many studies have reported good functional results in spite of residual deformity in patients treated by this manner of 'skilful neglect'.[204–207] Treatment consists of a standard sling until the acute inflammation has subsided. If the pain and inflammation persist, a steroid infiltration can be given into the ligamentous remnants in order to suppress the inflammation. After 10 days the patient is allowed to mobilize

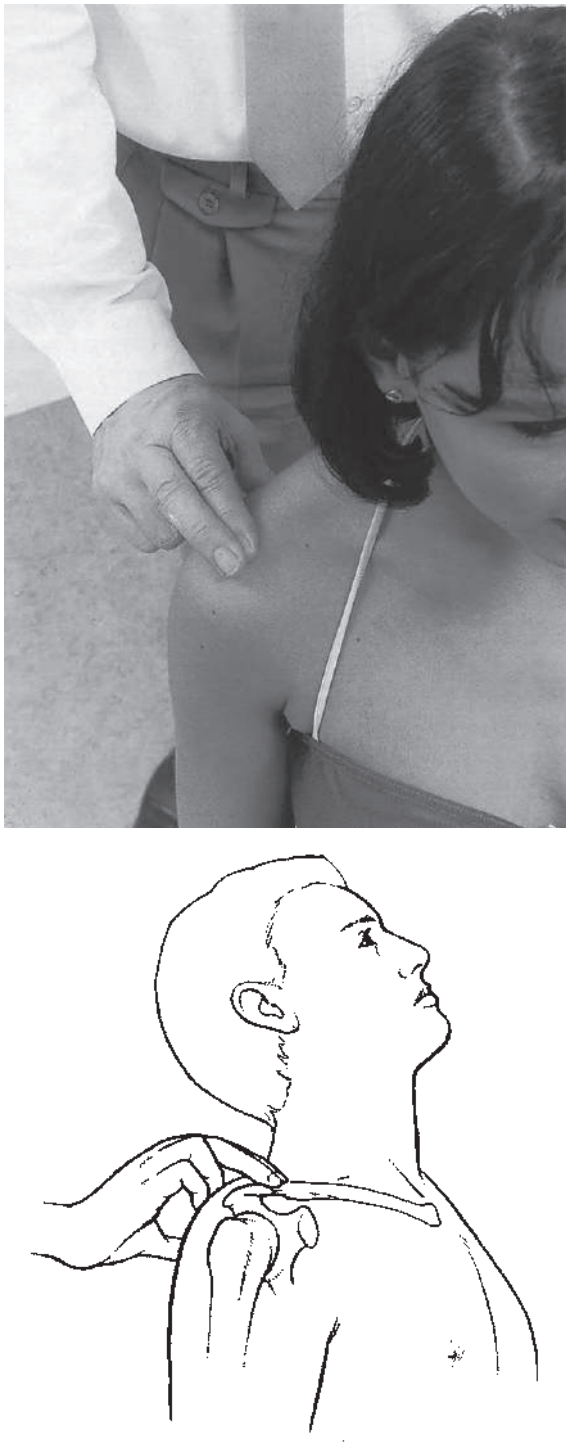

Fig 14.24 • Deep friction to the superficial acromioclavicular ligament.

the shoulder and is referred to a rehabilitation programme to strengthen the muscles of shoulder and shoulder girdle. Return to work or to sport is advised as soon as the shoulder can tolerate it. Several studies have shown that non-operatively treated patients with grade III acromioclavicular separations return to work earlier and with a lower complication rate than patients who have had surgery.[208,209]

Treatment of grade IV, V and VI injuries

Because of the severe displacement of the distal clavicle, surgical repair is advised.[210]

Special cases

Atraumatic osteolysis of the distal clavicle

Atraumatic osteolysis of the distal clavicle in athletes is a stress failure syndrome of the distal clavicle.[211] It is characterized by symptomatic resorption of bone over a period of weeks to many months. The origin is uncertain but the condition is usually related to strenuous physical activity.[212] There is never a history of any major injury to the acromioclavicular joint. It occurs principally in young athletes who have a long history of intense strength training.[213] Sporting endeavours with repeated episodes of significant trauma to the shoulder, or when the participant suffers repeated falls on to the point of the shoulder, have also been identified as precipitating causes of osteolysis.[214]

History and clinical findings are the same as in ordinary grade I sprain. As symptoms become more established, there is tenderness of the entire joint and some swelling can be palpated. Often a joint effusion can be aspirated.[215]

Diagnosis is by plain X-ray examination. Classically the radiographic changes are divided into three phases: lytic, reparative and 'burnt-out'. Optimal visualization of the acromioclavicular joint is only provided by taking an anteroposterior film with the X-ray beam tilted in a 25–30° cephalic direction.[216]

The natural history of the condition seems to run a self-limiting course of 1–2 years. Symptomatic treatment consists of modification of training activities and local infiltration of the acromioclavicular ligaments with triamcinolone.[217] Operative treatment is the exception and consists of resection of the distal clavicle,[218] which is usually performed arthroscopically.[219] The reported results are fair to good.[220]

Arthrosis of the acromioclavicular joint

Generally, a joint that is already arthrotic is more susceptible to the effects of exertion. This also applies to the acromioclavicular joint. The arthrosis as such normally gives rise to a vague ache in the C4 dermatome for some hours after activity. The pain usually wears off spontaneously. Sometimes it persists and, if this is so, the clinical picture is that of a grade I acromioclavicular sprain. Cure is easily achieved by steroid infiltration. If relapse occurs, sclerosant infiltration of the ligaments can be tried. If this is unsuccessful, the patient should avoid the precipitating activity for the rest of his life.

In ankylosing spondylitis, arthrosis of the acromioclavicular joint is very common and total ankylosis is often seen.[221]

Sprained coracoclavicular ligaments

History and examination

A sprain of the conoid and trapezoid ligaments is a particular hazard in sports such as squash or tennis, where the preliminary movement to a 'smash' may require the arm to be pulled far back.[222] It is also sometimes the result of a clavicular fracture.

(a)

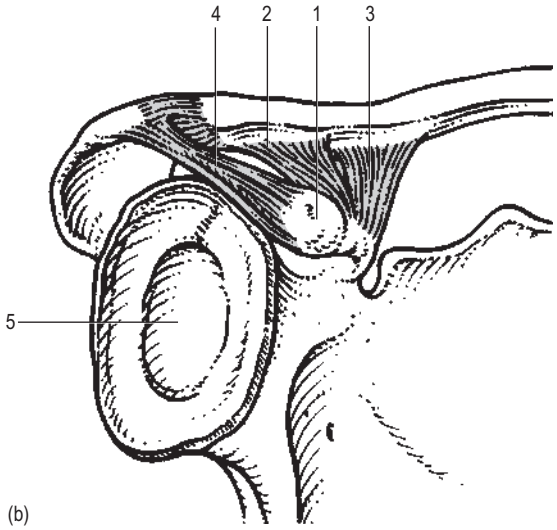

Fig 14.25 • (a) Infiltration of the clavicular insertion of the coracoclavicular ligament. (b) Anatomy: 1, coracoid process; 2, conoid ligament; 3, trapezoid ligament; 4, coracohumeral ligament; 5, glenoid labrum.

The clinical picture may be difficult to interpret. Pain is felt in the mid-clavicular area at the extreme of all passive arm and scapular movements. No limitation is found and resisted movements are painless. If the disorder is suspected, forced lateral rotation with the arm in horizontal abduction must be added to the clinical examination (see p. 229). This is usually the most painful test.

The lesion may be found at the superior side of the coracoid process or at the insertion on the inferior aspect of the clavicle. Differentiation between the two locations is made by palpation, which is best done with approximated scapulae. Careful comparison with the painless side should always be done because the coracoid process is always somewhat tender to the touch. In cases of doubt, a diagnostic local anaesthetic infiltration must be performed.

Differential diagnosis

Differential diagnosis is necessary, and includes the following disorders:

- *Sprained acromioclavicular joint*: the pain is felt more laterally at the tip of the shoulder. Passive horizontal adduction is the most painful test.
- *Subcoracoid bursitis*: this usually gives rise to a limitation of passive lateral rotation, which disappears when the test is repeated with the arm abducted to the horizontal.
- *Sprain of the subclavius muscle*: resisted shoulder depression is painful.
- *Subscapularis tendinitis*: the pain is felt more laterally, at the level of the axillary line. Resisted medial rotation is painful, as is passive lateral rotation.

Treatment

Because the coracoid attachment is deeply situated and the clavicular insertion is beyond the reach of the finger, both sites are treated by infiltration with steroid.

Technique: infiltration of the coracoid insertion

If tenderness is found at the coracoid process, 2 mL of triamcinolone are infiltrated at the superior aspect with the tip of the needle in bony contact. The typical ligamentous resistance must be felt. The whole amount is infiltrated drop-wise at, for example, 5–10 different places.

Technique: infiltration of the clavicular insertion

If palpation is painless, the problem lies at the clavicular insertion. A 3 cm needle is fitted to a syringe containing 2 mL of triamcinolone. The needle is inserted about 2 cm distal to the centre of the ligamentous insertion at the clavicle (Fig. 14.25). It is then moved further in until it meets bone. When ligamentous resistance is felt, the product is infiltrated drop by drop, starting just medial to the line of the acromioclavicular joint and over about 3 cm towards the midline until ligamentous resistance is no longer felt. During the whole procedure, the tip of the needle stays in bony contact. In some cases it may be of help to have the arm in full elevation, which brings the inferior aspect of the clavicle to lie anteriorly.

Follow-up

The patient is reassessed 1 week later and reinfiltrated if necessary. Results are fairly good as long as the activity that caused the lesion is avoided.

Chronic subdeltoid bursitis

A chronic subdeltoid bursitis is not the late result of an acute subdeltoid bursitis; it is chronic from the onset. It is therefore a clinical entity in itself, being far less painful than acute bursitis. Local inflammation and fibrotic adhesion formation between the acromial and tendinous parts of the bursa are the anatomical substrates of the lesion.[223] Also fluid may collect between the bursal walls. However, in the majority of cases, the lesion is localized with only one part of the bursa being affected.[224] Recently an increased amount of substance P was demonstrated in the subacromial bursal wall of patients with signs and symptoms that were attributed to chronic subdeltoid bursitis.[225]

History

The condition may affect all ages. It comes on spontaneously, or after injury complicates rheumatoid arthritis. Untreated, it does not show a great tendency for spontaneous healing and it can even persist for life. It is also not exceptional for those who have been cured by proper treatment to suffer a recurrence.

The pain is usually localized in the deltoid area but can spread further down the arm in the C5 dermatome. Sometimes it is felt only on activity, while at other times it is felt mainly at rest or even continuously, day and night. Consequently, the pain of chronic bursitis is not readily differentiated from C5 pain caused by other shoulder disorders.

Functional examination

The main difficulty with chronic subdeltoid bursitis remains the heterogeneity of the clinical pattern. Sometimes there is a mixed clinical picture of pain on some passive movements and pain on some resisted movements, with or without painful arc. Cyriax considered this pattern to be an 'incomprehensible bursitis'. It is quite possible that such a case is, in fact, a more evolved form of rotator cuff failure: a tendinous lesion of the bursal surface of the cuff tendons in combination with reactive inflammation of the bursa (see p. 250).

Most typically, chronic subdeltoid bursitis is characterized by a painful arc in the absence of any limitation of movement. The arc is sometimes the only positive clinical finding, can be very pronounced and is usually the most painful test. Often, in addition to this, the extremes of all passive movements also hurt.

Exceptionally, chronic subdeltoid bursitis may provoke limitation of movement in a non-capsular way. Limitation of either passive scapulohumeral abduction or passive internal rotation is present. All resisted movements are painless or equally painful.

Although the list given in Box 14.3 is not exhaustive, it describes one of the clinical pictures corresponding to a chronic subdeltoid bursitis.

Box 14.3

Clinical patterns of chronic subdeltoid bursitis

Most frequent patterns

- Painful arc only
- Pronounced painful arc
- Pain at the extremes of all passive movements
- Limitation of abduction or medial rotation
- All resisted movements painless or equally painful

'Incomprehensible bursitis'

- Pain on full passive lateral and/or medial rotation
- Pain at the end of all passive movements
- Painful arc
- Resisted abduction and lateral rotation painful
- Full passive lateral and medial rotation painful
- Painful arc
- Varying pattern of pain on resisted movements, which are sometimes transiently painful

If subdeltoid bursitis is suspected, palpation of the superficial part always follows the functional tests. For this the patient sits on a couch, the arm in the neutral position and the hand resting on the thigh for maximal relaxation. The whole deltoid area must be palpated and no single point overlooked. Palpation starts posteriorly below the outer end of the spine of the scapula and is continued laterally and anteriorly below the acromial edge. It is a good habit to start palpation away from the expected site of the lesion. It should always be done on both sides. Sometimes a local swelling or a small effusion is present.[226,227]

It must be stressed that the diagnosis always remains doubtful until it is confirmed by infiltration with local anaesthetic. Sonography can be used in the diagnosis of bursitis but the results should always be considered in relation to the clinical assessment, as asymptomatic 'bursitis' may be as prevalent as asymptomatic rotator cuff tears.[228–230] Naranjo *et al* identified sonographic signs of subdeltoid bursitis in 29% of asymptomatic shoulders,[231] while an MRI study identified changes consistent with subacromial bursitis in 100% of asymptomatic patients who had undergone rotator cuff repair.[232]

Differential diagnosis

The diagnosis of chronic subdeltoid bursitis is not always obvious and there are several other disorders of both inert and contractile structures which must be differentiated.

Sprain of the acromioclavicular joint

If the upper ligament is at fault, there is localization of the pain at the tip of the shoulder, lack of pain reference down the arm, and pain on palpation of the acromioclavicular joint line.

The situation is more complicated with a sprain of the inferior ligament. In this case, the pain may spread further into the deltoid area and is impossible to differentiate from the pain of

subdeltoid bursitis. A point in favour of the acromioclavicular joint is severe pain on passive horizontal adduction, a test which is usually less pronounced in bursitis. Nevertheless, the diagnosis should always be confirmed by an infiltration with local anaesthetic.[233]

Tendinitis

As, in chronic subdeltoid bursitis, one or more resisted movements may be positive, together with pain on passive movements and a painful arc, a disorder of a contractile structure must be eliminated. Most often, differentiation from supra- or infraspinatus tendinitis is needed, and less frequently the subscapularis structure. Differentiation is usually done by repeating the resisted movement in the supine position, because this relaxes most other structures except the one which is elicited. If the muscle is at fault, the resisted test remains positive to the same degree; in bursitis, the pain usually diminishes or disappears totally when repeated in the lying position. If resisted abduction is painful, it may be of help to repeat the test not only with the patient lying down but also with longitudinal traction. If this renders the test less positive, bursitis is most likely.

Subcoracoid bursitis

In subcoracoid bursitis the pain is more localized in the outer infraclavicular area and does not radiate into the arm. A slight limitation of passive lateral rotation is present, disappearing when the test is repeated with the arm abducted to the horizontal (see p. 239).

Sprain of the subclavius muscle

This provokes pain in the same area as in subcoracoid bursitis but resisted shoulder depression is painful.

Sprain of the coracoclavicular ligaments

Pain is felt in the mid-infraclavicular area. The most painful movement is passive lateral rotation in 90° horizontal abduction.

Aseptic necrosis

In its early stage, aseptic necrosis may give rise to limitation of a non-capsular type. The discrepancy between symptoms and signs is striking: a great deal of pain and only slight influence of the arm movements. Diagnostic infiltration in the subdeltoid bursa can be helpful; in cases of doubt, technetium scanning should be obtained.

Treatment

As a rule, only one part of the bursa is affected and palpation will reveal which part must be dealt with. If local tenderness is found on palpating the superficial part, this must be treated; if no local tenderness can be detected, the subacromial part must be at fault.

An infiltration of 10 mL of 0.5% procaine solution is administered. Procaine has the advantage in this disorder of being both diagnostic and curative. If no lasting benefit follows the first infiltration, procaine should be substituted by steroid in a subsequent infiltration.

Fig 14.26 • Infiltration of the superficial part of the subdeltoid bursa.

Technique: infiltration of the superficial part of the bursa

If local tenderness is found on palpation, the superficial part must be treated. The patient sits on a high couch with the arm in neutral position. The tender part of the superficial bursa is marked (Fig. 14.26). A 3 cm needle is fitted to a 10 mL syringe filled with a 0.5% procaine solution. The needle is inserted at the centre of the tender area and thrust in until it hits the bone. On withdrawal, a little of the procaine is injected. This manœuvre is repeated several times until all the procaine is divided over the whole lesion.

Technique: infiltration of the subacromial part of the bursa

If palpation is negative, the subacromial part of the bursa is at fault. To infiltrate this portion, the lateral edge of the acromion is first localized. A thin needle, 5 cm in length, fitted to a 10 mL syringe filled with 0.5% procaine, is inserted just underneath the middle of the outer acromial edge and in a slightly cranial direction (Fig. 14.27). It is inserted to its full length, meeting hardly any resistance. If the needle does encounter resistance, either the coracoacromial ligament or the capsulotendinous structures have been contacted and pain is felt. The needle should be slightly withdrawn and the direction adjusted. Occasionally an effusion is encountered in the bursa and must be evacuated by aspiration before injection of local anaesthetic.

Once the needle is correctly placed, the infiltration is given while withdrawing and reinserting it about four or five times. Fanwise infiltration is used in order to reach the whole of the subacromial bursa.

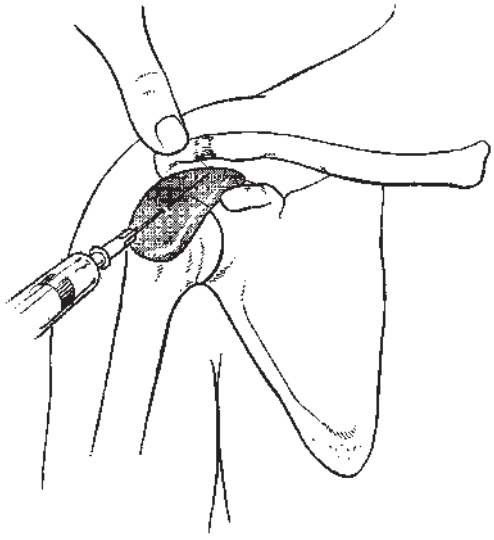

Fig 14.27 • Infiltration of the deep part of the subdeltoid bursa.

Follow-up

The patient is re-evaluated 1 week later. If there has been an improvement but not full recovery, the infiltration is repeated. Usually, three infiltrations are sufficient for full cure. If no improvement is obtained after the first infiltration, 5 mL of steroid should be substituted.

Some patients suffering from chronic subdeltoid bursitis never fully recover or tend to have frequent recurrences. They usually present one of the less comprehensible clinical pictures. This may be the consequence of a minor rupture in one of the rotator cuff structures, leading to the formation of adhesions and self-perpetuating inflammation. Definitive cure for this is often difficult to obtain. In such cases, the infiltrations may be repeated on a regular basis at increasing intervals until full cure is obtained and no relapse occurs.

Crepitating bursitis

After a previous bursitis with effusion, some patients may have crepitus on movements of the arm, which does not cause pain, merely a vague discomfort. No treatment is known.

Introduction

Functionally, shoulder muscles are of two types: stabilizing muscles and effector muscles. Stabilizing muscles (A, Fig. 15.1) are relatively small, with insertion tendons that lie close to, or even in, the substance of the fibrous capsule. Therefore they are not capable of causing significant shoulder movement but rather maintain the humeral head in the glenoid fossa. These stabilizing muscles are called the rotator cuff and include supra- and infraspinatus, teres minor and subscapularis. They all originate from the scapula, run partly under the acromial roof and insert on the humeral tubercles.

Effector muscles (B, Fig. 15.1) are much larger, with tendon insertions at a greater distance from the joint. Consequently, they produce powerful movements and are not primarily involved in stabilization. They are the deltoid complex, the pectoralis major, the latissimus dorsi and the teres major.

Although the standard clinical examination tests both muscle groups, the great majority of the positive findings point towards lesions of the rotator cuff, because lesions of the large effector muscles are extremely rare.

Rotator cuff

Rotator cuff disorder is one of the commonest afflictions of the shoulder and is a major cause of impairment of health in the young as well as in older individuals.[1]

Lesions of the rotator cuff should be recognized as different from those of other tendons in the body for a variety of reasons. The tendons of the rotator cuff blend intimately with each other and with the capsule. The insertion of the tendons, as a continuous cuff around the humeral head, permits the cuff muscles to provide an almost infinite variety of movements to

Functions of the rotator cuff

1. Rotate the humerus
2. Compress the humeral head
3. Provide muscular balance

rotate the head and to oppose unwanted movements generated by the larger effector muscles.[2] In addition, the long head of the biceps may be considered a functional part of the rotator cuff because tension in the tendon helps to compress the humeral head into the glenoid (Fig. 15.2).

Apart from their primary function (to rotate the humerus with respect to the scapula), the cuff muscles have two other actions: they compress the head of the humerus into the glenoid fossa and provide muscular balance (Box 15.1). The latter is mainly performed through eccentric contraction of the muscle. Both functions are extensively discussed in the online chapter *Excessive range of movement: instability of the shoulder*.

Pathology

Pathological changes associated with rotator cuff tendinopathy features are variable.

Inflammatory tendinitis is a reversible process, associated with an inflammatory infiltrate, increased vascularity and hyperaemic changes within the rotator cuff tendon.[3]

Partial rotator cuff tears may develop within the substance of the tendon on either the acromial (bursal) or articular surface of the tendon.[4] Most of the lesions occur near to the tendon insertion side. Full thickness tears are often initiated by a partial tear. They can be associated with a traumatic event or can progress with normal daily use of the arm.

Changes in the rotator cuff may also involve calcifying tendinopathy and rotator cuff arthropathy (degenerative glenohumeral osteoarthrotic disease associated with chronic massive rotator cuff tears).

The pathogenesis of rotator cuff disease has been associated with three factors: age-related degeneration, impingement and microvascular blood supply.

The primary cause of tendon degeneration is age.[5] Changes in the rotator cuff include diminution of fibrocartilage at the cuff insertion, diminution of vascularity, fragmentation of the tendon and disruptions of the attachment to the bone.[6,7]

Changes in the coracoacromial arch have been described in association with cuff disease and it is quite clear from both cadaver and clinical data that individuals with full thickness rotator cuff tears have changes in the acromial shape, with spur formation on the undersurface of the acromion and/or hypertrophy of the acromioclavicular joint.[8–11] Although these data indicate a strong association between the presence of cuff tears and alterations of acromial contour,[12–14] it is still unclear whether the change in acromial shape is the cause or the result of the cuff defect or if both are consequences of ageing.[15] Recent studies suggest that acromial deformity is usually developmental. Most acromial 'hooks' develop within the acromial ligament as traction spurs (analogous to the traction spur in the plantar ligament at its attachment to the calcaneus – see Fig. 15.11). The traction results from loading of the ligament by the cuff, which is increased when superior instability and cuff degeneration are present.[16,17]

Changes in the microvascular supply to the rotator cuff also have a possible role in the pathogenesis of rotator cuff lesions.[18] A hypovascular region exists at the 'critical zone' of the supraspinatus (the deep surface of the anterior insertion).[19,20] Microangiographic studies demonstrate that inadequate vascular supply to this critical zone is present in the adducted position of the arm.[21] Furthermore, microvascular supply changes within the thickness of the tendon: the acromial part has much better vascularity than the articular part.[22–24]

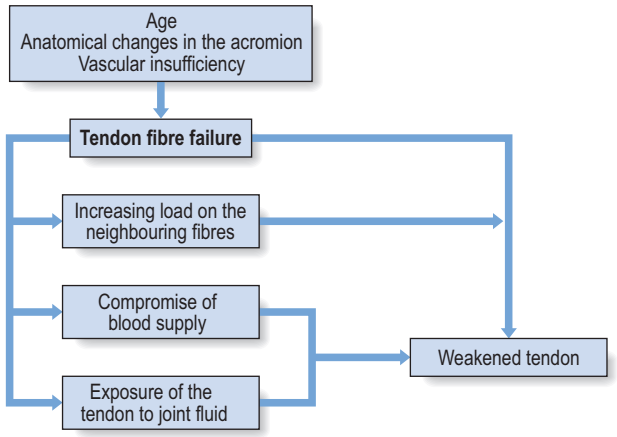

Fig 15.3 • Tendon fibre failure.

It is likely that a combination of age, anatomical changes and vascular insufficiency is responsible for rotator cuff 'failure'.[25] Throughout life the cuff is subjected to various adverse factors such as traction, compression, contusion, subacromial abrasion, inflammation and age-related degeneration. A lesion may start where the loads are the greatest and the vascular supply the lowest, i.e. at the deep surface of the anterior insertion of the supraspinatus.[26] Each fibre rupture then generates other adverse effects: it increases the load on the neighbouring fibres, it compromises the blood supply of the tendon fibres by distorting the microcirculation and it exposes increasing amounts of the tendon to joint fluid that contains lytic enzymes. The cuff is gradually weakened and at increased risk of further failure. With subsequent loading episodes the pattern repeats itself, rendering the cuff weaker and progressively more susceptible to additional failure (Fig. 15.3).[27]

Incidence

The incidence of rotator cuff tears has been studied both in cadaveric studies and in living subjects and found to range from 5 to 80%. All the studies show a strong relationship with age: rotator cuff tears are rare before age 40 and common after age 60.[28] However, almost all of the reported cadaver studies failed to correlate cuff disorder with a history of clinical symptoms (Table 15.1). Some of the most important studies in living subjects have concerned the prevalence of cuff lesions in asymptomatic patients (Table 15.2). They all demonstrated a high prevalence of tears of the rotator cuff in asymptomatic individuals, an increasing frequency with advancing age and compatibility with normal, painless functional activity.

It must be concluded from these studies that rotator cuff lesions are a natural correlate of ageing. They should be regarded as 'normal' degenerative attrition, not necessarily causing pain and functional impairment. This realization poses substantial questions about the anatomical diagnosis (magnetic resonance imaging (MRI) and sonography) of shoulder pain and of the indications for cuff surgery. Once again, it must be stressed that diagnosis and treatment should be based on clinical findings and not on the results of imaging.

Fukada *et al* (1987)[37]	13 (partial)	30% in cadavers >40 years No tears in cadavers <40 years
Sakurai *et al* (1998)[38]	61.5 (partial)	
Jiang *et al* (2002)[39] % partial and full thickness tears	11.5 (massive rotator cuff tears)	Average age 76.3 years

Diagnosis and treatment

Given the high prevalence rate of asymptomatic macroscopic rotator cuff lesions, it is unwise to rely solely on imaging techniques (sonography, computed tomography (CT), MRI) for a diagnosis.[49] The examiner should be wary of the common belief that what is found on technical investigation is always relevant to the cause of the patient's pain.[50] Diagnosis should first of all be made functionally; paraclinical and technical investigations have a secondary function only. During resisted movements, pain and weakness, separately or in combination with each other, are sought. If pain only is found, this points to an uncomplicated tendinitis or to a partial thickness lesion. A combination of pain and weakness brings a partial (full thickness) tendinous rupture to mind. Painless weakness is usually the outcome of a massive tear of a rotator cuff tendon or of a neurological problem. It is worth emphasizing once again that, when performing resisted movements at the shoulder, it is very important to use the correct technique, as has been explained earlier (see p. 214). If this is neglected, misdiagnosis can easily result.[51]

Treatment options are also determined only by the outcome of the clinical examination and not by the extensiveness of the (anatomical) lesion. Asymptomatic cuff lesions, for instance, in which the shoulder does not bother the patient but imaging studies document a partial or even full thickness lesion in the cuff tendon, should not receive treatment. However, if the rotator cuff lesion is symptomatic, it will usually not heal by itself because rotator cuff tendinitis is not self-limiting.[52]

Table 15.2 Incidence of rotator cuff tears in asymptomatic patients

Authors	Incidence (%)	Remarks
Petterson (1942)[40]	20 (partial and full)	50% in subjects 55–85 years of age
Milgrom *et al* (1995)[41]	50 (tears after age 50 years)	Rotator cuff lesions are a normal correlate of age; they often present without clinical symptoms
Sher *et al* (1995)[42]	15 (full), 20 (partial)	Significant increase of tears with age; defects are compatible with normal, painless, functional activity
Yamaguchi (2006)[43]	35.5% prevalence of a full thickness tear on the painless side	Sonography of 588 consecutive patients with unilateral shoulder pain
Tempelhof (1999)[44]	Rotator cuff tears in 23% 13% age 50–59 years 20% age 60–69 years 31% age 70–79 years 51% age >80 years	Ultrasonographic study of 411 asymptomatic volunteers
Shibany (2004)[45]	Complete rupture of the supraspinatus tendon in 6%	Ultrasound examination of 212 asymptomatic shoulders at 56–83 years (mean: 67 years)
Kim (2009)[46]	0% age 40–49 years 10% age 50–59 years 20% age 60–69 years 40.7% >70 years	Ultrasound and MRI investigation of asymptomatic individuals
Moosmayer (2009)[47]	Full thickness tears in 7.6% 15% age 70–79 years	420 asymptomatic volunteers aged 50–79 years
Yamamoto (2010)[48]	16.9% asymptomatic 20.7% total group	Prevalence of tears among the 683 residents of a mountain village in Japan

Initial treatment for a symptomatic cuff lesion should always be conservative, no matter what the result of imaging may be. Non-operative treatment consists of either deep friction transversely to the affected tendon fibres or local infiltration with small amounts of triamcinolone at the tenoperiosteal junction of the affected tendon. In recurrent cases it is wise to add functional exercises for strength and proprioception (see online chapter *Excessive range of movement: instability of the shoulder*).[53]

The effectiveness and safety of steroids for the treatment rotator cuff disease remains the subject of much controversy. Repeated injections with steroids are believed to produce tendon atrophy or to reduce the ability of damaged tendon to repair itself. Animal studies suggest that corticosteroids damage the ultrastructure of collagen molecules[54] and reduce collagen density, as well as inhibiting the reparative properties of tendon by inhibiting tendon cell migration and synovial fibroblast proliferation.[55] This has been shown experimentally to weaken collagen fibres and precipitate tendon ruptures.[56–58] In human subjects, repeated injections have been correlated with softening of the rotator cuff substance[59] and an inferior result of surgical repair.[60] Other studies, however, failed to find a deleterious long-term effect of corticosteroid injections in animal tendons,[61,62] and a recent case-controlled study suggests that corticosteroid use in patients with 'subacromial impingement' should not be considered a causative factor in rotator cuff tears.[63] Although rotator cuff disorders are generally believed to benefit from steroid injections, evidence for the efficacy of the injections is difficult to demonstrate. Most reviews have found conflicting results,[64] which can be explained mainly by the fact that very heterogenous populations with poorly designed subgroups were used.[65] In other studies that used a better anatomical classification, local triamcinolone infiltrations were shown to be superior to placebo[66–70] and to methylprednisolone[71] in reducing pain, improving active abduction and reducing functional limitation. The success rate of the infiltrations is further increased if precise diagnostic and infiltration techniques are used.[72] In a randomly allocated double-blind study, Hollingworth *et al* compared two different methods of corticosteroid injection. The method of anatomical injection after diagnosis by the technique of selective tissue tension gave a 60% success rate, compared with the method using tender or trigger point localization, which produced only 20% success.[73] Also, a recent meta-analysis concluded that injections of corticosteroids are effective for improvement for rotator cuff tendinitis for up to a 9-month period.[74]

We strongly believe in the beneficial effect of small-dose (10 mg) and targeted infiltrations of triamcinolone in the treatment of rotator cuff disorder. Potential hazards are minimal if a few necessary precautions are taken:

- The infiltration is always on the tenoperiosteal junction, never in the body of the tendon.
- The arm should be rested for 2 weeks following the infiltration.
- No more than three consecutive infiltrations should be given.

The operative treatment of rotator cuff lesions without rupture is acromioplasty: a wedge-shaped piece of bone is resected from the anterior surface of the acromion, along with the entire attachment of the coracoacromial ligament. The operative treatment of rotator cuff tear is cuff repair.

Calcifying tendinitis

Calcium deposits may form in the tendons of the rotator cuff. The aetiology is still a matter of speculation but it is generally accepted that degeneration precedes calcification. The incidence of calcification ranges from 3 to 20%[75,76] and in most instances the lesion is completely asymptomatic.[77] The highest incidence occurs in those aged between 31 and 50,[78,79] and calcification is absent in elderly patients. The disease is usually self-limiting with a variable natural course: 80% of calcific lesions show spontaneous resorption over a period of 3 years.[79] If the lesion causes symptoms, these are treated in the same way as uncomplicated tendinitis of the rotator cuff. The treatment of choice is infiltration with triamcinolone. If the pain reappears after initially successful treatment, the calcium deposits can be dissolved with weekly infiltrations of procaine

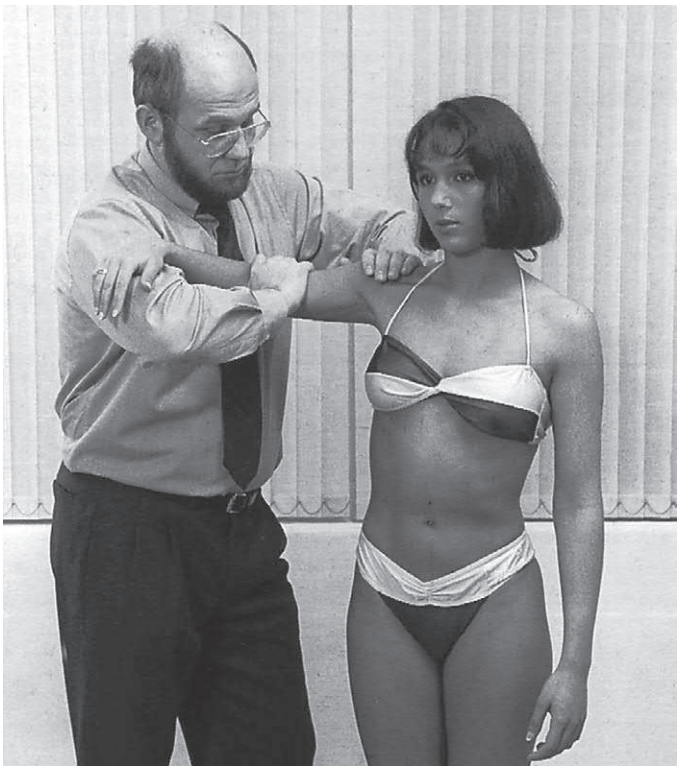

Fig 15.4 • Resisted horizontal adduction.

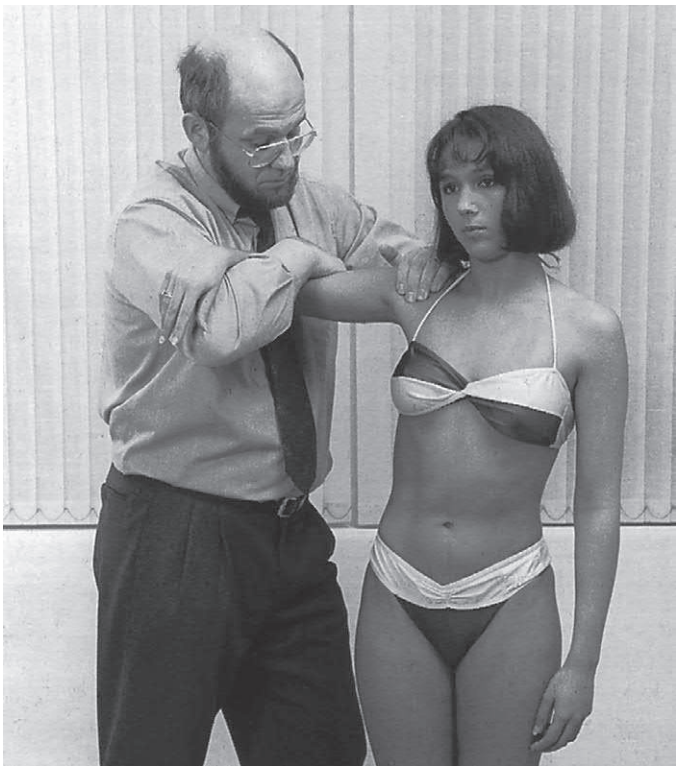

Fig 15.5 • Resisted horizontal extension.

0.5%.[80] Surgical intervention is seldom necessary but if it is indicated, most calcifications can easily be removed by arthroscopic procedures.[81] In recent years extracorporeal shock wave therapy has been proposed as an alternative to operative treatment.[82,83]

Resisted abduction

Pain

Pain on resisted abduction is the consequence of a lesion of either the deltoid or the supraspinatus muscle.

Deltoid muscle

The deltoid is very seldom at fault, although a lesion can sometimes occur as a result of direct injury. The lesion usually lies in the muscle belly.

Disorders of the deltoid cannot provoke a painful arc, because no part of it can be trapped between two osseous structures. Therefore the presence of a painful arc excludes a deltoid lesion. If any doubt exists, two accessory tests are used:

- *Resisted horizontal adduction* (Fig. 15.4): the examiner stands at the painful side and stabilizes this shoulder with one hand. With the other hand, he grasps the patient's arm just above the elbow and brings it into horizontal abduction. The patient is now asked to push the arm forwards against the examiner's hand. This tests the anterior portion of the deltoid.
- *Resisted horizontal extension* (Fig. 15.5): this is the exact opposite of the previous test. The patient is asked to push backwards, the examiner applying counterpressure in an anterior direction. The posterior fibres of the deltoid are tested in this movement.

Treatment

A lesion in the muscle belly of the deltoid responds equally well to deep transverse friction or to infiltration with 20–30 mL of procaine 0.5% once a week, for about 3 weeks. Friction is given on alternate days until full cure is achieved.

Supraspinatus

Clinical experience shows that the most frequent reason for pain on resisted abduction is tendinitis of the supraspinatus muscle, which is by far the most common tendinous lesion at the shoulder. The tendon may be affected at four different sites; these each give rise to a slightly different clinical picture but are all characterized by a common major finding, which is pain on resisted abduction.

Most of the lesions occur at the tenoperiosteal insertion into the greater tuberosity. Inflammation and partial tears may develop within the substance of the tendon on the acromial surface (bursal side) or the deep surface (articular side of the tendon).[84] If situated on the deep part, pain on full passive elevation is also present. This is believed to be caused by the abutment of the deep surface of cuff insertion against the glenoid rim at the extremes of motion (Fig. 15.6).[85] If situated on the bursal part of the tendon, a painful arc is found. Cyriax regarded this as the most common cause of a painful arc on

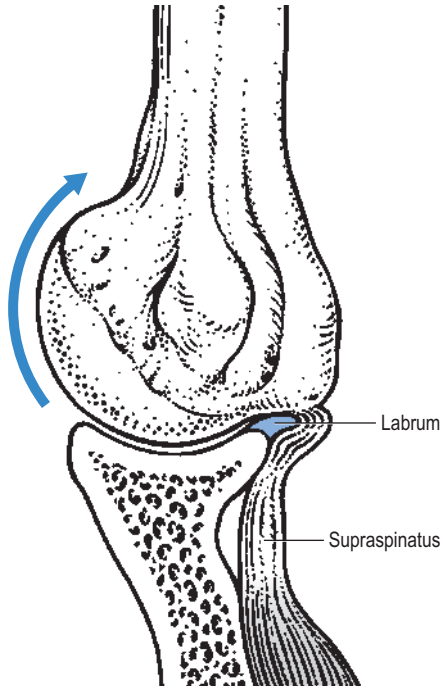

Fig 15.6 • On full passive elevation the undersurface of the supraspinatus tendon may become squeezed against the upper labral rim.

shoulder elevation.[86] A third possibility is a lesion that involves both superficial and deep aspects tenoperiosteally. In this case, pain on full passive elevation is present, together with a painful arc (Fig. 15.7).

The lesion sometimes lies at the musculotendinous junction, just beneath the acromion. In this case, the only sign is pain on resisted abduction. Because this type of lesion is rare, its presence should always be confirmed by a diagnostic infiltration with local anaesthetic.

Figure 15.8 summarizes the differential diagnosis of painful resisted abduction.

Treatment of tenoperiosteal lesions

The lesions situated at the tenoperiosteal insertion can be treated either by deep friction or by infiltration with steroid. Friction takes longer but has a more definite effect; steroids work quicker but there may be a tendency to recurrence.

Localization by palpation

The main problem in treatment is finding the structure involved. Although the tendon lies quite superficially, many have difficulty in localizing it. It cannot be easily localized with the arm in the neutral position at the side. Although the greater tuberosity points laterally in this position, part of the insertion can be covered by the outer rim of the acromion. Moreover, all structures here feel the same on palpation. Therefore, it is

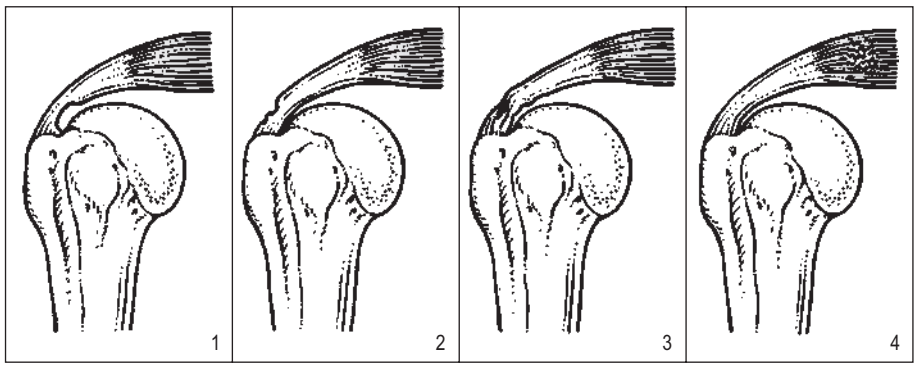

Fig 15.7 • Accessory signs indicate the exact localization of the supraspinatus lesion: 1, pain at the end of passive elevation; 2, painful arc; 3, painful arc and pain on full passive elevation; 4, no localizing sign.

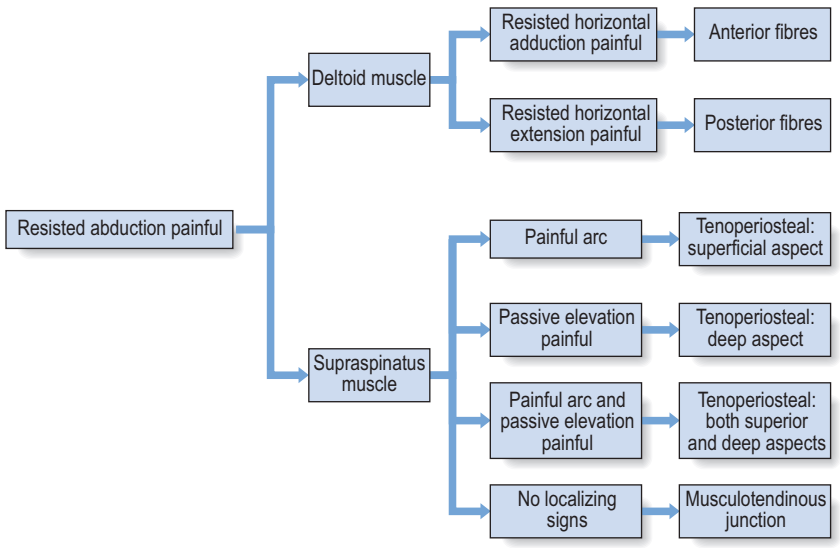

Fig 15.8 • Differential diagnosis of painful resisted abduction.

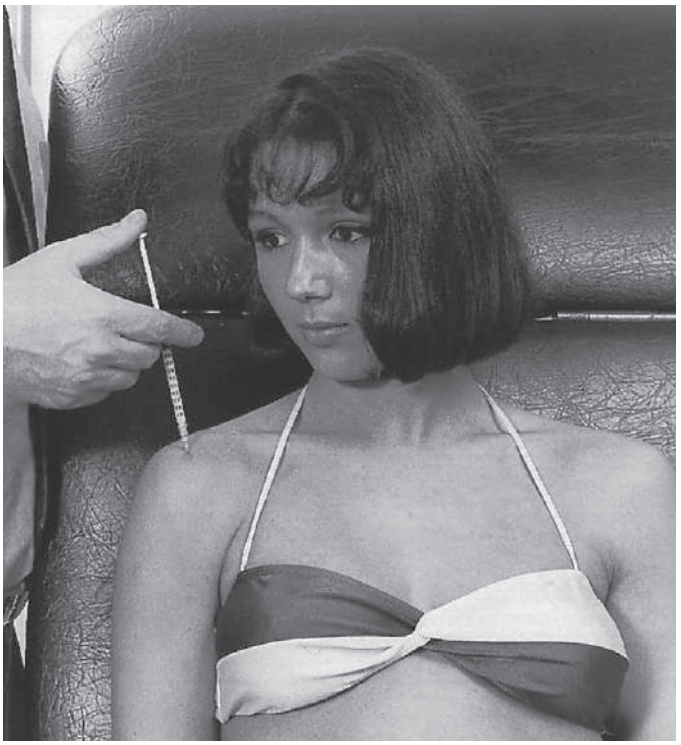
Fig 15.9 • Position for localization of a tenoperiosteal lesion of the supraspinatus.



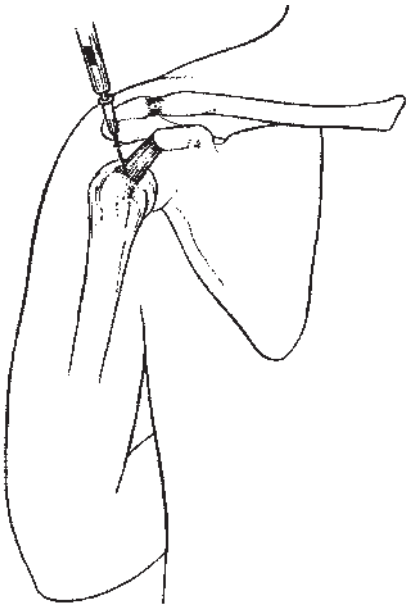


Fig 15.10 • Infiltration of a tenoperiosteal lesion of the supraspinatus.

better to bring the upper arm into full medial rotation by asking the patient to put the lower arm behind the back, with the elbow bent to 90° (Fig. 15.9). In this position the tenoperiosteal insertion lies anterior to the acromion.[87,88] The fibres at the insertion are now situated in a sagittal plane because the tendon curves around the base of the coracoid process as a result of the medial rotation.

First, bony landmarks are defined. Starting at the posterior acromial angle, the lateral rim of the acromion is localized. The finger then moves over to the anterior acromial border, until the acromioclavicular joint is met. The supraspinatus insertion lies lateral to this joint line, just anteriorly to the acromion.

Next, the infraclavicular fossa is palpated. This is best started medially, at the level of the coracoid process. The finger is moved laterally, retaining close contact with the anterior border of the clavicle and acromion. Initially, the finger digs smoothly into the deltoid muscle, and continues to do so until the tenoperiosteal insertion of the supraspinatus is reached. Then a much tougher resistance is felt under the finger, which does not sink in deeply. The supraspinatus insertion has a width of about 1.0–1.5 cm. It is important to define the medial edge of this insertion accurately, since it permits the localization of the rest of it. The lateral edge is more difficult to palpate because the fibres merge with the anterior of the infraspinatus tendon.

Technique: infiltration of the supraspinatus

A tuberculin syringe, filled with 1 mL of triamcinolone, is fitted to a 2.5 cm needle. The patient sits in the same position as for palpation, the arm behind the back. After the insertion has been precisely located, the needle is thrust in vertically downwards at its centre (Fig. 15.10). The needle glides in smoothly initially, until it encounters the tenoperiosteal

junction, at which point the typical tendinous resistance is felt. When the needle is thrust in a little further, it is arrested against the bone. Then 1 mL of triamcinolone is infiltrated at 5–10 different places over an area of 1 cm^2, in close bony contact. During the whole infiltration, a typical counter-pressure is felt.

After-pain is seldom severe and wears off spontaneously. The arm should be rested for about 2 weeks, and reassessment follows after 2 weeks. If the clinical examination is still positive, a second infiltration is given. One to three infiltrations are usually curative.

Treatment that leads to good but temporary results is a common experience in supraspinatus tendinitis. After one or two infiltrations the pain has disappeared but recurs a few months later. The patient should then be sent for standard radiography of the shoulder. If some intratendinous calcification is confirmed, 4–5 weekly infiltrations with 5 mL of procaine 2% are administered. In most cases this is sufficient to dissolve the calcium deposits and to alleviate the pain. If no calcification is visible, the patient must be referred to the therapist for deep transverse friction because it is unwise to infiltrate the tendon repeatedly, even with small doses such as 10 mg of triamcinolone. In cases of recurrent tendinitis it is also good practice to look for an underlying cause. This may be a small multidirectional or superior instability or an anatomical divergence in the acromial roof that causes recurrent impingement. The diagnosis and treatment of the former have been discussed earlier (see online chapter *Excessive range of movement: instability of the shoulder*). The diagnosis of the latter is through a lateral X-ray that visualizes the so-called 'supraspinatus outlet' – the space between the coracoacromial roof and head of the humerus (Fig. 15.11). If there is an anatomical divergence in the supraspinatus outlet, and the tendinitis tends to recur despite proper treatment, surgical decompression (deletion of anterior and inferior parts of the roof) is highly recommended.[89]

The treatment of supraspinatus tendinitis is summarized in Figure 15.12.

Technique: deep friction to the supraspinatus

Patients who opt for the longer but more certain way are best treated by friction. The same goes for athletes and in cases of recurrence after previous infiltrations with steroids. Friction works better on the superficial part rather than on deeper lesions.

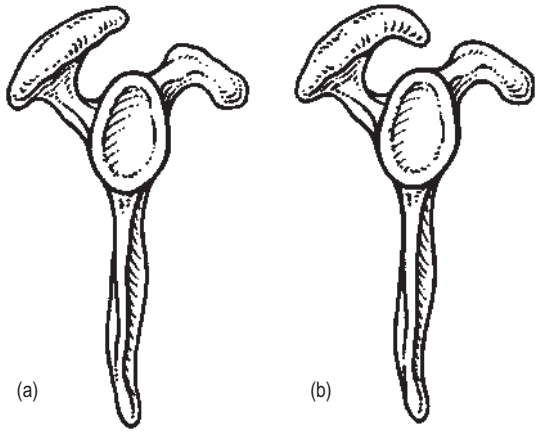

Fig 15.11 • Supraspinatus outlet: (a) normal acromion; (b) hooked acromion.

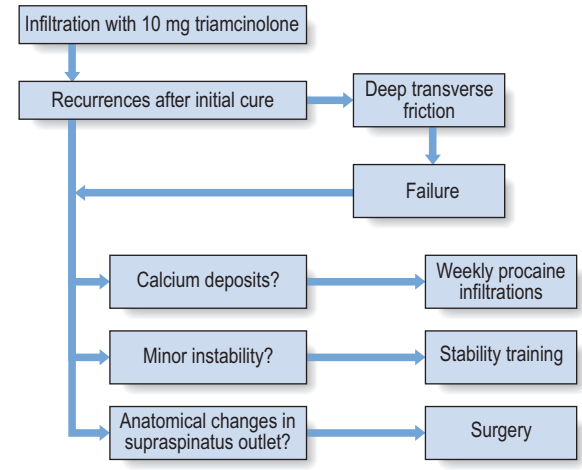

Fig 15.12 • Treatment of supraspinatus tendinitis.

The patient adopts the same position as for infiltration: seated with the back against the couch, the arm behind the back. The therapist stands laterally on the patient's painful side. The index finger of the ipsilateral hand, reinforced by the middle finger, is placed at the medial edge of the insertion. The hand is meanwhile stabilized by the thumb placed against the lateral aspect of the upper arm, almost vertically under the index finger (Fig. 15.13). When the index finger is pulled outwards over the tendon, pressure is applied. This is the active phase of the friction. The pressure is directed caudally, not towards the clavicle – easily obtained if the stabilizing thumb is placed rather low on the upper arm, the nail of the finger that applies friction thus pointing upwards.

Friction is given three times a week for about 20 minutes each time. Normally, 10 sessions suffice. The patient should rest the arm during the whole course of treatment. Improvement can be expected after about five sessions.

Treatment of musculotendinous lesions

The only effective treatment is deep transverse friction, but before this is undertaken the diagnosis must always be confirmed by an infiltration of local anaesthetic.

Technique: deep friction to musculotendinous lesions

The patient sits on a chair with the arm abducted sideways to the horizontal, the elbow and forearm resting on a couch. In this position the musculotendinous junction lies in the supraspinous fossa at the angle between the scapular spine and the acromion, just posterior to the clavicle. The therapist stands at the pain-free side facing the shoulder. The ipsilateral middle finger reinforced by the index finger is placed deeply into the scapuloacromial angle, holding the slightly bent finger parallel to the muscle (Fig. 15.14). Friction is given by pronation–supination movements of the lower arm, the active moment being in supination.

Friction is applied for about 15 minutes. Cure is expected after about 10 sessions.

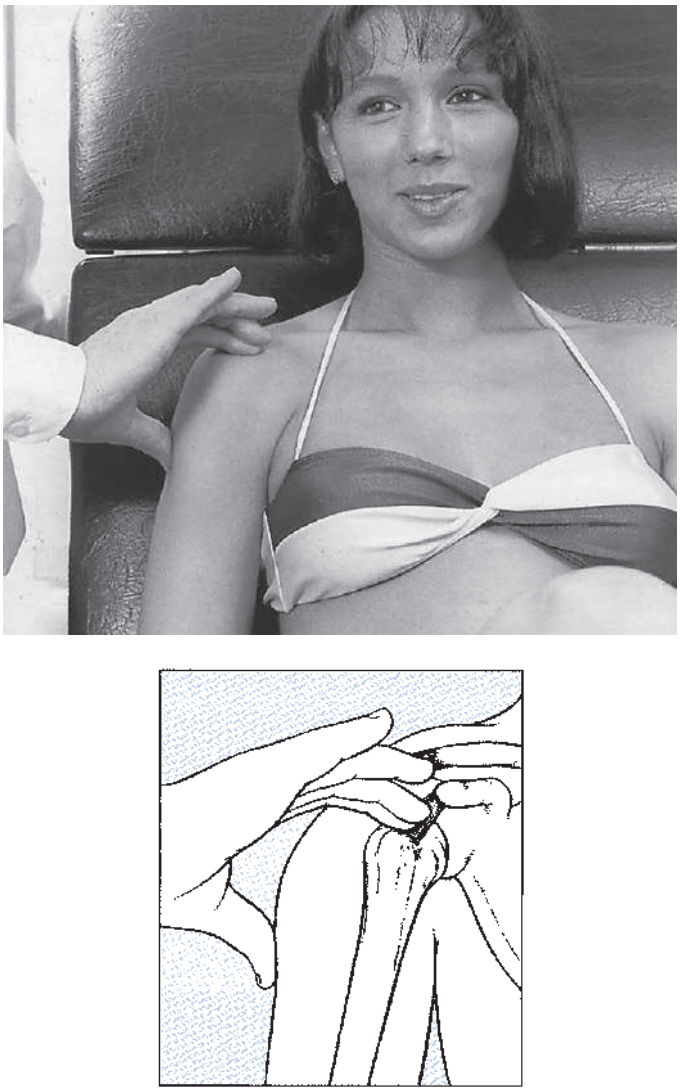

Fig 15.13 • Treatment of a tenoperiosteal lesion of the supraspinatus: deep friction.

Painful weakness

If resisted abduction is found to be both weak and painful, a partial rupture of the supraspinatus tendon is most likely.[90]

Ruptures of the rotator cuff occur most frequently at the supraspinatus tendon. A full-thickness defect usually starts at the critical zone (articular side of the anterior part near to the bicipital groove) and may propagate either in the direction of the infraspinatus or towards the subscapularis tendons.[91,92]

The pain felt in a partial rupture of the supraspinatus is the same as in uncomplicated tendinitis. The patient usually does not mention any weakness; this is found only during clinical examination on resisted abduction, which is also painful. To rule out weakness caused by pain alone, resisted abduction is tested again after infiltration of local anaesthetic. The only differential diagnosis is metastatic infiltration of the acromion – a very rare disorder. Here the pain is localized. On clinical examination a painful arc is found, together with pain and gross weakness on resisted abduction. Imaging techniques confirm the diagnosis.

Treatment

Conservative treatment is reasonable for most partial ruptures of the supraspinatus tendon.[93] Treatment is relief of pain, achieved by infiltration of 1 mL of triamcinolone at the tenoperiosteal insertion and into the most distal part of the tendon. The same position and technique are used as for an uncomplicated tendinitis.

Infiltration of a partially ruptured tendon is not without danger. Disappearance of inflammation and pain usually removes the natural reserve towards movement and load. A weakened tendon in combination with increased load must inevitably lead to further ruptures and disaster. Before any decision to infiltrate is made, the patient must be warned about the dangers. Furthermore, if complete rest cannot be fully guaranteed, the therapist must stop infiltrations and refer the patient for deep transverse friction.

If the treatment leads to good but only temporary results, the same measures should be taken as in uncomplicated but recurrent supraspinatus tendinitis.

Painless weakness

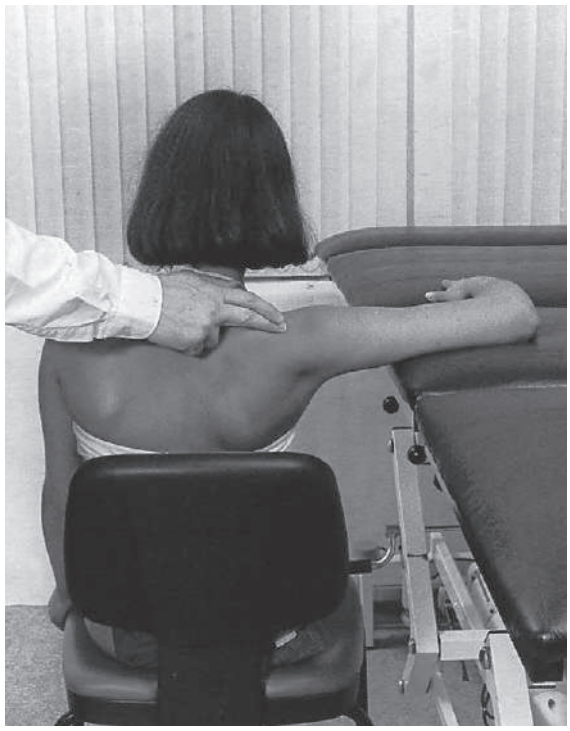
A painless inability to abduct the shoulder actively can be caused by either a complete rupture of the supraspinatus tendon or a neurological lesion.

Total rupture of the supraspinatus tendon

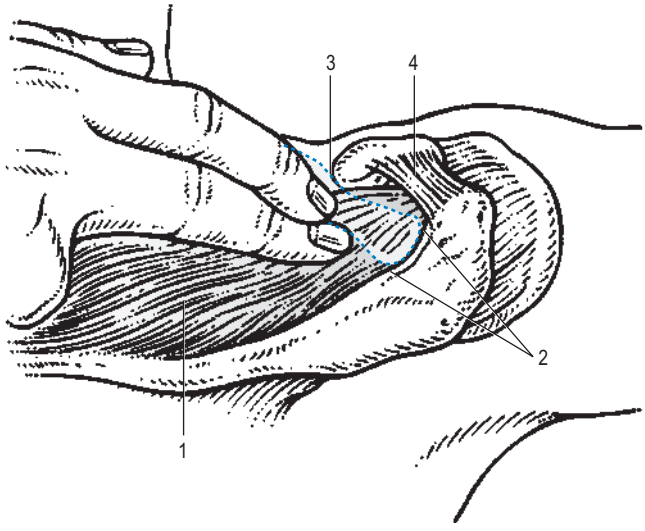
The supraspinatus muscle initiates active elevation of the arm and is active during the entire arc of abduction. It is responsible for about 50% of the torque and can abduct the joint without action of the deltoid.[94] Therefore a total rupture of the supraspinatus tendon presents as painless weakness on resisted abduction.

In massive tears of the supraspinatus, the patient is unable to abduct the arm actively. This is caused not only by loss of muscular power but also by loss of the passive stabilizing effect of the tendon.

Previously it was believed that the arm could not be abducted actively by the deltoid muscle alone if some contraction of the supraspinatus did not initiate the movement.[95] However, studies in which the suprascapular nerve and the axillary nerve were blocked have shown that both the supraspinatus and the deltoid muscles are capable of initiating elevation of the arm, in both sagittal and coronal planes.[96–98] This is not in accord with what is found clinically. When the supraspinatus tendon is massively ruptured, the patient is unable to initiate active scapulohumeral abduction. Starting from a position of 0° (the arm hanging by the side), the deltoid muscle only pulls the humerus upwards. Elevation is then only produced by rotation of the scapula in relation to the thorax and not by any movement between scapula and humerus. This is explained by the superior displacement of the humerus that occurs during active contraction of the deltoid in the absence of an intact



(a)



(b)

Fig 15.14 • (a) Deep friction to a musculotendinous lesion of the supraspinatus. (b) Anatomy: 1, supraspinatus muscle; 2, acromioclavicular joint; 3, clavicle (transparent); 4, coracoacromial ligament.

supraspinatus tendon.[99,100] In a normal situation the rotator cuff muscles form a supplementary musculotendinous glenoid which, in conjunction with the osseous glenoid, holds the humeral head stable. Experimental sections of the supraspinatus tendon also show the humeral head to move in a cranial direction until the superior humeral load is applied directly to the acromion (Fig. 15.15).[101] This phenomenon has been referred to as 'the spacer effect'[102] and is one of the most significant plain radiographic signs of massive cuff deficiency.[103]

Symptoms and signs

The lesion usually affects middle-aged and elderly people. In patients under 40 years of age a rupture is usually acute and results from indirect trauma, such as a fall on the outstretched hand.[104,105] In most cases the rupture is due to a chronic failure of the tendon: repeated failure of small groups of fibres leads to progressive weakness of the supraspinatus, making it increasingly susceptible to damage from lesser loads.[106,107] The observation that major cuff defects may occur without recognized injury has led to the concept of 'creeping tendon failure'.[108]

An acute trauma is usually accompanied by a sharp pain and followed by complete inability to raise the arm actively. The pain remains severe for the first few days and diminishes progressively, later becoming bearable without drugs but still sufficient to interfere with normal activities.

On clinical examination active elevation is limited to about 30°, which is fully accounted for by scapular rotation: no active humeroscapular movement is noted. A very pronounced painful arc is present when the elevation is performed passively. On muscular testing there is a complete but painless weakness of resisted abduction. After a few weeks the supraspinatus becomes atrophic; the deltoid maintains its normal size and strength. Although the patient cannot actively elevate the arm from 0°, active elevation becomes possible if the arm is passively moved through the first 30°.

Frequently, because the patient is unable to move the arm actively, an immobilizational arthritis will set in after a few months and a capsular pattern emerges (see p. 228).

Treatment

Because most total ruptures occur insidiously in the elderly, surgical correction to restore normal function will not be the first option.[109] Some defects cannot be repaired simply because they only offer 'rotten cloth to sew' (McLaughlin).[110] Many defects do not need to be repaired because they exist without causing much in the way of clinical symptoms.[111] However, surgery should always be considered in a younger patient with a significant acute tear in a previously normal shoulder,[112,113] and in the patient with a chronic tear associated with significant symptoms and not responding to conservative treatment. Fair functional results have been observed using open[114,115] and arthroscopic techniques,[116] but it is important to bear in mind the fact that repair does not restore the quality of the tendinous tissue. Reported recurrence rates after rotator cuff repair range between 15% and 90%.[117,118] Because rotator cuff integrity is important to its function,[119] long-term results of repair are better in younger patients with acute tears.[120,121]

For most supraspinatus ruptures the treatment of choice is conservative. The primary aim is to get rid of the pain. To that end, an infiltration with 10 mg of triamcinolone should be given at the remnants of the insertion into the humeral tuberosity to abolish the painful arc, following the same procedure as for uncomplicated supraspinatus tendinitis. The therapist should try to reach the inflamed tissue because infiltrating the gap is useless. Therefore the typical counterpressure on syringe and needle should be felt during the entire

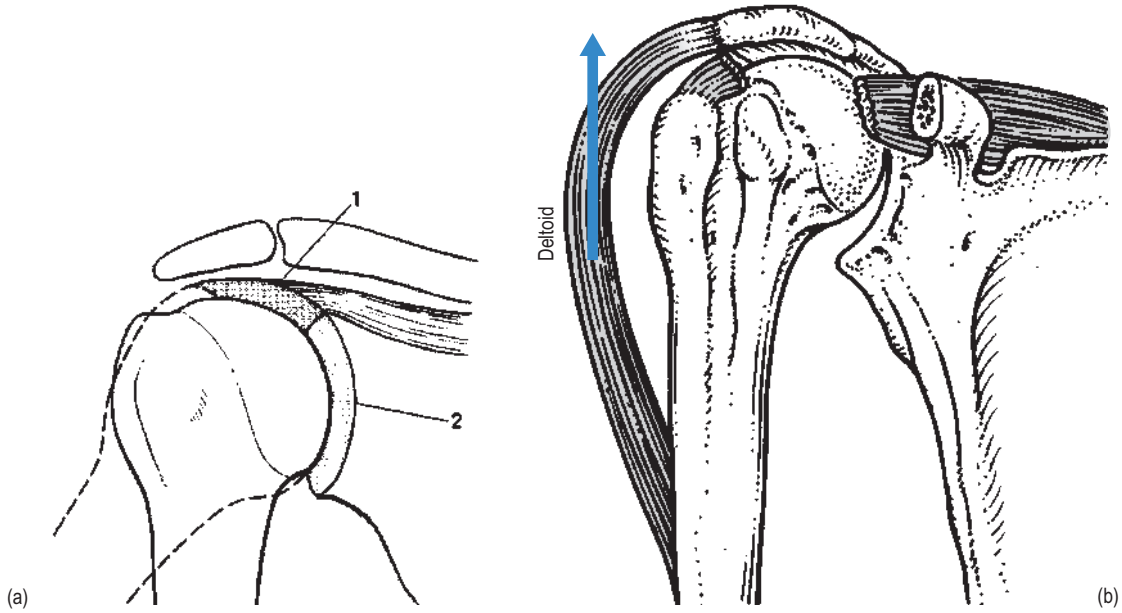


Fig 15.15 • (a) The glenoid: 1, tendinous; 2, osseous. (b) Spacer effect: massive rupture of the supraspinatus leads to a cranial subluxation of the humeral head during deltoid contraction.

procedure. Once the painful arc has gone, patients should be encouraged to use the arm normally. To lift the arm up, they should initiate elevation via a swinging movement of the trunk so that the arm is thrown laterally until it reaches the point where the deltoid muscle becomes effective. It is also wise to prescribe functional exercises for the antagonists of the deltoid and the remaining rotator cuff muscles. In spite of the slight disability, the function of the joint is usually good and the patient should be capable of doing light work.[122–124] Outcome studies report good to fair results in 60–90% of conservatively treated supraspinatus ruptures.[125–127]

Neurological lesions

Several neurological disorders may provoke painless weakness on resisted abduction.

Axillary nerve palsy

This may follow a subluxation of the humeral head. The axillary nerve innervates the deltoid muscle. Differential diagnosis is based on testing the strength of both the deltoid and infraspinatus muscles. Isolated painless weakness of abduction is found. A painful arc is not present, which differentiates this disorder from a supraspinatus rupture. Active elevation is difficult but possible (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Suprascapular nerve palsy

This is most often the result of idiopathic neuritis, and seldom of an injury. The suprascapular nerve innervates both supra- and infraspinatus muscles. Weakness of abduction and lateral rotation is present. This disorder can be differentiated from a combined supra- and infraspinatus rupture by the absence of a painful arc (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Fifth cervical root palsy

The C5 root innervates both spinatus muscles, the deltoid and the biceps brachii. Weakness on abduction and lateral rotation of the arm and on flexion of the elbow is present (see p. 155).

See (Fig. 15.16) for a summary of resisted abduction.

Resisted adduction

Pain

A painful but strong resisted adduction movement of the arm may be caused by a lesion of one of the adductor muscles, a sprain of the acromioclavicular joint or tendinitis of the long head of the biceps.

It may happen that isometric movements indirectly provoke pain in structures other than the ones that are supposed to be tested. Cyriax called this phenomenon 'transmitted stress'. During strong resisted adduction with the arm hanging alongside the body, the strong actions of the latissimus dorsi and pectoralis major pull indirectly on the acromioclavicular joint. Resisted adduction may therefore also provoke local shoulder pain in a chronic strain of the acromioclavicular joint. The pain will then be localized within the C4 dermatome and other passive tests will point to the acromioclavicular joint (see p. 241).

Pain on resisted adduction of the arm may rarely be caused by a tendinitis of the long head of the biceps at the glenoid origin. Cyriax arrived at this conclusion after finding that resisted adduction proved to be painful with the elbow in extension but not if it was kept in flexion. As a consequence, the structure at fault must overlie both shoulder and elbow

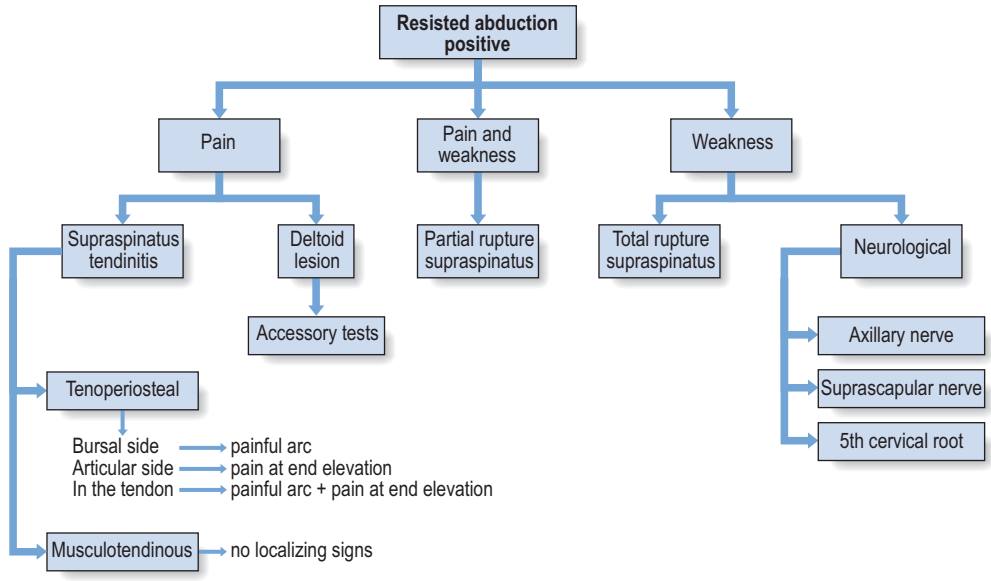

Fig 15.16 • Resisted abduction positive.

(see p. 269). The pain is mainly felt under the acromioclavicular joint.

More often, however, a positive test will indicate a lesion of one of the adductors: pectoralis major, latissimus dorsi, teres major and teres minor.[128] An important element in distinguishing between them is the localization of the pain. Pain in the thorax anteriorly suggests the pectoralis major and posterolaterally the other three muscles. Axillary pain may be the result of a problem in the pectoralis major, teres major or latissimus dorsi.

The four adductors can be more accurately differentiated by additional tests. Because the pectoralis major, latissimus dorsi and teres major are medial rotators and the teres minor a lateral rotator, resisted medial and lateral rotation of the arm is the next test to perform in order to arrive at an exact diagnosis.

The pectoralis major muscle can be tested on its own by resisted horizontal adduction with the arm forwards (Fig. 15.17a). The examiner stands on the painful side. One hand is placed on the patient's shoulder. With the other hand, the patient's arm is grasped just above the elbow and brought anteriorly to the horizontal. The patient is now asked to exert further medial force against the examiner's hand. The same can be achieved, but with loss of assessment of muscle strength, when the patient pushes both hands against each other holding both arms horizontally in front of the body.

Further differentiation is done by a resisted extension movement (Fig. 15.17b), which involves the latissimus dorsi, teres major and teres minor muscles. The patient tries to move the arm backwards with the arm hanging down and the examiner applying anteriorly directed counterpressure.

The only further differentiation required is between a lesion of the latissimus dorsi and the teres major. Because the latissimus dorsi also causes side flexion of the trunk and depression of the scapula, while the teres major does not, testing resisted side flexion towards the painful side and resisted scapular depression may be helpful.

Because lesions of the teres minor and teres major are extremely rare, these structures are not discussed in detail.

Pectoralis major

Lesions of the pectoralis major may be the result of overuse or of direct injury.

The lesion usually lies in the muscle belly, either in its lateral lower portion or in the fibres just below the outer portion of the clavicle (Cyriax:[86] p. 145). In rare instances, the pain is felt at the shoulder and radiates down the inner aspect of the arm. The problem must then be sought at the insertion at the crest of the greater tubercle.

It should be noted that in severe lesions of the pectoralis major, full passive elevation of the arm and resisted adduction and medial rotation are positive. In minor lesions, resisted medial rotation is sometimes negative.

The functional tests are followed by palpation, best performed with the patient's arm slightly abducted and the hand resting on the iliac crest.

Differential diagnosis is a rib fracture. In fracture in the anterior thorax, the same tests as in pectoralis major strain are painful. Additionally, all movements of the thoracic spine influencing the site of fracture are painful as well, as is deep inspiration.

Treatment

Infiltration of the muscle belly with procaine usually has a good therapeutic effect. Two or three infiltrations suffice. If not, or if the lesion lies at the insertion, infiltration can be replaced by deep transverse friction.

Technique: infiltration of the pectoralis major

The patient adopts the half-lying position and puts the hand on the affected side on the iliac crest. A 4 cm needle is fitted to a syringe filled with 10–20 mL of procaine 0.5%. After accurate palpation, the lesion is held between thumb and index finger and the needle is introduced between them obliquely

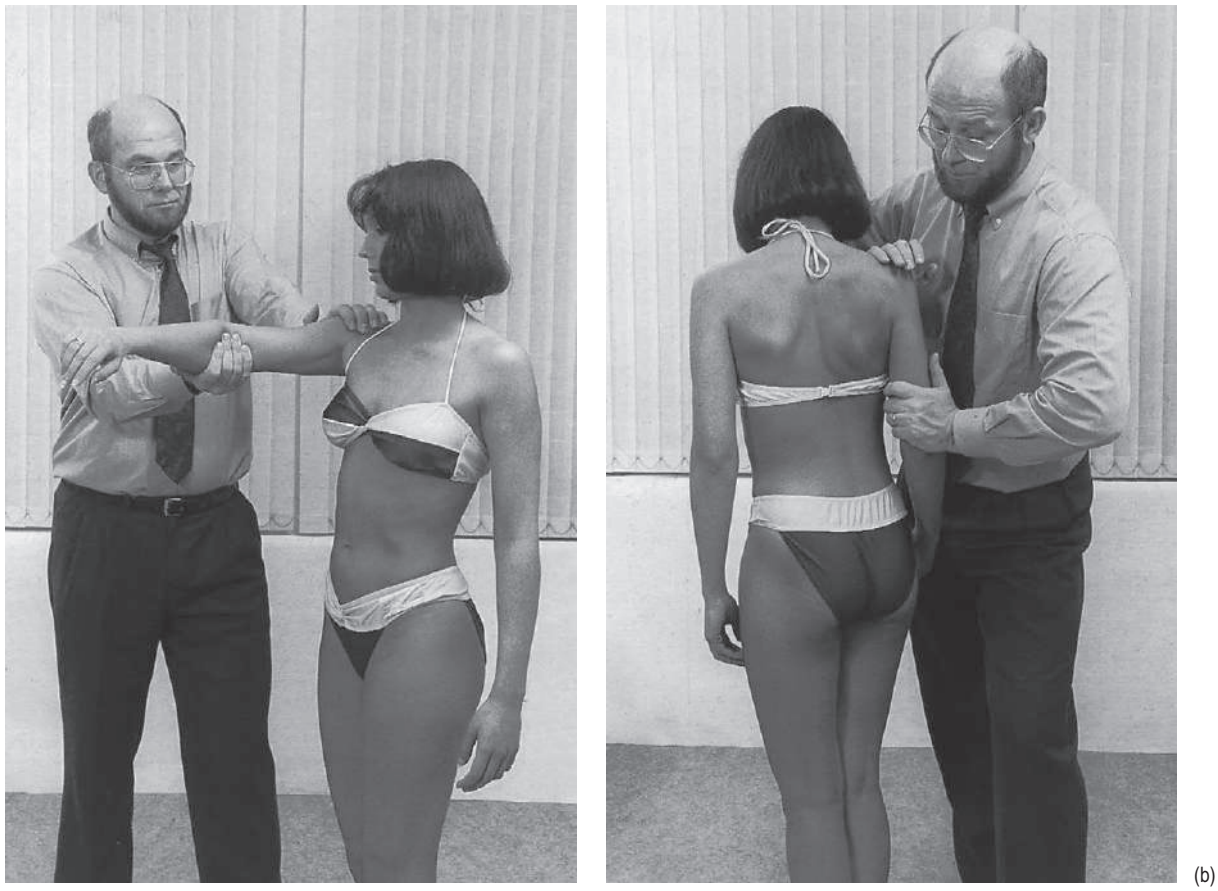

Fig 15.17 • Resisted horizontal adduction with the arm forward (a) and resisted extension (b).

and to its full length. The finger and thumb are kept in this position during the infiltration, to feel whether the product is deposited at exactly the right place (Fig. 15.18). The injection is given while withdrawing the needle. The syringe is emptied gradually, over about five withdrawals and reinsertions.

Technique: deep transverse friction to the pectoralis major

Palpation will demonstrate whether the lesion lies in the belly or the insertion of the muscle and so determine the friction method.

- *To the muscle belly*: massage is best given with the patient in the half-lying position and the hand resting on the iliac crest, so that the upper arm is somewhat abducted. This brings the pectoralis major more into prominence. The therapist sits facing the patient at the painful side. With the ipsilateral hand, the painful spot is taken between fingers and thumb and pulled laterally while pressure is applied (Fig. 15.19). This is the active moment of the friction. Massage is given for 20 minutes. Cure is normally obtained after 10 sessions.
- *To the insertion*: if palpation shows the lesion to lie at the insertion, deep friction is the only treatment. First the bicipital groove is localized, which is best done by putting the finger proximally between the minor and major

Fig 15.18 • Infiltration of the pectoralis major belly.

Fig 15.19 • Deep transverse friction to the pectoralis major belly.

humeral tubercles and in the long axis of the arm. By rotating the arm alternately medially and laterally, the groove can be identified. The therapist sits facing the patient at the painful side and places the contralateral thumb between the fibres of the deltoid muscle at the outer aspect of the bicipital groove. Counterpressure is applied over the dorsal aspect of the arm by the other fingers. Friction is given by pronation–supination movements.

Latissimus dorsi

Lesions of the latissimus dorsi are sometimes met with in gymnasts and water-skiers but are rare. They are usually found laterally at the uppermost part of the muscle belly. On clinical examination, full passive elevation of the arm and resisted adduction and medial rotation are painful.

Treatment

The responses to infiltrations with procaine and deep friction are equally good. The infiltration technique is the same as for the pectoralis.

Fig 15.20 • Deep transverse friction to the latissimus dorsi.

Technique: deep transverse friction to the latissimus dorsi

The patient lies prone, the hand on the iliac crest. The therapist faces the patient's painful side. The tender area is taken between thumb and fingers of the ipsilateral hand, and friction is performed by pulling the hand laterally (Fig. 15.20).

Painful weakness

Ruptures of the pectoralis major follow extreme muscle tension or direct trauma, or a combination of both. They have been reported in gymnastics or after a fall.[129,130] The lesion is more common in weightlifting and is caused in particular by a bench press.[131] The rupture usually occurs at the lateral fibres when the bar is at its lowest (loading of the fibres that are maximally stretched).[132,133]

In an acute injury there is sharp and burning pain, sometimes accompanied by significant swelling and ecchymosis. Passive elevation of the arm is very painful and somewhat limited. Resisted adduction and medial rotation of the arm are painful[134] and weak.

The functional tests are followed by palpation for tenderness and for a gap, and are best performed with the patient's arm slightly abducted and the hand resting on the iliac crest (see Fig. 15.19).

Treatment consists of surgical repair. Results are usually good to excellent.[135]

Painless weakness

A severe C7 root palsy can provoke painless weakness of adduction (see p. 156). Resisted extension of the elbow is also remarkably weak. The triceps reflex is sluggish or absent, together with some weakness on flexion of the wrist, more

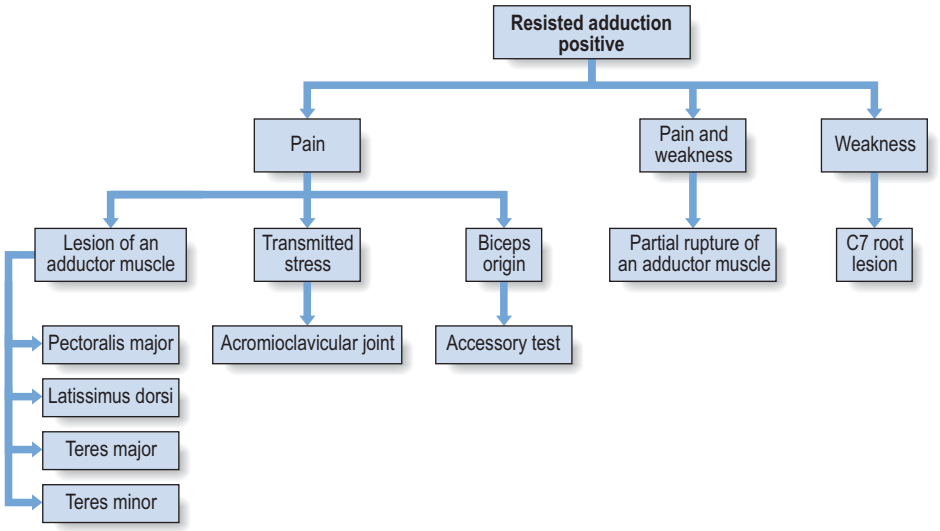

Fig 15.21 • Resisted adduction positive.

rarely on extension or on both. Numbness of the second and third fingers is usually present.

See Fig. 15.21 for a summary of resisted adduction.

Resisted lateral rotation

The main lateral rotators of the shoulder are the infraspinatus and teres minor. The former is by far the stronger of the two. The teres minor also adducts, so that resisted adduction offers the key to differential diagnosis.

Pain

If both resisted lateral rotation and resisted adduction are painful, the teres minor is at fault, although this is extremely uncommon. In contrast, when resisted lateral rotation is painful but other resisted movements are normal, the lesion lies in the infraspinatus.

Infraspinatus

There are some localizing signs of lesions of the infraspinatus. A painful arc indicates that the lesion lies at the superficial part of the tenoperiosteal insertion. If full passive elevation causes pain, the deep part of the tenoperiosteal insertion is affected (Fig. 15.22). If, apart from resisted lateral rotation, no other tests are painful, the lesion is in the body of the tendon or at the musculotendinous junction.[136,137] Palpation will disclose the exact location of the lesion.

Treatment

A lesion at the tenoperiosteal insertion of the infraspinatus can be treated either by deep friction or by infiltration with steroid. The general remarks made for the supraspinatus also apply here. The superficial part responds better to friction than does the deep aspect. It takes longer to achieve a cure by friction than by steroid infiltration but recurrence is less frequent. The body of the tendon is only treatable by deep friction.

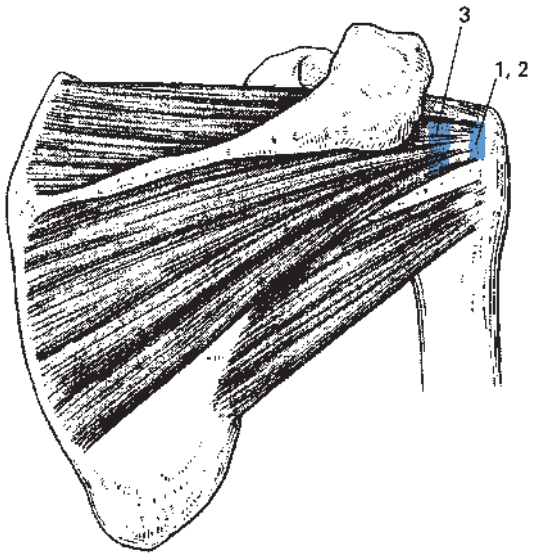

Fig 15.22 • Lesions of the infraspinatus; 1, superficial aspect tenoperiosteal insertion; 2, deep aspect tenoperiosteal insertion; 3, body of tendon.

Palpation

The patient lies prone, resting on the elbows, the shoulders vertically above them. The elbows are flexed to 90°. The upper arm of the affected side is brought into slight lateral rotation by asking the patient to hold the edge of the couch. In this position the whole infraspinatus structure is within the reach of the finger. In order to tighten the tendon and to bring it further laterally from underneath the acromion, the patient moves the shoulder slightly over towards the painful side.

First the spine of the scapula is palpated, then the posterior angle of the acromion and the lateral acromial edge. In the infraspinal fossa, the muscle belly of the infraspinatus is located and, when the fingers are moved further towards the greater tuberosity, the musculotendinous junction, the tendon and finally the tenoperiosteal insertion are located. The latter is

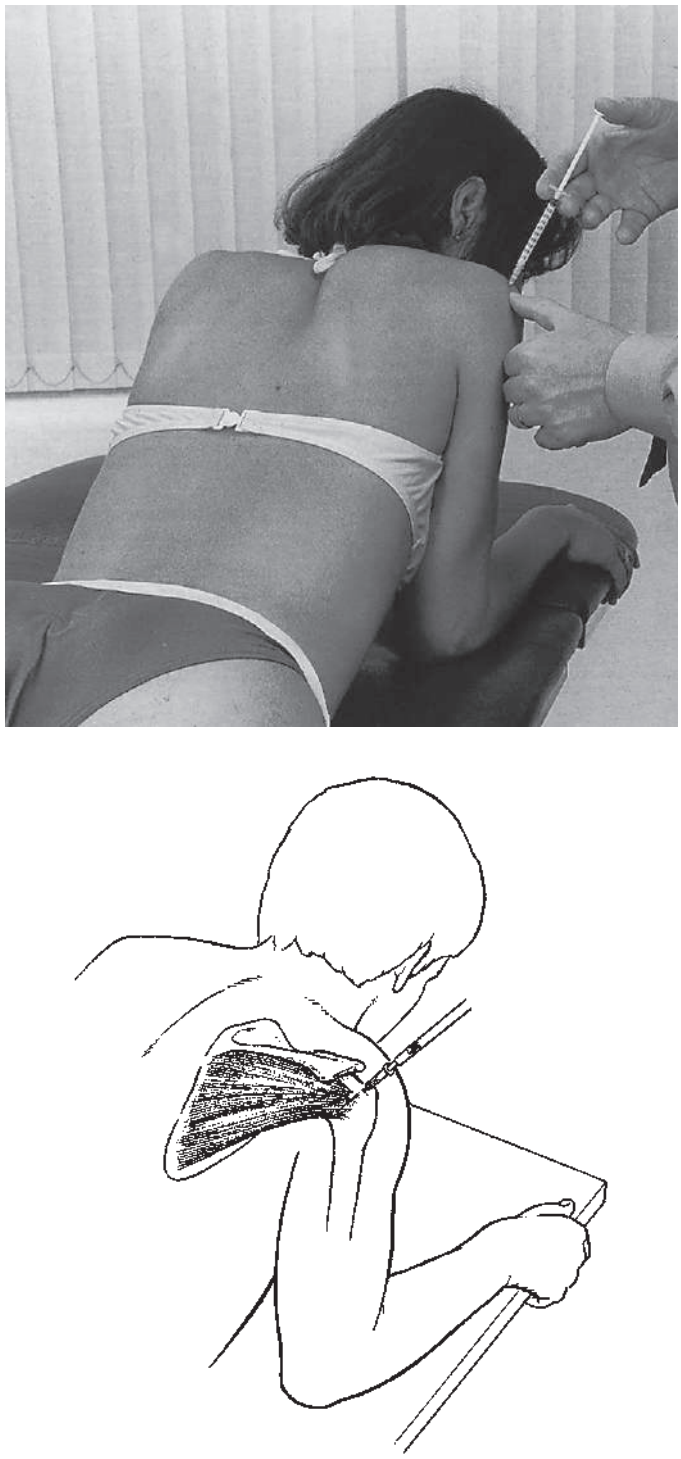

Fig 15.23 • Infiltration of the infraspinatus.

about 2 cm wide and lies partly lateral to the outer rim of the acromion and partly lateral behind the acromial angle.

Technique: infiltration of the infraspinatus tenoperiosteally

A 1 mL syringe is filled with 10 mg of triamcinolone and fitted to a 3 cm long needle. After the landmarks have been located, the needle is introduced in an anterocaudal direction, aiming at the tenoperiosteal insertion, which is reached after passing through soft tissue for about 2 cm (Fig. 15.23). Just before bone is reached, the tough tendinous resistance of the insertion is felt. The total amount is now injected in 5–10 slightly different sites. At each partial injection, strong counterpressure is felt.

The patient should rest the arm for about 2 weeks and is then re-examined. If pain remains, a second infiltration is given. Two infiltrations normally suffice.

Technique: deep friction to the infraspinatus

Deep friction is indicated in athletes, if infiltration has been unsuccessful or when the body of the tendon is affected.

The patient lies in the same position as for infiltration. The therapist stands at the painful side. The thumb of the ipsilateral hand is placed on the lesion, while counterpressure is applied with the other fingers at the front of the shoulder (Fig. 15.24). The body of the tendon feels like a cord, whereas the tenoperiosteal insertion feels more like a flat resistance just covering the underlying bone.

Friction is undertaken in a caudocranial direction by pronation–supination movements of the arm. The active moment is on supination. To avoid blisters, a piece of cotton wool between thumb and skin can be used: indeed, it may be necessary because in this position the skin is stretched, which allows the finger to glide over it too easily. Firm skin contact must be maintained.

Friction is given for 20 minutes, three times a week, and is usually curative after 10–15 sessions.

It may be difficult for the patient to hold this position for 20 minutes, so a break in treatment and sitting up for a few minutes should be allowed.

A specific case: abduction and lateral rotation against resistance are both painful

Both resisted abduction and lateral rotation are frequently painful on clinical examination and often there is a painful arc. This clinical pattern usually causes differential diagnostic difficulties that are not always easy to solve (Fig. 15.25).

No painful arc

If a painful arc is not present and both resisted abduction and lateral rotation are equally painful, the question is whether a supraspinatus or an infraspinatus tendinitis is present or whether both structures are inflamed. The test of resisted lateral rotation is first repeated, asking the patient to pay special attention to holding the elbow against the body when pushing the forearm sideways. Abducting the arm at the same time as resisted lateral rotation is performed could render the latter falsely painful when supraspinatus tendinitis is present. If the patient has difficulty in performing the test correctly, a sheet of paper should be placed between the elbow and the body during the test.

If both tests are still painful when correctly performed, they should be repeated in a supine position, which fully relaxes all the shoulder structures not intended to be tested. If one test becomes painless, the other one remaining painful, full value is given to the latter. For example, if resisted lateral rotation remains painful and resisted abduction becomes negative, the infraspinatus is at fault. If, on testing in the supine position, both tests remain painful, it is more likely that the

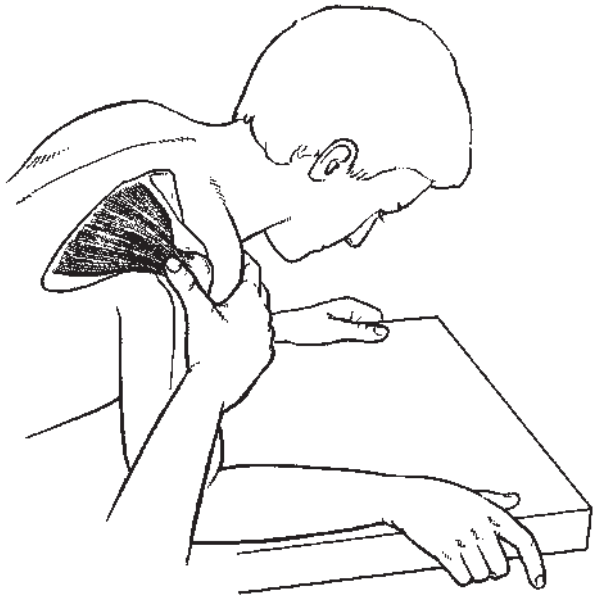

Fig 15.24 • Deep friction to the infraspinatus.

supraspinatus is at fault because this structure is more frequently affected. To obtain diagnostic certainty an infiltration with local anaesthetic is necessary and is the only way to determine whether the supraspinatus, infraspinatus or both together are affected.

Painful arc

If a painful arc is also found, then the following lesions may be present:

- Chronic subdeltoid bursitis
- Supraspinatus tendinitis

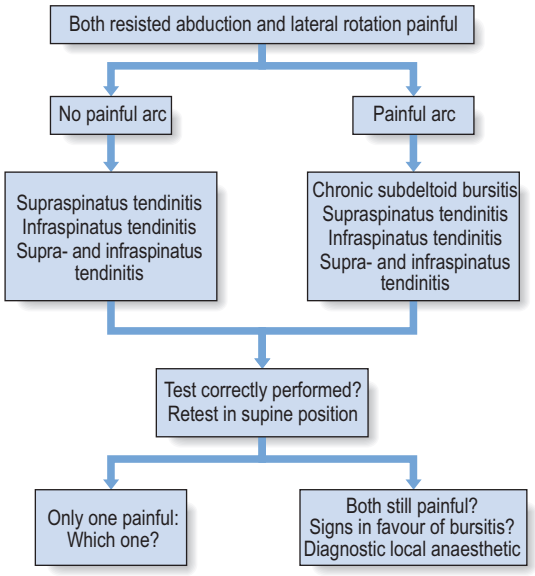

Fig 15.25 • Differentiation between subdeltoid bursitis and infra- and supraspinatus tendinitis.

- Infraspinatus tendinitis
- Tendinitis of both supraspinatus and infraspinatus.

If a painful arc is present, the tests should be repeated standing and lying.

Signs in favour of chronic bursitis

Presence of these signs makes it more likely that chronic bursitis is present:

- Very pronounced painful arc
- All passive movements painful at full range
- Tests are less painful in a supine position
- Resisted movements become less painful with axial traction, which prevents the humeral head approaching the coracoacromial roof
- Tenderness of the superficial part of the subdeltoid bursa on palpation
- Infiltration of the deep part of the bursa with local anaesthetic abolishes the pain.

Signs in favour of supraspinatus and infraspinatus lesions

Presence of these signs means it is more likely that tendinitis is the problem:

- Less pronounced painful arc
- Testing standing and lying are similarly painful
- Testing resisted abduction under axial traction is equally painful
- Tender spot in the tendon or tenoperiosteally
- Infiltration of the suspected tendon with a local anaesthetic diminishes the pain.

Painful weakness

Painful weakness on resisted lateral rotation is caused by a partial rupture of the infraspinatus tendon. The treatment

is the same as for uncomplicated tendinitis at the insertion. The same remarks as for the treatment of a partial rupture of the supraspinatus also apply here: infiltrations are not given in athletes but rather only if the patient can guarantee complete rest.

Painless weakness

If resisted lateral rotation is painlessly weak, differential diagnosis between the following lesions must be made.

Muscular disorder: total rupture of the infraspinatus tendon

This usually happens in patients over 50 years old who have suffered from overstrain or trauma, very often a fall.

Infraspinatus tears may present in isolation or in combination with a partial or total rupture of the supraspinatus tendon. The infraspinatus defect then propagates in a posterior direction from an established full thickness tear in the supraspinatus.[138]

As in supraspinatus tears, the lesion usually develops in patients over 50 years of age and is often asymptomatic (see p. 145). The lesion results from a combination of wear and tear and repetitive minitrauma. Sometimes the tear occurs suddenly during an acute overload or a fall.

Acute symptoms will be a painful arc on active and passive elevation and pain on full lateral rotation. Resisted lateral rotation is extremely weak but painless. The painful arc is caused by impingement of the tendon remnants between the greater tuberosity and the coracoacromial roof; the pain at the end of lateral rotation is caused by squeezing against the bulging posterior labrum. After some time (often many months), the inflammation decreases and the pain disappears. Resisted lateral rotation remains weak.

Chronic tears are characterized by marked and visible atrophy in the infraspinatus fossa. Secondary to the permanent loss of the infraspinatus, the patient can no longer bring the arm into full lateral rotation. This reduces the elasticity of the anterior capsule of the shoulder and results in a permanent isolated limitation of external rotation. The impaired external rotation leads to the typical 'hornblower's sign': bringing the hand to the mouth is only possible in internal rotation of the arm with accompanying excessive elevation of the elbow. Hornblower's sign has a 100% sensitivity and 93% specificity for irreparable degeneration of the infraspinatus.[139,140]

Treatment

When a painful arc is present, an infiltration is given in the tendinous remnants. For this, 1 mL of triamcinolone is infiltrated at the tenoperiosteal insertion, using the same technique as for uncomplicated tendinitis. It is repeated after about 2 weeks if the painful arc has not fully disappeared.

Abolishing the pain is only half the treatment. To prevent later limitation of lateral rotation, older patients are instructed to move the arm regularly into full lateral rotation with the help of the other arm or by twisting the trunk to the contralateral side while the forearm is stabilized against a fixed object.

Surgical treatment should be considered in younger patients with acute traumatic ruptures.

Neurological disorders

C5 root palsy

Resisted abduction of the arm and flexion of the elbow are also weak (see p. 155).

Suprascapular nerve palsy (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*)

Suprascapular nerve entrapment is usually an acquired neuropathy secondary to compression of the nerve in the bony suprascapular notch. Chronic mechanical irritation may be caused by overhead activities such as raquet sports, lifting and volleyball. Direct trauma, compression (e.g. backpacking) or a fracture of the scapula may also cause the lesion.[141] Sometimes it is idiopathic.

Symptoms are constant pain in the trapezius and scapular area for about 3 weeks, followed by functional disturbances in the arm (difficulties in performing overhead activities of the arm). Clinical examination reveals normal movement of neck, scapula and shoulder. Resisted movements show some painless weakness of abduction (although the supraspinatus is paralysed, the deltoid remains fully active) and gross but painless weakness of lateral rotation (the infraspinatus is completely paralysed).

Spontaneous cure is the rule in an idiopathic 'neuritis'. The pain disappears within 3 weeks, weakness within 6–12 months.[142]

During the last few decades, there have been several reports of isolated infraspinatus muscle paralysis in volleyball players. The reported incidence in high-level volleyball players is between 25 and 45%.[143,144]. Usually the finding is accidental and the disorder without any complaint: no pain, no loss of function, and even no reduced efficiency in playing volleyball.[145] The most plausible pathomechanism for this suprascapular neuropathy is traction or stretching of the nerve.[146] This traction injury may occur when repetitive overhead activities result in local nerve strain that exceeds the passive tolerance of the nerve.[147,148] In one study the players with suprascapular nerve entrapment displayed significantly greater shoulder mobility than those without.[149]

Neuralgic amyotrophy

This usually affects young males and starts with central neck pain, later spreading towards both shoulders and arms. Finally it leaves one arm and remains only in the other one. The pain is very severe and may last for about 6 months. Right from the onset, muscular involvement is visible. Often wasting is present together with a total palsy, not just weakness. It affects muscles of both sides, irrespective of segmental origin. Paralysis of the infraspinatus and the triceps, extensors of the fingers or extensors of the thumb is a common pattern (Cyriax:[86] p. 90) (see p. online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Myopathy

Bilateral painless weakness of the upper limbs can be the result of myopathy affecting serratus anterior, deltoid and both

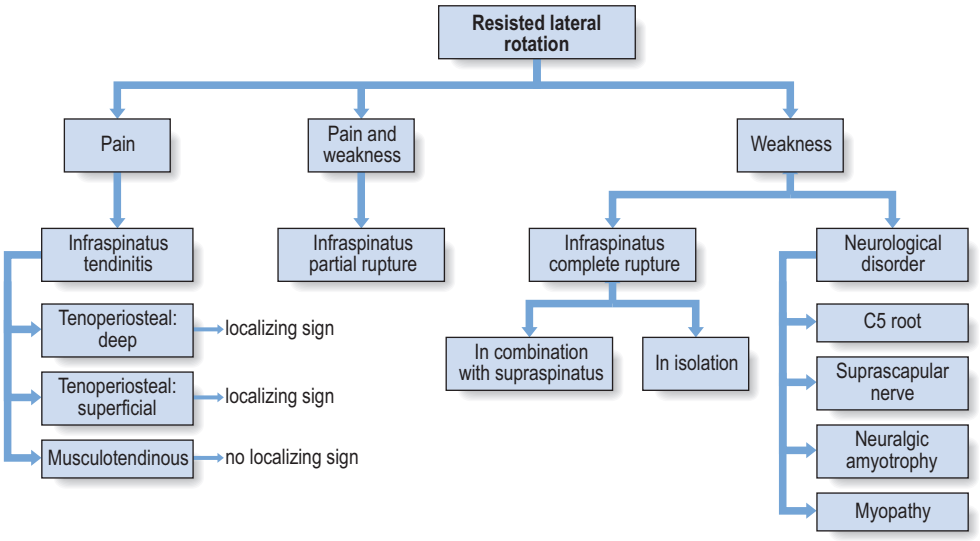

Fig 15.26 • Resisted lateral rotation.

spinatus muscles. If this is the case, then pronounced weakness and wasting of both spinatus muscles and of the serratus anterior muscle are present. Because of the muscular weakness there is sometimes some degree of immobilizational arthritis.

See Figure 15.26 for a summary of resisted lateral rotation.

Resisted medial rotation

Pain

Four different structures are tested on resisted medial rotation: subscapularis, pectoralis major, latissimus dorsi and teres major. The latter three are adductors as well and have been discussed previously (see above). If resisted adduction is painless, the lesion must lie in the subscapularis, the insertion of which is large and flat.

Subscapularis

The upper portion of the subscapularis inserts through a collagen-rich tendon into the lesser tuberosity. The rest (about 40%) of the tendon inserts into the humerus below the lesser tubercle and medial to the bicipital groove. Here the insertion is directly from muscle to bone.[150]

Tendinitis of the subscapularis can be localized tenoperiosteally in the cranial or caudal part of the tendon. Lesions in the muscle belly or in the tendon itself do not seem to occur. A lesion in the cranial part causes a painful arc because of impingement under the coracoacromial arch.[151] If the caudal portion is affected, the accessory test of passive horizontal adduction is painful as a result of pinching of the lesion between the lesser tuberosity and the coracoid process. Full active and passive elevation and full lateral rotation may be painful as well, because they stretch the subscapularis. Passive lateral rotation can even be so painful that it seems limited. To exclude arthritis, the examiner must gently try to bring the arm to full range, so as to confirm that limitation does not exist.

Treatment

Tendinitis of the subscapularis can be treated by friction or infiltration. Friction is a rather painful and difficult technique and so preference is often given to infiltration.

Technique: anatomical localization by palpation

The patient sits on the couch, the hand of the affected side resting on the thigh and the arm rotated slightly laterally. The bicipital groove is now located at the anterolateral aspect of the arm. This is best done at the proximal part, between the two tuberosities. In this position the lesser tuberosity points anteriorly, the greater tuberosity laterally. The examiner places one thumb longitudinally between the tuberosities. Using the other hand, the patient's arm is moved into lateral and medial rotation. On lateral rotation the lesser tuberosity contacts the thumb in the groove, while on medial rotation it is the greater tuberosity which comes in contact with it.

Once the lesser tuberosity has been identified, the finger is placed at the anteromedial aspect of it and, further distally, at the lesser tubercular crest. This is where the insertion of the subscapularis is found: partly on the lesser tuberosity, partly on its crest. The total width is about 3 cm.

The insertion does not offer any particular sensation to the palpating finger: it feels as hard as bone. Depending on the localizing sign (painful arc or passive horizontal adduction positive), the proximal or the distal half of the structure must be dealt with. Before any treatment is started, the affected part is carefully palpated to localize the most painful region. Palpation vaguely around the insertion must be avoided because this area is always tender.

Technique: infiltration of the subscapularis

A 3 cm needle fitted to a syringe filled with 1 mL of triamcinolone is inserted at the subscapularis insertion in the middle of the most painful part, and directed towards the bone (Fig. 15.27). Just before the humerus is reached, tendinous resistance is felt. As always, the infiltration is given in droplets. This time the needle is moved along a line in a craniocaudal direction over about 1.5 cm so as to include the whole lesion.

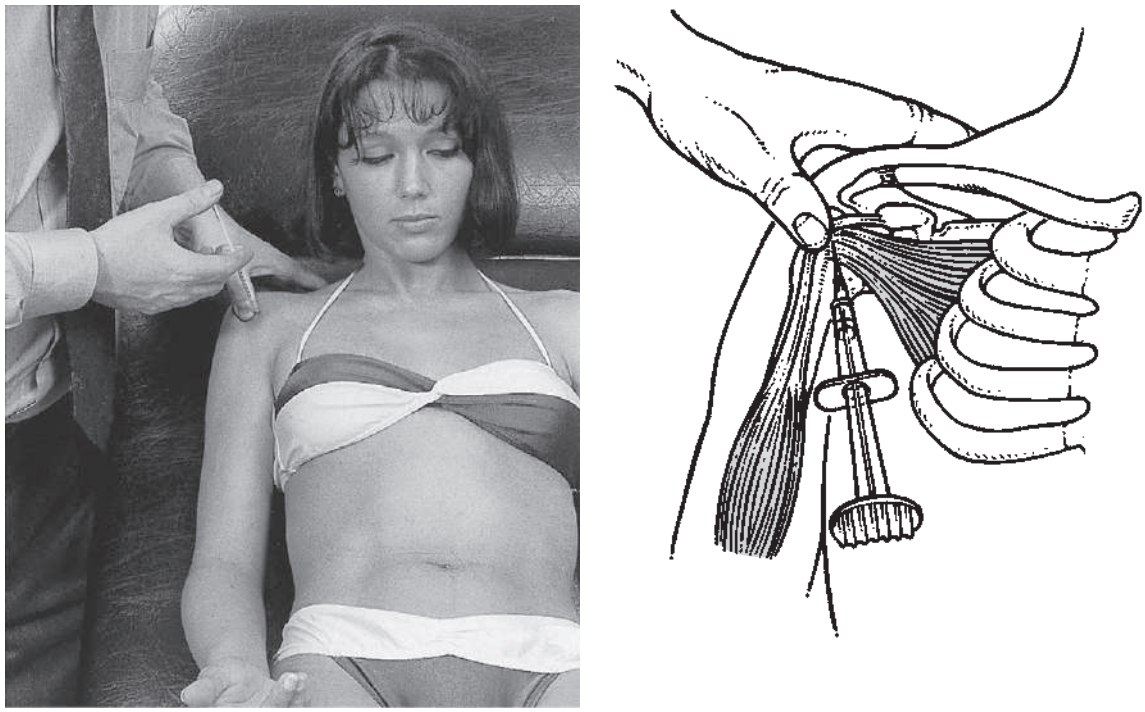

Fig 15.27 • Infiltration of the subscapularis.

Counterpressure is experienced during the infiltration. Care must be taken not to move the needle too far laterally, so as to avoid infiltrating the tendon of the long head of biceps, which could lead to its early degeneration.

The patient is told to avoid using the arm for about 2 weeks and then reassessed. If full cure is not attained, infiltration is repeated. Results are usually very good, as long as the correct point has been dealt with. Recurrences are less frequent than in supra- or infraspinatus tendinitis.

Technique: deep friction to the subscapularis

This form of treatment is mainly used in recurrences or in patients who refuse steroids.

The patient is brought into the half-lying position, the arm in slight lateral rotation. Palpation is done in the same way as for infiltration.

The therapist stands on the affected side and faces the patient. The contralateral hand is used. Beginning at the coracoid process, the thumb is brought just underneath it and the other fingers curved laterally around the arm, on to the back of the shoulder. The thumb is now pulled laterally while pressure is applied in a posterior direction. During this movement two tendinous structures are momentarily felt slipping under the thumb; these are the coracobrachialis muscle and the short head of the biceps. By moving the thumb yet further laterally, while maintaining some dorsal pressure, the anteromedial edge of the deltoid is reached and is pulled to the side. Finally the lesser tuberosity is contacted (Fig. 15.28a). The hand is now turned into a vertical position (Fig. 15.28b), still keeping the deltoid to the side.

Friction is given by a flexion–extension movement at the wrist, the active moment being when the thumb moves upwards. During the whole procedure the deltoid is kept to the side. This is a painful, difficult and, for the therapist, tiring technique. Progress towards cure tends to be slow and it may take about 1 month's friction before the patient starts to get better. Only two-thirds of patients can be fully cured in this way and, if no improvement has occurred after 1 month of friction, it is useless to continue and an infiltration should be given.

Painless weakness

Rupture of the subscapularis tendon

Tears of the subscapularis tendon occur either in isolation or as a propagation of a supraspinatus tear.[152] The former usually is the result of a hyperextension–external rotation trauma or follows an anterior dislocation of the shoulder.[153] The lower part of the muscle is mostly affected, where the insertion is more or less directly from muscle to bone. In the latter, the lesion is more proximal at the lesser tubercle, the distal part of the tendon remaining unaffected.[154,155] In traumatic rupture there may also be an excessive range of passive lateral rotation. Weakness of internal rotation can also be demonstrated by the 'lift-off' signs described by Gerber and Krushell: the patient places the arm in internal rotation with the dorsum of the hand on the sacroiliac joint. If the patient is unable to rotate the arm internally any further and lift the hand off the pelvis, incompetence of the subscapularis is suspected.[156]

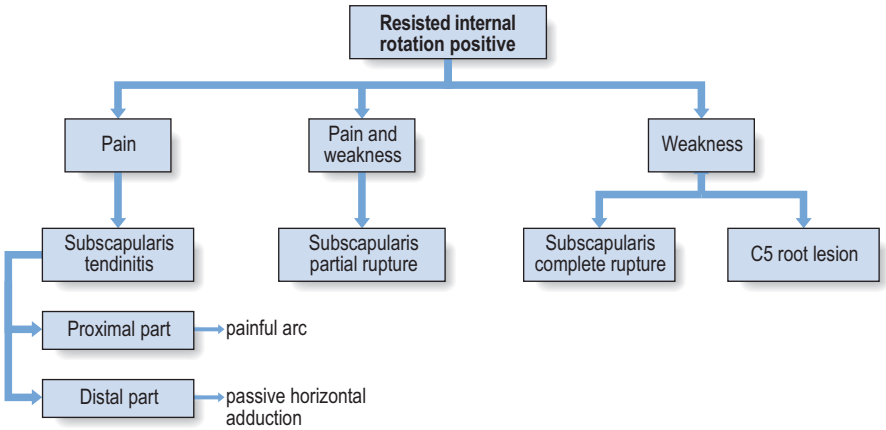
Treatment

Isolated traumatic tears of the subscapularis are best treated with surgery.[157] The surgical outcomes are less favorable when other tendons are involved.[158] If the condition remains painful, an infiltration with corticosteroid into the remnants at the tenoperiosteal insertion can be helpful.

(a) (b)

Fig 15.28 • Deep friction to the subscapularis. (a) Preparative position of the hand. (b) Position of the hand for friction.

Fig 15.29 • Resisted internal rotation positive.



Neurological lesion

Internal rotation is controlled by C5 and C6

In painless weakness of internal rotation, a lesion of these nerve roots should be ruled out.

See Figure 15.29 for a summary of resisted internal rotation.

Resisted elbow flexion

An examination of the shoulder is incomplete until the biceps has been tested. The muscle mainly moves the elbow but, as it crosses the shoulder joint, it can be the cause of pain around the shoulder as well. For this reason, resisted flexion of the elbow must always be included when the shoulder is assessed.

Pain

A positive test implicates the biceps. If pain is felt in the shoulder area, it is unlikely that the brachialis muscle is at fault, because a lesion in this muscle is more likely to cause pain around the elbow. The diagnosis can be confirmed by testing resisted supination of the forearm with the elbow flexed. If this is positive, the brachialis muscle is excluded.

The classification of biceps lesions can be divided into tendinosis of the biceps and biceps instability. The former may be an impingement lesion or occurs in isolation as a primary lesion of the biceps tendon.[159]

Lesions of the biceps can lie at different levels. Only those that can provoke pain at the shoulder are discussed here. These are tendinitis of the long tendon at the glenoid insertion, in its intra-articular course and at the bicipital sulcus (Fig. 15.30). Lesions of the muscle belly and further down are discussed in Chapter 19.

Lesion of the long bicipital tendon at the glenoid origin

Strain on the glenoid from the working biceps is greatest when the arm is in overhead abduction and lesions are usually caused in throwing athletes by traction injuries.[160,161] The pain is usually felt underneath the acromioclavicular joint but may radiate in the C5 dermatome. Besides pain on resisted flexion and supination of the elbow, resisted adduction of the arm will

also show positive. When the resisted adduction is tested again, this time with the elbow flexed, it becomes painless. This phenomenon is explained by the constant-length phenomenon on a structure spanning two joints (see Ch. 4): the degree of stress on the painful tissue in one joint depends on the position in which the adjacent joint is held.

Treatment

The condition can usually be treated successfully with one or two infiltrations of 20 mg of triamcinolone.

Technique: infiltration of the long bicipital tendon

The condition can be treated by infiltration only. The patient lies supine, the arm in 90° elevation, and the elbow flexed at a right angle. An assistant now turns the arm into 45° lateral rotation. In this position, the bicipital groove lies on a line extended from the anterior margin of the acromion.

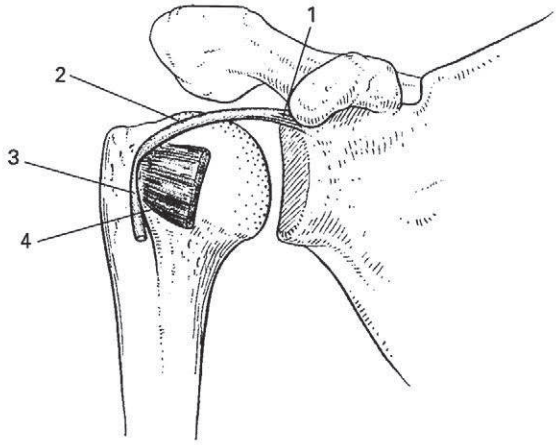


Fig 15.30 • Lesions of the biceps at the shoulder: 1, at the glenoid insertion; 2, at the intra-articular course of the tendon; 3, at the tendon in the sulcus; 4, subscapularis muscle.

A 2 mL syringe is filled with 20 mg of triamcinolone and a 4 cm needle fitted to it. One thumb is placed just beyond the acromion at the groove. The needle is inserted just distally to the thumb parallel to the bicipital sulcus and aiming at the glenoid (Fig. 15.31). It is then moved further in between the humeral tuberosities until it strikes the glenoid. A tough resistance is felt just before touching the bone. The steroid is infiltrated here in drops so that the whole insertion is treated. During the infiltration some counterpressure is felt.

The patient is re-examined after 2 weeks and, if necessary, the infiltration is repeated.

Intra-articular lesion of the long head of biceps

Pain on resisted flexion and supination of the elbow is found, together with a painful arc, which shows that the lesion lies at the intra-articular part of the tendon. As this part of the tendon lies intra-articularly, an intra-articular injection with 2 mL of steroid is required.

Lesion in the sulcus of the long head of biceps

The only positive sign is pain on resisted flexion and supination felt at the upper part of the arm. There is a full range of movement and a painful arc is absent. Palpation localizes the lesion in the sulcus.

Technique: deep friction to the long head

This lesion responds well to deep friction. The patient adopts the half-lying position, the palm of the hand on the thigh and the elbow at the side. The greater tuberosity then points laterally, the lesser tuberosity anteriorly. The sulcus lies in between the tubercles. In order to locate the groove precisely, the first part of the procedure for palpation for subscapularis tendinitis is performed (see above).

The therapist sits at the side, facing the patient. The patient's arm is put into a degree of lateral rotation. The thumb of the

Fig 15.31 • Infiltration of the long bicipital tendon at the glenoid.

Fig 15.32 • Deep friction to the long head of the biceps.

contralateral hand is put flat in the sulcus, the tip pointing cranially and the radial side in contact with the medial aspect of the sulcus. In this position the thumb lies on the medial aspect of the tendon. The other fingers apply counterpressure at the back of the arm. Pressure towards the bone is applied with the thumb.

With the other hand the therapist grasps the patient's lower arm, the elbow bent to 90°, and brings the arm into medial rotation until the radial side of the frictioning thumb comes in contact with the outer edge of the sulcus (Fig. 15.32). During this movement the tendon glides under the thumb and friction is achieved. The arm is now brought back into lateral rotation while releasing the pressure on the tendon (passive moment).

Treatment is carried out for 20 minutes, three times a week. Two to four sessions should be sufficient.

Alternative technique

Instead of the patient's arm being rotated, pronation–supination movements of the therapist's contralateral arm have the same effect. The active movement is on supination.

Snapping the long head of biceps

Biceps instability is seen most commonly in throwing athletes. Motion is often accompanied by a palpable snap or pop at a certain position in the arc of rotation.[162]

According to Slätis and Aalto, a rupture of the intertubercular transverse ligament allows for no appreciable medial or lateral movement of the tendon.[159] The key structure which guides the tendon in its groove is the medial portion of the coracohumeral ligament, which inserts at the lesser tubercle. It fills the space between the upper margin of the subscapularis and the anterior border of the supraspinatus. If it is transected, the long tendon of the biceps can easily be displaced medially.

Instability test

Dislocation of the biceps is tested with the biceps instability test of Abbott and Saunders.[163] The arm, abducted to 90° and fully rotated externally, is slowly brought to the side and rotated slightly internally. A palpable and even audible and sometimes painful click is noted as the biceps tendon, now forced against the lesser tuberosity, becomes subluxated or dislocated from the groove.

Rupture of the biceps tendon

Classically, the rupture takes place at the proximal part of the long head of the tendon. It is usually the result of degeneration and occurs spontaneously, provoking almost no discomfort. Distal ruptures are infrequent and are more often encountered in younger patients, usually as a result of local trauma, such as a direct blow.

Patients are usually male and over 50 years of age. Sometimes a loud crack is heard at the moment of rupture, with some transient pain in the upper arm. The most significant sign is the prominence that persists from the distal displacement of the muscle belly, best visible on contraction. On testing, no appreciable loss of muscle power is found.

Usually treatment is not required, although, in cases of less than 6 weeks' standing, surgical correction may be successful.[164]

Painless weakness

Fifth cervical root palsy

Painless weakness is found on resisted abduction and lateral rotation of the arm and on resisted flexion of the elbow.

Sixth cervical root palsy

Weakness is found on resisted flexion of the elbow (biceps and brachialis), resisted supination (supinator brevis), resisted extension and radial deviation of the wrist (extensor carpi radialis longus and brevis).

Resisted elbow extension

Pain

If this movement causes pain at the shoulder, it is logical to think of a lesion of the triceps, although this is very uncommon. On contraction of the triceps, the head of the humerus moves towards the acromion. If a lesion lies between one of the tuberosities and the coracoacromial roof, it can be pinched. Therefore pain on resisted extension of the elbow usually means the same as a painful arc. To exclude a lesion of the triceps definitively, palpation of the muscle can be used. If it is positive, it should always be followed by diagnostic infiltration with local anaesthetic because local tenderness is often present, even in normal circumstances.

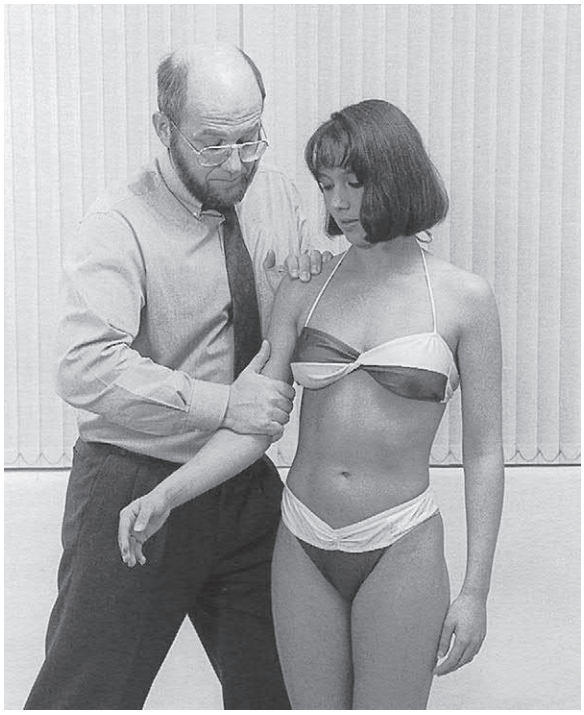

Fig 15.33 • Resisted flexion.

Painless weakness

Weakness on extension of the elbow is mainly the result of C7 root palsy caused by a C6 cervical disc lesion. Spontaneous pain is felt at the dorsal aspect of the arm and is increased by movements of the neck. Resisted extension of the elbow is painless. The latissimus dorsi (adduction of the arm) and the radial flexor, seldom the extensors, of the wrist may also be reduced in power. Theoretically the triceps reflex should be impaired, but in practice it seldom is.

Resisted flexion of the arm

The patient is asked to push the arm forwards against the examiner's hand, the latter applying counterpressure in the opposite direction (Fig. 15.33). Pain on this movement alone is the outcome of a lesion of the coracobrachialis muscle, which is rare. Although resisted adduction should also be painful, in practice it is not.

The lesion normally lies at the upper part of the coracobrachialis. Thus it can give rise to pain felt in the upper outer chest, radiating towards the inner side of the arm. It is treated by deep transverse friction.

Referred pain 277
Pain referred to the elbow 277
Pain referred from the elbow 277
History 277
Inspection 278
Functional examination 278
Passive movements 278
Resisted movements 279
Resisted tests of the flexors and extensors of the wrist 279
Palpation 280
Accessory tests 281

Referred pain

One of the rules of referred pain is that the further distally the lesion lies, the more accurately the patient can localize it. It is therefore reasonable to start off with the clinical examination of the elbow and, only when this seems to be negative, to check the cervical spine, the shoulder girdle and the shoulder.

Pain referred to the elbow

Pain referred to the elbow from structures that lie higher up the limb is one possibility. The localization of the pain indicates the segment in which the lesion lies: the lateral aspect of the elbow is formed by the C5 dermatome, the anterior aspect by C6, the inner aspect by T1–T2 and posteriorly by C7.

Pain referred from the elbow

Pain referred from the elbow is uncommon. A lesion at the origin of the extensor carpi radialis brevis may give rise to pain radiating down the posterior aspect of the forearm to the hand as far as the third and fourth fingers. A lesion at the distal bicipital insertion radiates down the proximal and palmar aspect of the forearm. Proximal reference of elbow pain is very rare.

History

The history is not very important in elbow problems but some questions should be asked.

- *Where is the pain?* The location of the pain is usually closely related to the site of the lesion. When the patient indicates exactly where the symptoms are felt, all causes that cannot produce pain in that area are automatically excluded.
- *How did it all start?* Did the symptoms start spontaneously or has there been any trauma; if so, what type? If the onset was spontaneous, did it begin suddenly or gradually, or as the result of a particular activity?
- *What was the evolution?* Was there any change in the location, intensity or frequency of the painful episodes? Did the pain spread and, if so, where to? This may indicate the dermatome and, in consequence, the segment in which the lesion must be sought.
- *Is there any functional loss?*
- *Has the elbow ever been swollen?* If the swelling came on after trauma, how soon did it appear? Immediate general effusion is probably the result of a haemarthrosis; gradually increasing swelling usually indicates the presence of synovial fluid. Spontaneous swelling may be the result of an impacted loose body or a rheumatoid condition.

© Copyright 2013 Elsevier, Ltd. All rights reserved.

Localized swelling may occur in bursitis or in some exceptional cases of tennis elbow.

- *What influences the pain?* Is the pain constantly present, or does it come on during or after either general or specific activity? In an arthrotic or arthritic joint the maintenance of a particular posture at the extreme of the possible range may become very painful. Release from this position is usually very uncomfortable. 'Twinges' when picking up objects (e.g. a telephone or a coffee pot) with an outstretched elbow is a well-known symptom in tennis elbow.
- *Are any other joints involved?* In rheumatoid-type conditions other joints may be affected.

Inspection

Inspection may reveal diffuse or local swelling: arthritis causes a more generalized effusion, whereas other lesions (bursitis and tendinitis) may give rise to more localized swelling. There may also be redness of the skin or muscular atrophy.

Functional examination

The examination consists of 10 tests: four passive movements and six resisted movements.

Passive movements

The passive movements (Fig. 16.1) are used to examine the inert structures: the joint, the capsule, the capsular ligaments and the bursae. It is also clear that, by passively testing the elbow, one also indirectly stretches or pinches muscular and tendinous structures.

The range of movement is ascertained and the end-feel noted.

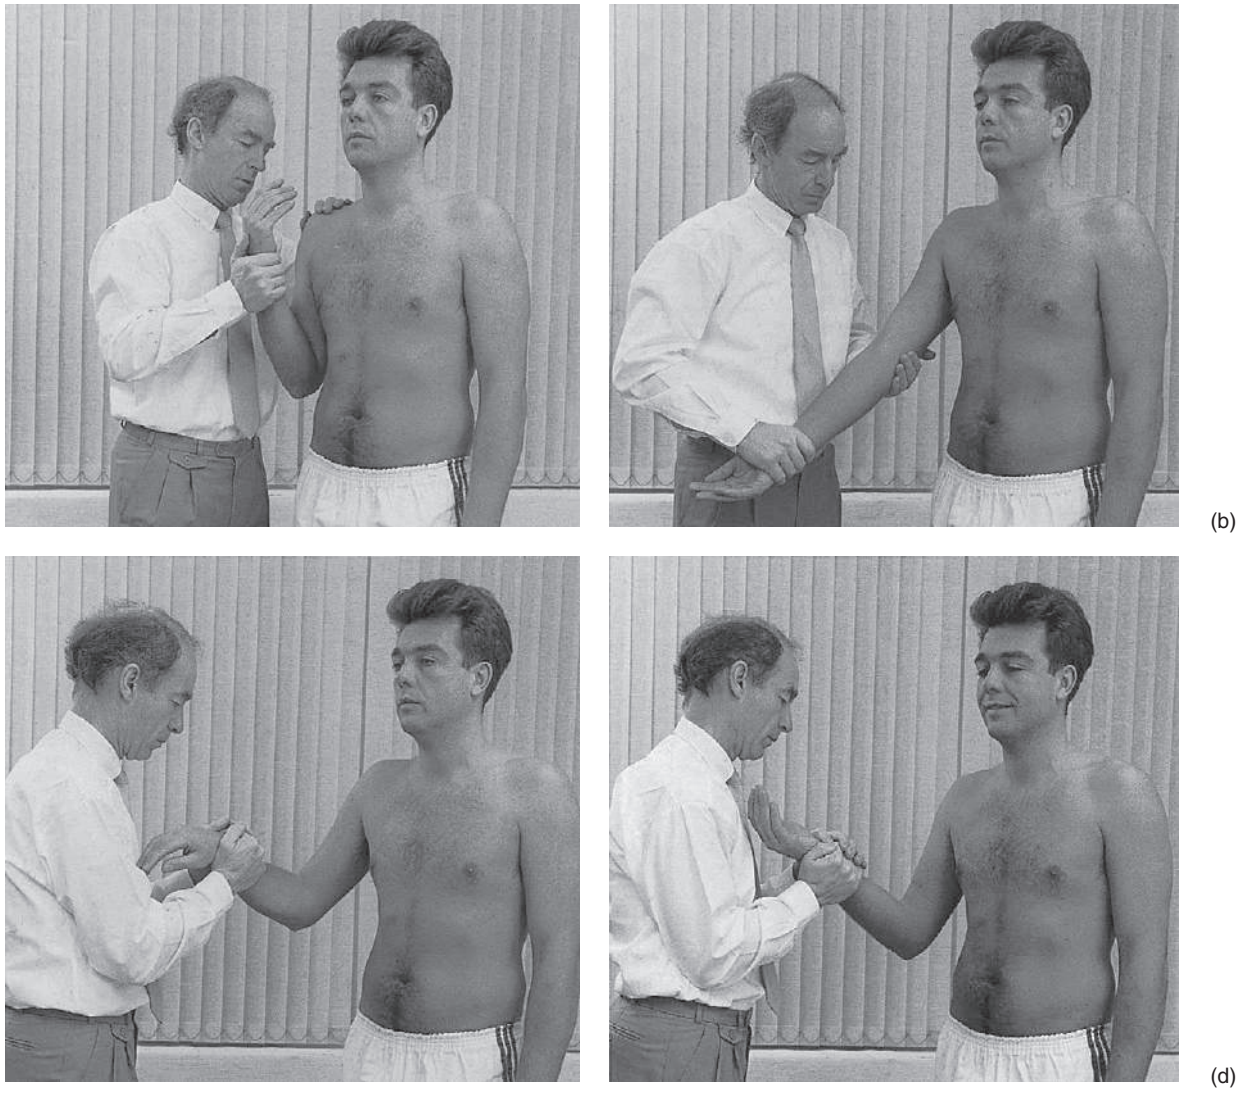

Fig 16.1 • Passive movements: (a) flexion, (b) extension, (c) pronation, (d) supination.

The four passive tests give the examiner an idea of the behaviour of the inert structures around the elbow. The pattern that is formed suggests a lesion of either the capsular type – arthritis, in the joint between forearm and humerus or in the upper radioulnar joint – or the non-capsular type.

Passive flexion

The examiner places the contralateral hand at the dorsal aspect of the patient's shoulder to prevent the body from trying to move backwards in order to escape from the pain. The ipsilateral hand takes hold of the patient's forearm just proximally to the wrist and moves the joint as far into flexion as possible (Fig. 16.1a).

The normal end-feel is one of tissue approximation as the muscles of the forearm come in contact with the brachial muscles at an angle of about 160°.

Passive extension

With the contralateral hand, the examiner takes hold of the patient's upper arm at the level of the olecranon. The ipsilateral hand is put at the distal end of the patient's forearm. Both hands move in opposite directions so as to extend the elbow (Fig. 16.1b).

The normal end-feel in passive extension is hard and bony, caused by the olecranon coming into contact with the posterior aspect of the humerus, and by tightening of the anterior capsule of the joint. As the forearm now lies in line with the upper arm, the angle of extension is 0°. In instances of over-extension, the angle may become 5–10°.

Passive pronation

The elbow is bent to a right angle. The examiner stands in front of the patient and grasps the distal forearm just proximal to the wrist with both hands. The heel of the contralateral hand is placed at the palmar aspect of the ulna, the fingers of the other hand at the dorsal aspect of the radius. A simultaneous movement of both hands presses the wrist into full pronation (Fig. 16.1c).

The extreme of movement is characterized by an elastic, capsular end-feel as the 85° range is approached. Together with passive supination, this movement tests the integrity of the upper radioulnar joint. Pain at the end of the range may also be a localizing sign in tendinitis of the insertion of the bicipital tendon on to the radial tuberosity, because of pinching of the tendon between the radial tuberosity and the ulna.

Passive supination

The position of the examiner's hands is slightly changed: the heel of the ipsilateral hand applies pressure at the dorsal aspect of the ulna and the fingers of the other hand pull at the palmar aspect of the radius. The forearm is twisted into supination as far as it goes (Fig. 16.1d).

Normally the capsular end-feel is noted at about 90°.

Resisted movements

The same four movements are repeated but against isometric resistance to examine the contractile structures (Fig. 16.2).

Resisted flexion

The patient holds the forearm in supination. The examiner puts the contralateral hand on top of the patient's shoulder to prevent it from moving upwards during the contraction. The other hand is placed on the distal forearm with the examiner's forearm held vertically, to prevent the patient's forearm from moving as the flexor muscles are contracted (Fig. 16.2a).

The muscles thus tested are the brachial biceps, the brachialis and the brachioradialis. The brachialis is a strong flexor and the brachioradialis is clinically unimportant.

Resisted extension

Again the contralateral hand is placed on top of the patient's shoulder. The other one is placed vertically under the patient's forearm and prevents the arm from moving downwards (Fig. 16.2b). If necessary, in a very strong patient, the examiner's own elbow may be supported on the thigh.

The muscles that are tested with this movement are the triceps and, secondarily, the anconeus muscle.

Pain at the shoulder during this movement has the same applications as painful arc (see online chapter *Disorders associated with a painful arc*).

Resisted pronation

The patient's forearm is held in the neutral position between pronation and supination. In order to prevent any movement during the resisted movement, the examiner's hands should be placed as follows: the ipsilateral hand, held in supination, is placed under the patient's distal forearm; the contralateral hand, held in pronation, is placed on top. The patient is asked to perform a pronation movement and resistance is supplied by the heels of both hands (Fig. 16.2c).

This movement mainly tests the pronator teres muscle but will also be painful in the presence of golfer's elbow.

Resisted supination

The hands are placed in a slightly different position from the previous test so that there is resistance against the palmar aspect of the distal ulna and the dorsal aspect of the distal radius (Fig. 16.2d).

In this test, the brachial biceps is tested with respect to its secondary function, and also the supinator brevis muscle.

Resisted tests of the flexors and extensors of the wrist

There are two muscle groups – *the flexors and extensors of the wrist* – that control wrist movements but lie at the elbow and therefore can give rise to symptoms around this joint. They should be systematically tested in the elbow examination.

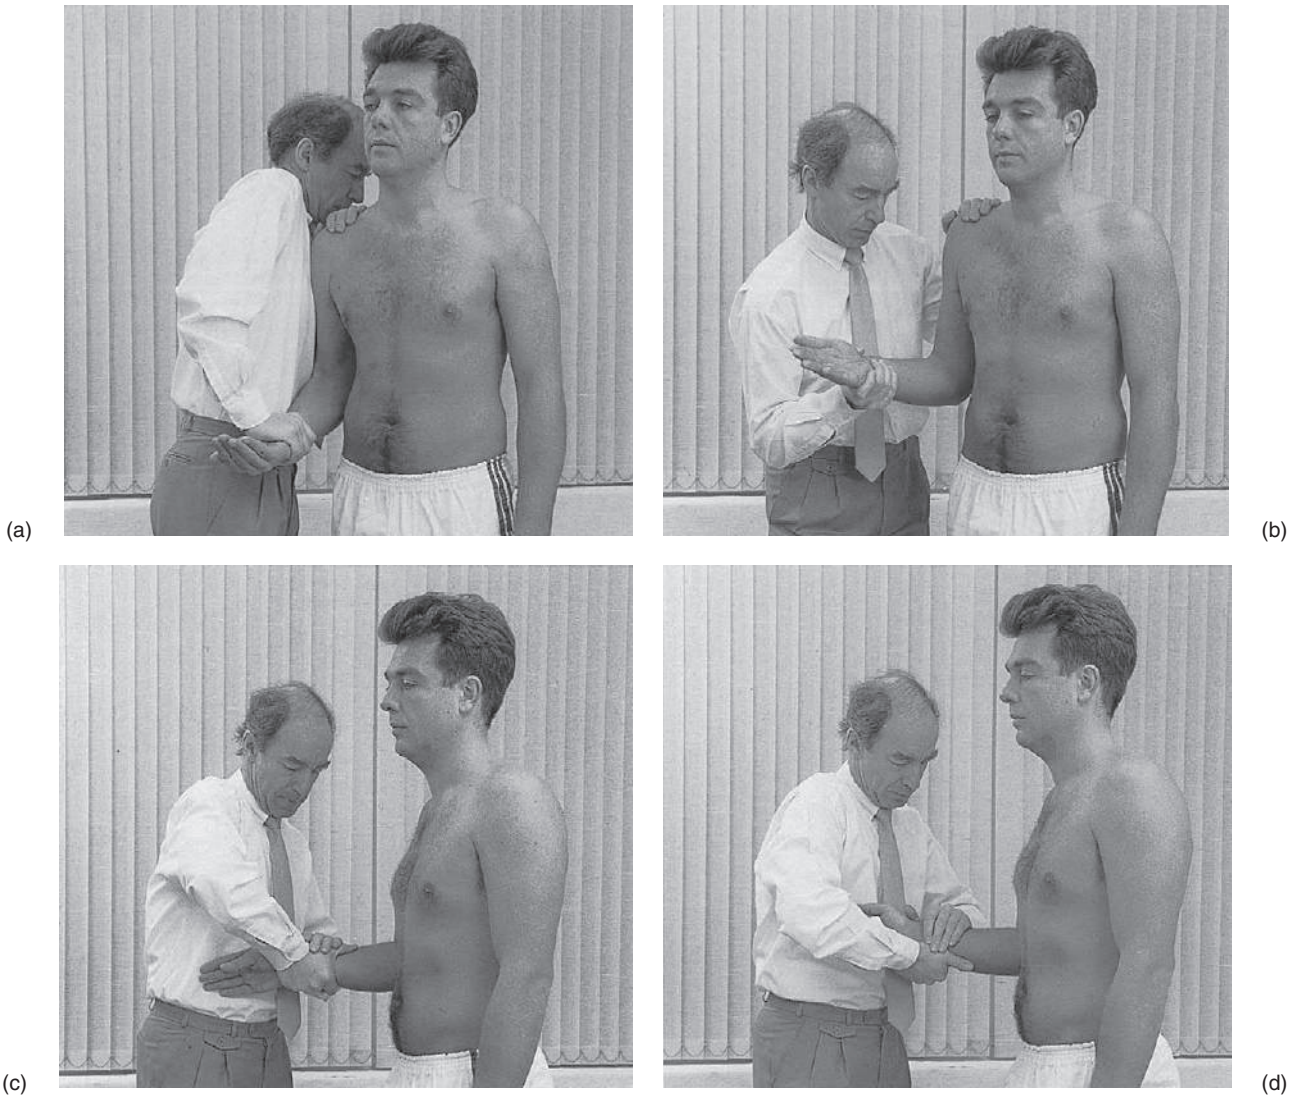

Fig 16.2 • Resisted movements: (a) flexion, (b) extension, (c) pronation, (d) supination.

The patient's elbow is held in extension, so as to put maximum stress on these structures (Fig. 16.3).

Resisted flexion of the wrist

The patient's hand is held palm downwards. The examiner passes the contralateral arm under that of the patient and grasps the forearm just proximally to the wrist in order to fix the upper limb. The upper arm lies under the patient's elbow and holds it in full extension. The hand of the other arm is now brought into the palm of the patient's hand and resists the patient's attempt to flex the wrist (Fig. 16.3a).

The following muscles are tested: flexor carpi radialis, flexor carpi ulnaris, flexor digitorum superficialis and flexor digitorum profundus.

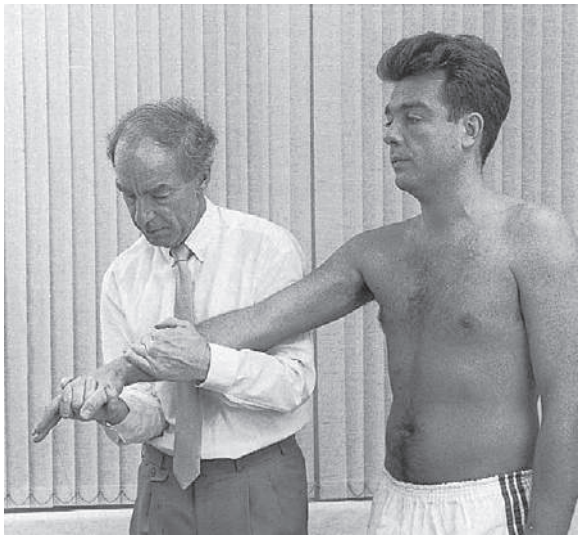
Resisted extension of the wrist

The patient remains in the same position as in the previous test. The examiner puts the hand on top of the patient's hand to resist an attempt to execute an extension movement (Fig. 16.3b).

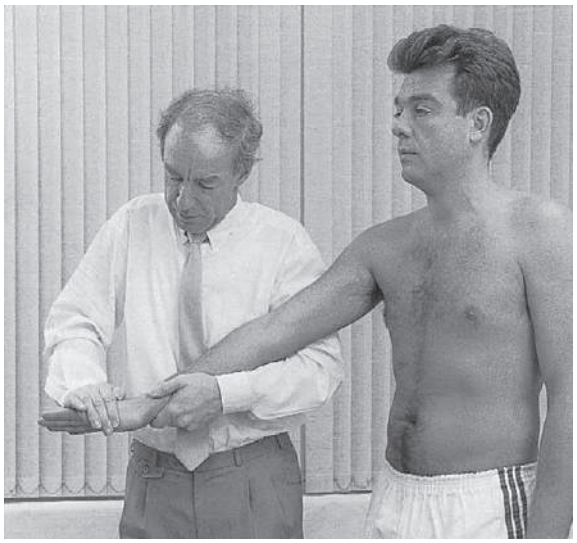
The muscles tested are the extensors of wrist and fingers: extensor carpi radialis longus and brevis, extensor carpi ulnaris, extensor indicis proprius, extensor digitorum communis and extensor digiti minimi.

Palpation

After the clinical examination (and only if it is likely to supply more information), the elbow is palpated.



(a)



(b)

Fig 16.3 • Resisted movements: (a) flexion and (b) extension of the wrist.

The elbow joint can be palpated either at rest or during movement, in order to detect warmth, swelling, synovial thickening (palpation laterally over the head of the radius), crepitus or clicking. The muscle or tendon at fault is palpated to define the exact site of the lesion.

Accessory tests

Resisted extension of the wrist with the fingers actively flexed

The patient is asked to flex the fingers actively by pressing the fingertips into the palm of the hand. Resisted extension of the wrist is now executed, as already described (Fig. 16.4).

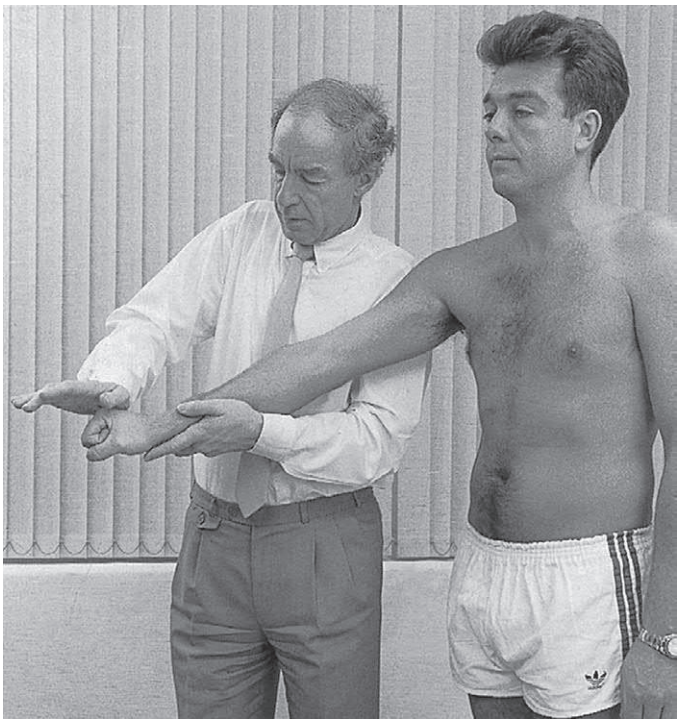


Fig 16.4 • Accessory test: resisted extension of the wrist with the fingers actively flexed.

Resisted radial and ulnar deviation

With the elbow in extension and the wrist in the neutral position between flexion and extension, radial and ulnar deviation are tested against resistance (Fig. 16.5). These tests differentiate between a lesion of the radial extensors or flexors of the wrist or of the ulnar extensors or flexors.

Resisted extension and flexion of the fingers

When a lesion of the finger extensors has been diagnosed, the examiner may test resisted extension of each finger in turn (Fig. 16.6a) to find out which tendon is at fault.

If a finger flexor is affected, resisted flexion of each finger (Fig. 16.6b) may disclose the exact tendon.

Resisted supination in extension

In order to differentiate between lesions of the brachial biceps and the supinator brevis muscle, this test should be performed. When the arm is brought into extension, the action of the biceps is diminished considerably but the supinator contracts normally.

5. Accessory tests

Tinel's sign

Percussion to the ulnar nerve in the groove between the olecranon and the medial epicondyle (Fig. 16.7) gives rise to distal paraesthesia in the territory of the ulnar nerve – in the forearm and the hand – Tinel's sign. This test can be used to assess the progress of regeneration of the sensory fibres of the nerve. The most distal point where the pins and needles are felt indicates the limit of regeneration.

The clinical examination is summarized in Box 16.1.

Interpretation of the clinical examination of the elbow

Limited range of movement

Capsular pattern

The capsular pattern at the elbow is characterized by limitation of flexion and extension (Fig. 18.1), flexion usually being more limited than extension, although equal limitation of both movements does occur. Rotations remain full and painless except in advanced arthritis, in which they can be painful at the end of the range.

The following conditions are the most common.

Traumatic arthritis

A traumatic arthritis presents as an isolated condition at the joint between humerus and ulna; hence there is isolated impairment of flexion and extension. The arthritis can be the result of either trauma (not necessarily severe) or – in middle-aged or elderly patients – overuse of the joint.

The patient usually states that, immediately following an injury or the day after doing heavy work or exertion, the elbow hurts diffusely. The pain is quite constant, and there is stiffness and difficulty in moving the joint.

Clinical examination shows a capsular pattern: flexion and extension movements are markedly limited and painful; rotations are of full range and painless.

On palpation, some swelling may be detected. If the swelling came on immediately after an accident, it is probably caused by blood and this should be aspirated at once. If not, the effusion is secondary and disappears as soon as the arthritis subsides. Also, a positive fat pad sign on a lateral radiograph – a response to distension of the joint capsule – is indicative of intra-articular fluid.[1,2]

There are two situations that are worthy of attention.

Fracture of the olecranon

The olecranon lies superficially and is therefore very vulnerable. Injury to the elbow, and especially a fall on a bent elbow, may result in fracture of the olecranon. It is, of course, tender to the touch and marked articular signs are found on examination: warmth, swelling and limitation of passive movement in the capsular pattern.[3,4] Resisted movements are also positive in that isometric extension, an action of the triceps muscle, is painful and weak (see also p. 453). Radiography confirms the fracture and its type: it is mostly displaced but stable, and then requires surgery. When it is not displaced, immobilization suffices.[5]

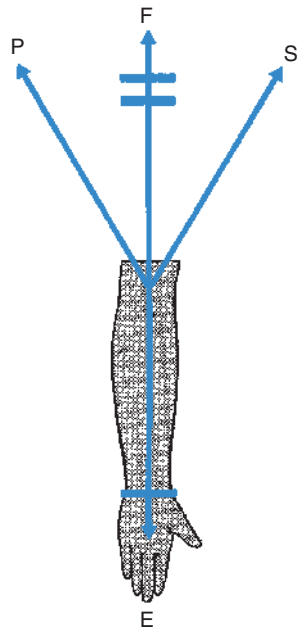

Fig 18.1 • Capsular pattern. F, Flexion; E, extension; P, pronation; S, supination.

Fracture of the head of the radius

Radial head fractures account for about 30% of all elbow fractures and mostly occur as a result of falling on to an outstretched hand.[6] They are most common in females.[7]

Should pronation and supination both hurt in an acute traumatic arthritis at the elbow, the head of the radius is almost certainly fractured. A radiograph confirms the diagnosis.

Treatment options for radial head fractures include conservative treatment, excision, open reduction–internal fixation, and arthroplasty, all depending on the type of fracture and the degree of displacement.[8,9]

Warning

Traumatic arthritis in combination with pain on pro/supination and/or painful weakness during isometric testing is suggestive of an intra-articular fracture.

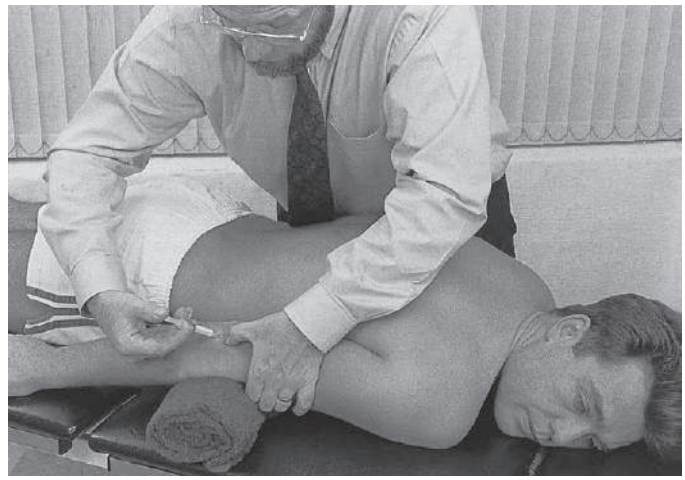
Treatment

Traumatic arthritis recovers spontaneously but may take several months. Treatment with massage and/or exercises only irritates the joint and is therefore contraindicated.

The treatment of choice consists of two intra-articular injections of 20 mg of triamcinolone acetonide. The injection is given when the patient is first seen. The arm is kept in a sling for a couple of days. A week later a second injection is given and the joint should have recovered in 2 weeks' time.

Technique: intra-articular injection

The patient lies prone on a couch with a small pillow under the elbow. The arm is held by the side with the forearm fully supinated. In this position the joint lines between humerus and radius and the radial side of the olecranon are both easily felt. A 2 mL syringe is filled with triamcinolone acetonide 10 mg/mL and a 2 cm thin needle is fitted. The needle is inserted at the joint line and aimed slightly obliquely under the olecranon (Fig. 18.2).



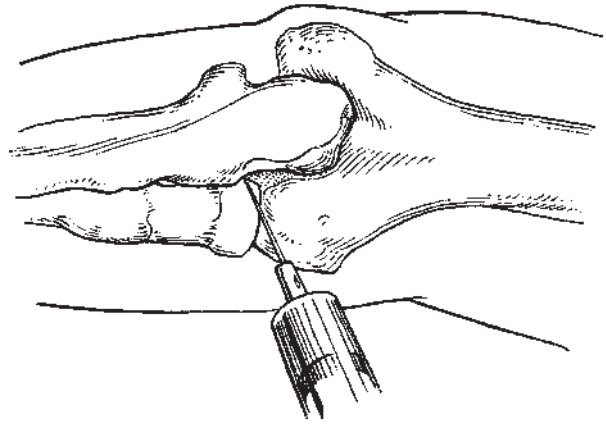


Fig 18.2 • Intra-articular injection.

Rest in flexion

Another valuable treatment is rest in flexion. It can be used in those patients who cannot tolerate an injection. As soon as the patient is seen, the elbow is immobilized in as much flexion as possible by means of a collar-and-cuff bandage. Every day the elbow is flexed more, until full movement can be achieved; thereafter it is held in this position for 2 weeks. The elbow is then rested in slightly less flexion. Three days later the joint is re-examined and, if the range of flexion is still full, the forearm is allowed to extend a little further. Some 6 weeks later, the patient reaches the stage in which the arm can be worn in a sling. After 2 or 3 months, movements of the elbow should be full and painless. Another static progressive splinting method by means of a turnbuckle splint has proved to be useful in the treatment of long-standing post-traumatic stiffness of the elbow.[10,11]

Arthrosis

This condition may come on spontaneously in late middle age[12] and is often bilateral. It may also occur as the result of a fracture or dislocation.[13] Intra-articular distal humerus fractures, for example, are most often associated with the development of degenerative joint disease over time.[14] Repeated minor injuries[15,16] or a loose body in the joint may also account for early arthritic changes.[17]

The patient, most often a male,[18] complains that, after he uses his elbow excessively, the joint aches slightly. He may also find the inability to fully straighten the arm inconvenient.

On examination a slight capsular pattern is found with a hard end-feel on flexion. The end-feel on extension is also hard but this is because of capsular contracture and is not the normal bone-to-bone end-feel. There may be coarse crepitus. The radiograph may show the arthrotic changes, although a positive radiograph can also be compatible with full range and painless function at the joint.

The differential diagnosis is neuropathic arthropathy,[19] which presents with gross painless limitation of movement in the capsular pattern.

An arthrotic joint does not of itself give rise to the sort of symptoms that warrant treatment. What may happen is that, on top of the arthrosis, a traumatic arthritis develops as the result of overuse. This can be treated as outlined earlier. Loose bodies are quite common and may also complicate the arthrosis (see below).

Monoarticular steroid-sensitive arthritis

A seronegative arthritis may occur, confined to one elbow joint. The pain is spontaneous in onset and the elbow very soon starts to swell.

A marked capsular pattern is found and, in due course, some limitation of pronation and supination may occur. In the acute and subacute stages, the end-feel is of muscle spasm. The joint is warm to the touch and synovial thickening can be found on palpation over the head of the radius laterally. In advanced cases muscle atrophy may also be seen. If, after some years, crepitus is present, it is of the silky type.

On radiography, decalcification and later erosion of cartilage may be visible.

Treatment with intra-articular triamcinolone suspension (see earlier) is symptomatically very effective in monoarticular steroid-sensitive arthritis; it stops the pain but produces hardly any change in the amplitude of movements. The patient may be pain-free for many months, whereupon the injection can be repeated without fear of steroid arthropathy because the elbow is not a weight-bearing joint.

Crystal synovitis

Gout (uric acid crystals) and pseudogout (calcium pyrophosphate crystals) seldom affect the elbow joint during a first attack (in only 4.5% of gout cases)[20] but more frequently cause acute olecranon bursitis.[21] As disease develops, polyarticular attacks may occur, in which case the elbow joint is affected in 30% of cases.

The sudden unprovoked onset and the shiny red appearance of the joint are characteristic.

The following diagnostic criteria may be useful in gout. When uric acid crystals are found in the synovial fluid during microscopic, chemical or histological examination, or tophi are seen on the ears, the diagnosis is certain, as it also is when two of the following four criteria are present: history of a typical attack of gout at the big toe; history of two typical attacks of gout at another joint; clinical picture of tophus; remission within 48 hours of the acute attack after the administration of colchicine or phenylbutazone.[22]

Haemarthrosis

Haemarthrosis may occur after injury to the joint, especially an intra-articular fracture or a direct contusion of the joint capsule, or, less commonly, in haemophilic patients. Bleeding into the joint leads to gross swelling and a marked capsular pattern.[23] Aspiration must be carried out immediately to avoid destruction of cartilage.

Rheumatoid-type arthritis

Polyarticular rheumatoid arthritis may affect the elbow joint. Apart from the gross swelling, rapidly ensuing limitation of extension is typical.[24] The elbow is also one of the sites of predilection, together with the knee and shoulder, for chondromatosis. Pigmented villonodular synovitis occurs most commonly at the knee, followed by elbow and ankle.[25]

In these and the other rheumatoid-type arthritides, systemic medication is required, and sometimes even a surgical approach. Good results have been reported with total elbow arthroplasty.[26–33]

Septic arthritis

A bacterial infection of the elbow joint is always very serious. It may not only lead to total destruction of the joint but may also be life-threatening.[34]

It can be the result of an open injury to the joint (e.g. open fracture), penetration of a foreign body (e.g. rose or bramble thorns during gardening or fruit picking) or direct inoculation of a bacterium during intra-articular injection, especially injection of a steroid suspension. It can also be caused by haematogenous dissemination from focal infections: dental abscess, cystitis, urethritis, skin infections. These causes are very dependent on the patient's resistance to infections: patients with diabetes, renal failure or a deficient immune system (e.g. rheumatoid arthritis) are more likely to suffer from haematogenous dissemination followed by a septic arthritis.[35–37]

Symptoms start suddenly and are easily recognized. The joint shows the signs of a hyperacute inflammation: a great deal of pain, gross swelling, redness, warmth and gross limitation of movement in the capsular pattern. There are also general

symptoms, such as high fever, a toxic appearance, pallor, loss of appetite and rigors.

Treatment consists of systemic antibiotic therapy and daily local aspiration[38] and drainage by arthroscopy.[39]

Tuberculous arthritis

Elbow tuberculosis is a rare disease which accounts for 1–3% of all cases of osteoarticular tuberculosis.[40] The diagnosis is very difficult to make because of the insidious onset with mild and non-specific local or systemic symptoms. The radiological findings are also non-specific in the early stage. Tuberculosis of the elbow is therefore easily misdiagnosed as degenerative arthritis or rheumatoid arthritis.[41] Several months after the onset of symptoms, there is pain at night, and examination reveals a gross capsular pattern and a spastic end-feel. The radiograph reveals periarticular osteopenia, bone erosion and joint space narrowing.[42] On haematological testing, the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are elevated.[43]

The gold standard for the diagnosis of tuberculous arthritis is identification of *Mycobacterium tuberculosis* either directly or after culture of the synovial fluid.[44]

Non-capsular pattern

Limitation of flexion or extension in isolation

Loose body in the joint

A loose body in the elbow joint is not uncommon and may hinder normal movements. It prevents the joint either from moving into full flexion, leaving extension free (Fig. 18.3), or from moving into full extension, leaving flexion free (Fig. 18.4). It then changes the hard end-feel of extension into a rather soft one.

Three different clinical pictures can be considered, depending on the age group in which they appear: adolescents, adults or the elderly.

In adolescence

A loose body is a common cause of elbow trouble in adolescents and is the only non-traumatic cause of arthrosis encountered in a young person. The condition does not occur before the age of 14 and usually results from osteochondritis dissecans, mostly on the humeral capitellum,[45,46] or an intra-articular chip fracture, conditions that may lead to exfoliation of one or more fragments of bone covered by articular cartilage.[47] Osteochondritis dissecans is not uncommon in young female gymnasts with hyperextension and valgus of the elbow.[48–50] It also affects young pitchers or athletes involved in high-demand, repetitive overhead activities.[51,52]

The history is quite typical: the young person states that the elbow joint locks suddenly, usually in flexion. It is impossible to straighten the elbow to full range because of the pain. In a few days, the condition gradually subsides. One or more of these attacks may have occurred in the past, with pain-free episodes in between.

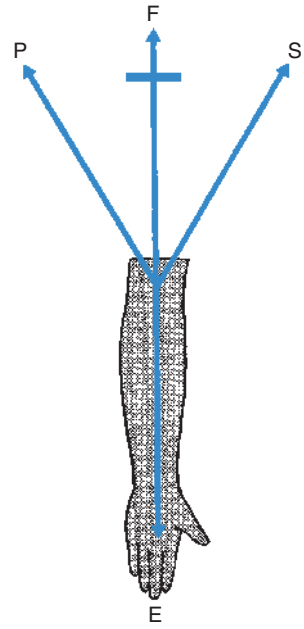

Fig 18.3 • Non-capsular pattern with limitation of flexion.

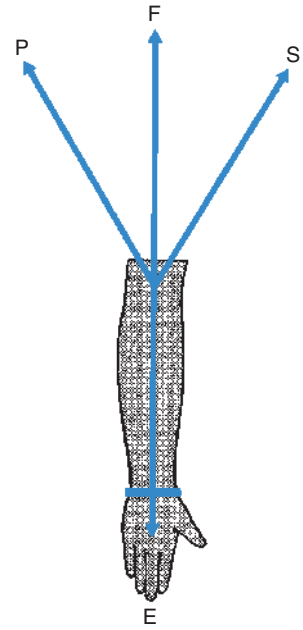

Fig 18.4 • Non-capsular pattern with limitation of extension.

Clinical examination during an attack shows a non-capsular pattern: limitation of passive extension with a soft end-feel. During a pain-free period, examination is negative; the diagnosis is suggested by the typical history.

Diagnosis can be confirmed by anteroposterior radiography performed with the elbow in 45° of flexion,[53] because in this

position the X-ray beam is almost parallel to the gap between the fragment and the underlying capitellar bone. Recently, magnetic resonance imaging (MRI) has been suggested for assessing osteochondritis dissecans,[54] and sonography also seems to be effective.[55,56]

If the patient is seen during an attack, manipulative reduction can be carried out. However, arthroscopic[57,58] or surgical[59] removal of the loose piece(s) should always be advised for the following reasons: as the loose body has an osseous nucleus and still lies within its nutrient synovial fluid, it may grow and the condition may worsen at each attack. It is also important to realize that the loose body is considerably larger than it may seem on a radiograph, as it is covered with radiotranslucent cartilage. If surgery is not performed, loose bodies may finally cause gross arthrosis.[60] Limitation of extension may considerably hinder activities and should therefore be prevented.

In a normal joint in adulthood

The cause of loose body formation in adults is usually traumatic, the injury having chipped off one or more pieces of cartilage. Middle-aged patients who develop a loose body may have multiple cartilaginous fragments in the joint that do not show on radiography; these do not tend to cause arthrosis.

The history is not as typical as it is in young people; the patient does complain of attacks of pain at the elbow, during which exertion increases the pain, but gradual unlocking in the following days does not occur; hence the importance of the clinical examination. Unless these patients are properly examined, they are thought to suffer from tennis elbow.

A very clear non-capsular pattern is found with limitation of either flexion or extension, depending on the position of the fragment. If the loose body lies in the triangle formed by the humeral capitellum, the head of the radius and the base of the coronoid process of the ulna, extension is slightly limited, while flexion remains full and painless. The end-feel on passive extension is soft. When the loose piece of cartilage lies anteriorly, flexion is quite limited, the fragment catching between the anterior aspect of the humerus and the tip of the coronoid process (Fig. 18.5).

A loose body that limits extension can usually be reduced. Manipulation under strong traction shifts the loose piece of cartilage to a position at the back of the joint. It then no longer blocks movement, which becomes normal again. The manipulation can be repeated each time derangement occurs. Nothing else should be done, unless recurrence is very frequent, in which case removal during arthroscopy would be a possibility.[61,62]

A loose body that limits flexion cannot be reduced by manipulation, but limitation of flexion, unless gross, is not a major concern. The alternatives in this case are: arthroscopic or surgical removal or nothing, depending on the patient's age, preference and functional disablement.[63] If nothing is done, there is some danger that the loose body will become embedded and be responsible for a permanent limitation of flexion.

Technique: manipulative reduction of a loose body

The patient sits on a couch. The arm is abducted to the horizontal and the elbow bent to a right angle. An assistant grasps

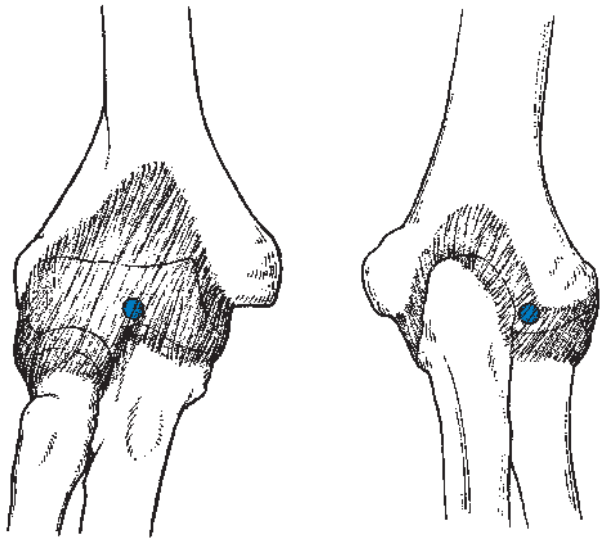

Fig 18.5 • Location of a loose body in a normal joint. Left, loose body in the anterior part of the joint limiting flexion. Right, loose body in the posterior part of the joint limiting extension.

the patient's arm just proximal to the elbow with both hands and fixes the arm against the couch. A second assistant steadies the patient's thorax with a hand on the lower ribs; the other hand holds the shoulder on the affected side against the couch. When assistants are not available, the patient's body and arm can be fixed with straps.

In this manipulation different elements are incorporated: traction, movement from flexion towards extension, and rotation movements, either pronation or supination (Figs 18.6 and 18.7).

The manipulator puts the contralateral foot against that of the first assistant vertically below the patient's elbow. This is the fixed point around which pivoting takes place as the elbow is moved from flexion towards extension. The patient's lower forearm just proximal to the wrist is then grasped with both hands. The position of the hands is slightly different, depending on the chosen rotation (see Fig. 18.6). The use of the manipulator's body weight is then able to exert the traction required to distract the joint. Pivoting on the foot, movement is gradually made from flexion towards extension while the patient's forearm is moved in either pronation or supination through the full range. At the last moment as extension is approached, the manipulator's trunk is side-flexed away from the patient to exert maximal traction. Extension movement is not performed beyond the degree of limitation; if this should happen, it would, of course, result in traumatic arthritis of the joint.

After each attempt, extension is re-examined. The chosen rotation is continued for as long as the signs improve. When no further improvement is found, the alternative rotation can be tried. Treatment should be stopped when the end-feel has become normal – i.e. hard.

One does not expect to reach a painless range of movement during the manipulation session but the change in end-feel

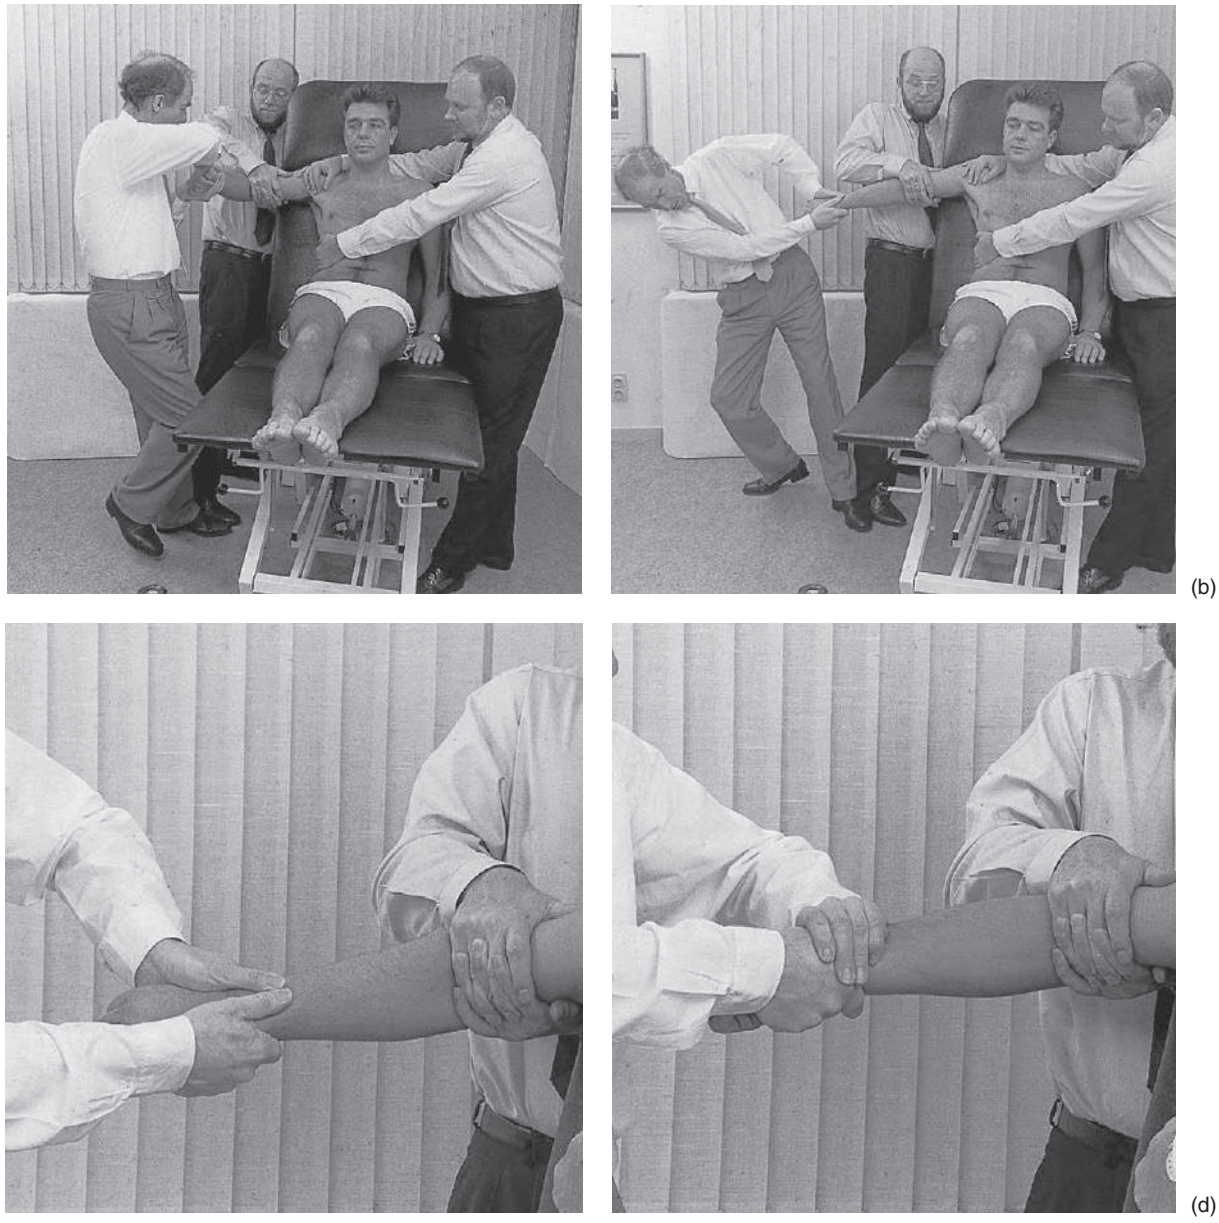

Fig 18.6 • Manipulative reduction of a loose body. (a) Starting position; (b) end position using the pronation technique (easiest and most commonly used). (c) Detail of hand position for this technique. (d) Detail of hand position for the supination technique (more difficult and less often necessary). This technique is not shown in a general view. Use straps to hold the patient when assistants are not available.

indicates that the loose fragment has moved. The slight traumatic reaction consequent on the original subluxation of the loose body will subside in the days following. The patient is seen after a couple of days and, if necessary, the manipulation is repeated.

In an arthrotic joint in middle or old age

Again the history is very indicative. The patient is middle-aged or elderly and possibly mentions a slight aching in the elbow as the result of the arthrosis. In addition, attacks of pain are reported that last about a week. The symptoms come on gradually (over the course of a few hours) and disappear even more gradually (over the course of some days).

Between attacks, the elbow presents a capsular pattern with a hard end-feel at the end of the achievable range, the result of the arthrosis. During the attacks the limitation becomes of the non-capsular type; it has a soft end-feel and is particularly restricted.

The fragments are osseous and visible on radiographs. However, it is possible to have loose bodies in the joint without having attacks of internal derangement.

Manipulative treatment can be performed during the attacks, although it is not strictly necessary because the condition subsides spontaneously. It is enough to explain the mechanism to the patient. Alternatively, arthroscopic removal can be considered.[64,65]

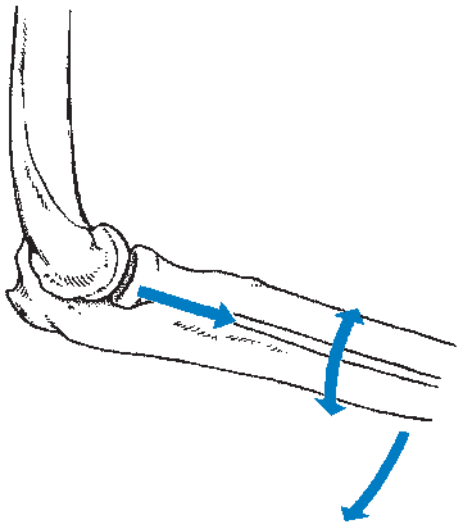

Fig 18.7 • The movements in manipulative reduction of a loose body. The illustration shows the three elements of the technique: traction, movement from flexion towards extension, and rotation.

Limitation of extension in tennis elbow

In some cases of tennis elbow, a slight limitation of passive extension may be found with a softish end-feel. The primary signs of tennis elbow will, of course, suggest the diagnosis (see p. 304).

Acute limitation of supination and extension in children

Radial head subluxation also known as pulled elbow, dislocated elbow or nursemaid's elbow, is one of the most common upper extremity injuries in young children under 8 years of age. The injury usually occurs when forceful longitudinal traction is applied to an extended and pronated arm,[66] as in lifting a child by the forearm or pulling the forearm of a resisting child. This manœuvre is immediately followed by pain and limitation of movement; the elbow is held flexed at about 90° and in pronation – hence the French name, 'la pronation douloureuse'.[67]

A 'pulled elbow' is actually a displacement of the annular ligament between the capitellum of the distal humerus and the radial head. The latter is pulled distally through the annular ligament, which becomes displaced from its normal position covering the radial head, into the radiohumeral joint (Fig. 18.8).[68]

The subsequent disturbance of the lower radioulnar joint is responsible for the limitation of supination. Ultrasonography of the radiohumeral joint shows that the distance between the radial head and the capitellum is increased, probably because of the interposition of the annular ligament into the radiohumeral joint.[69] A radiograph of the wrist shows a distal shift of the radius compared to the ulna, which is restored after manipulation.[70]

Reduction is easy. Sometimes spontaneous reduction occurs just by bringing the forearm into supination and flexion, as in examining for passive flexion of the elbow.[71,72] When this does not happen, manipulation is performed.[73]

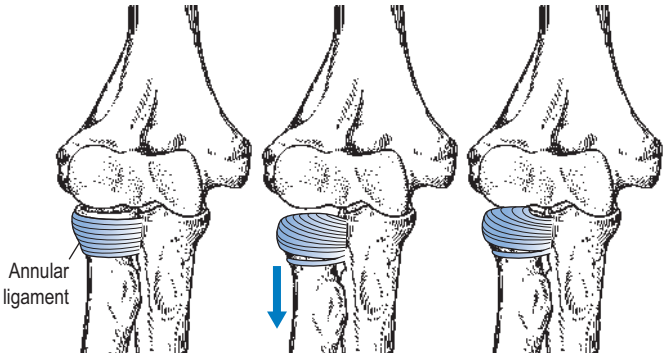

Fig 18.8 • Annular ligament displacement between the capitellum of the humerus and the radial head.

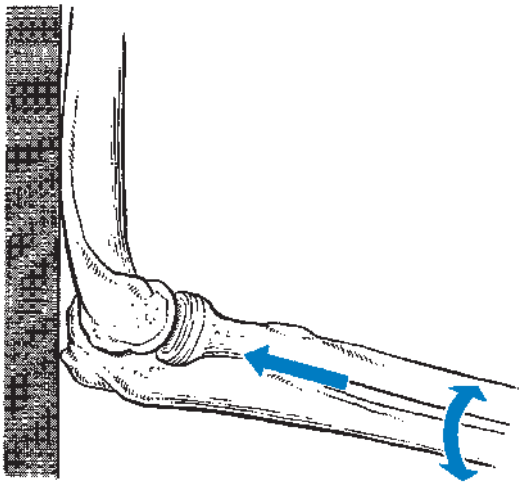

Fig 18.9 • Manipulative reduction of the 'pulled elbow'. This illustration shows the two elements incorporated in the technique: compression and rotation.

Technique: reduction of a 'pulled elbow'

The child is asked to stand against a wall. The upper arm is abducted and the elbow flexed to a right angle. The manipulator grasps the child's lower forearm with the ipsilateral hand and pushes the radius upwards towards the humerus by pressing the elbow against the wall. In the mean time, the forearm is rapidly rotated to and fro to the end of the range in either direction (Fig. 18.9). Suddenly, on full supination, the radial head reduces with a palpable click.

Limitation of pronation

The bicipitoradial bursa is located at the insertion of the distal biceps tendon. In supination it surrounds the biceps tendon. In pronation, the radial tuberosity rotates posteriorly, which compresses the bicipitoradial bursa between the biceps tendon and the radial cortex (Fig. 18.10).[74]

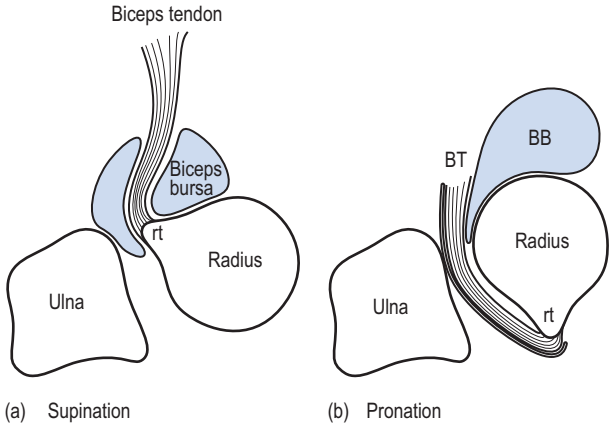

Fig 18.10 • During pronation, the bursa is compressed between the radius and the radial shaft. BB, bicipitoradial bursitis; BT, biceps tendon; rt, radial tuberosity.

When inflamed, the bursa may enlarge and produce symptoms and signs.[75] Classically, patients with cubital bursitis present with a mass in the cubital fossa and pain at the anterior aspect of the elbow,[76,77] together with symptoms and signs resulting from compression of one of the branches of the radial nerve.[78] In our experience, most cases of bicipital bursitis present only with cubital pain and a painful limitation of the pronation with a soft end-feel. The condition can be treated with infiltration of 20 mg of triamcinolone suspension. The same technique is used as for bicipital tendinitis but the infiltration is done somewhat more proximally between the tendon and the bone of the radius (see p. 299).

Full range of movement

Pain on full passive supination

Occasionally the proximal radioulnar joint may become sprained as the result of overuse. As the pain is felt at the outer side of the elbow, the patient may be misdiagnosed as suffering from tennis elbow. On examination, however, full but painful passive supination is the only positive finding. This lesion has no tendency to spontaneous cure.

Treatment consists of one or two intra-articular injections with 20 mg of triamcinolone suspension. The second injection is given 2 weeks after the first. The patient is cured after a few weeks. As this joint lies within the common joint capsule, the same technique as described earlier is used.

Pain on full passive pronation

This sign usually accompanies the primary signs of a bicipital tendinitis (see below) and indicates that the lesion lies at its attachment to the radial tuberosity. In the unusual circumstances in which bicipital tendinitis is absent, pain on passive pronation should be regarded as a bicipitoradial bursitis.[79]

Ligamentous lesions

Ulnar collateral ligament

Partial or total rupture of the ulnar collateral ligament resulting from overhand throwing has been described extensively in athletes.[80–82] Most affected individuals are high-level baseball pitchers, tennis players and javelin throwers. This condition is often complicated by irritation of the ulnar nerve.[83] Usually the lesion results from chronic overuse of the elbow leading to ligamentous insufficiency, even in the absence of a singular catastrophic episode of ligament failure.[84]

Commonly athletes note a history of recurrent elbow pain after or during throwing, without a specific injury.[85] On physical examination there may be a capsular pattern if the lesion is acute. In chronic lesions, the standard clinical examination will be entirely negative and the joint must be tested for valgus instability. For this purpose the moving valgus stress test has been found to be extremely useful, given its high degree of sensitivity and specificity.[86] The patient lies supine with the arm abducted and externally rotated. The elbow is in neutral rotation.[87] The examiner then applies and maintains a constant moderate valgus torque to the fully flexed elbow while gradually extending it. The test is positive if the medial elbow pain is reproduced within the arc between 120 and 70°.[88]

Surgical intervention may be necessary when conservative treatment fails and in a patient who wants to return to highly competitive sports.[89,90]

In young throwing athletes, repetitive high valgus stress and pull by the common flexor tendon may result in subtle stress fracture of the medial epicondyle epiphysis. It manifests with pain at the medial aspect of the elbow and diminished throwing distance and effectiveness. The medial epicondyle is very tender to the touch and a slight capsular pattern may be found. This lesion is called 'medial epicondylar stress lesion' or 'little league elbow'.[91–93]

Radial collateral ligament

A lesion of the radial collateral ligament occurs rarely as the result of repetitive isolated varus stress but mostly after complete elbow dislocation.[94] It may lead to posterolateral rotatory instability, giving rise to symptoms such as clicking, snapping and locking.[63] Tests, such as the lateral pivot shift or posterolateral rotatory drawer test, have been devised for confirming the diagnosis.[95] In recurrent problems, surgical reconstruction or repair seems to give good results.[96]

Bursitis

Olecranon bursitis

Because the bursa is superficial it is very vulnerable. The lesion can be provoked by repetitive direct pressure – for example, leaning the elbow on a table – or by falling heavily on to the bent elbow. It is often associated with occupational or sports trauma, or systemic conditions, such as rheumatoid arthritis, gout, tuberculosis and rheumatic diseases (e.g. chondrocalcinosis, xanthomatosis).[97,98]

The symptom is pain at the posterior aspect of the elbow. The signs depend on the type of bursitis present. In acute cases due to trauma or infection, there is swelling over the olecranon which varies in size from a slight distension to an egg-sized swelling. A variable amount of heat and redness is also found. In more chronic cases, slight swelling is the only sign. The functional examination is usually negative, although full passive flexion may cause some discomfort, described as 'tight'. Palpation reveals tenderness over the tip of the olecranon. In chronic lesions palpable thickening of the bursal wall may be present.

Differential diagnosis must be made between a traumatic bursitis and an infected bursa. Septic bursitis presents with heat and redness of the skin and pain on resisted extension of the elbow.[97,98] Analysis of the bursal fluid obtained through aspiration may be helpful.[99]

Sometimes aspiration alone will not prevent the fluid from reaccumulating because of continued movements of the elbow. Adding non-steroidal anti-inflammatory drugs will then hasten symptomatic improvement. Arthroscopic excision can be used when conservative treatment fails.[100] Septic bursitis should be treated immediately with antibiotic therapy and/or drainage. Sometimes, in the most stubborn cases, surgical excision is necessary.[101]

Weakness on resisted extension of the wrist 313
Resisted flexion of the wrist 313
Pain 313
Weakness 316

Unlike the shoulder, combined lesions of the elbow are quite rare. Therefore positive resisted movements usually indicate a lesion of one contractile structure only.

Resisted flexion of the elbow

Pain

The biceps and brachialis muscles are tested during resisted flexion, which should be performed with the elbow bent at a right angle – the neutral position between flexion and extension and also the one in which elbow flexion strength is maximal[1,2] – and the forearm held in active supination. This is the best position to test the biceps muscle,[3] which is more often strained than the brachialis.

Electromyographic studies confirm decreased activity of the biceps when flexion is performed in pronation.[4–6]

Biceps muscle

If the biceps muscle is at fault, resisted supination will also be painful. There are four possible localizations, indicated by the site of the pain (Fig. 19.1).

Pain at the shoulder

If resisted flexion and resisted supination elicit pain at the shoulder, the lesion should be sought in the upper extent of the long head of biceps, either in the bicipital groove, or higher up in its intra-articular course, or even at its attachment to the glenoid labrum.

Rupture of the long head of biceps is one of the commonest tendinous ruptures. It causes scarcely any symptoms, except the appearance of a round ball of muscle at the lower part of the arm when the patient flexes the elbow. Resisted flexion remains painless and strong, the brachialis muscle still functioning as the strongest flexor of the elbow – only 8% of elbow flexion strength and approximately 21% of forearm supination strength is lost.[7] Treatment is not required.

Pain at the mid-arm

The lesion may lie in the muscle belly itself, usually in the lower half. It is very often the result of a single excessive strain. The patient complains of anterior brachial pain during flexion movements. The symptoms may continue indefinitely, especially in those patients who continue exerting their arm. Even when the patient is prepared to take relative rest, spontaneous cure may require 2 years to occur.

A lesion in the belly of the biceps presents with two particular features: (a) it usually lies at the posterior aspect of the

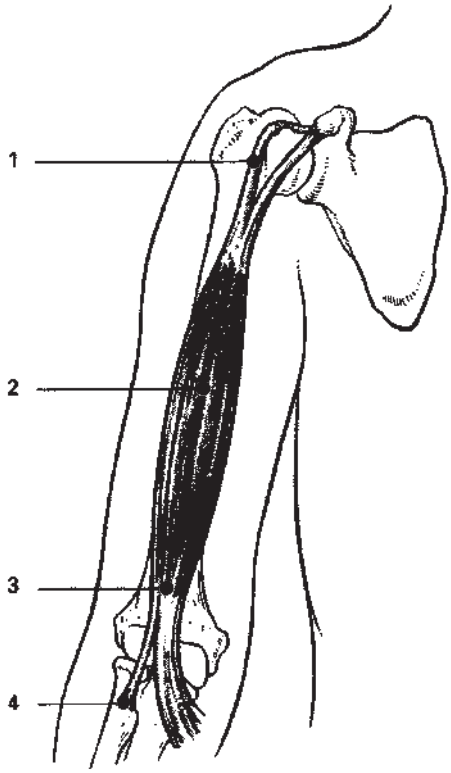

Fig 19.1 • Sites of lesions in the biceps: 1, tendon in bicipital groove; 2, muscle belly; 3, musculotendinous junction; 4, tenoperiosteal insertion.

muscle belly – therefore the tender spot must be palpated with a pinching grip; (b) the site is not always especially tender to the touch – it may therefore be difficult to find the exact localization by palpation. Diagnostic infiltration with a local anaesthetic may then be very helpful and, in cases of recent onset, the infiltration may even prove curative. Even if this is not the case, it shows exactly where the lesion lies so that the therapist knows where to give deep transverse friction, a treatment which is curative in a few weeks, except in very chronic cases – lesions which have lasted for more than 5 years may sometimes prove intractable.

Technique: deep friction to the biceps belly

The patient is in a half-lying position and the forearm rests on the thigh, so that the muscle belly is well relaxed.

The therapist grasps the muscle belly at the point of the lesion with the ipsilateral hand in a pinching grip, holding the fingers well flexed, which enables the posterior aspect of the muscle to be reached (Fig. 19.2). The hand is then pulled anteriorly. This results in a transverse friction to the muscular fibres, which can be felt to pass under the fingers. The hand is then brought back to the starting position without losing contact with the patient's skin. The manœuvre thus has two phases: an active phase, when the hand is pulled anteriorly, and a passive phase, when the hand is brought backwards again.

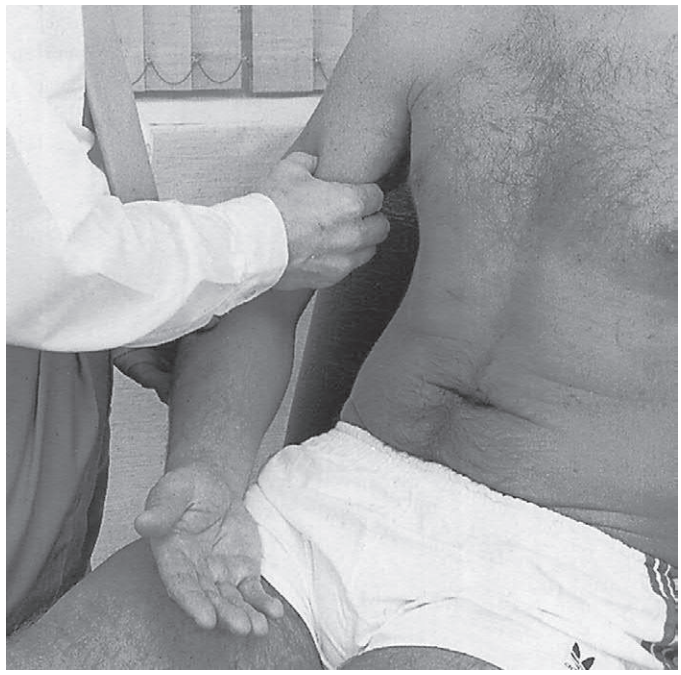

Fig 19.2 • Deep friction to the biceps muscle belly.

Pain at the lower arm

Palpation with a pinching grip shows the lesion to lie at the musculotendinous junction but again it is only possible to be sure of this after diagnostic infiltration with a local anaesthetic. Tendinitis at the body of the lower tendon of the brachial biceps does not occur.

Deep transverse friction is, in our experience, the only treatment. Without proper treatment the lesion may cause pain indefinitely, having occurred at a point where the natural mobility of muscle is restricted by the presence of tendinous strands.

Technique

The same technique is used as described earlier. The position of the hand and fingers, as well as the amplitude of the movement, are adapted to the volume of the structure at the musculotendinous junction.

Pain at the elbow

When pain is felt at the anterior aspect of the elbow, probably with some radiation down the front of the forearm as far as the wrist, a lesion at the tenoperiosteal insertion to the radial tuberosity should be suspected.

Apart from the usual signs on examination, a localizing sign is present – pain at full passive pronation. This is the result of the bicipital insertion being pinched between the radial tuberosity and the shaft of the ulna as the radius turns over the ulna during pronation.[8] Palpation is not necessary and would even be negative, as tenderness cannot be elicited by probing with a finger.

The treatment of choice is infiltration with triamcinolone. Because it is difficult to infiltrate the entire lesion accurately in the absence of localizing tenderness, up to three infiltrations may be necessary.

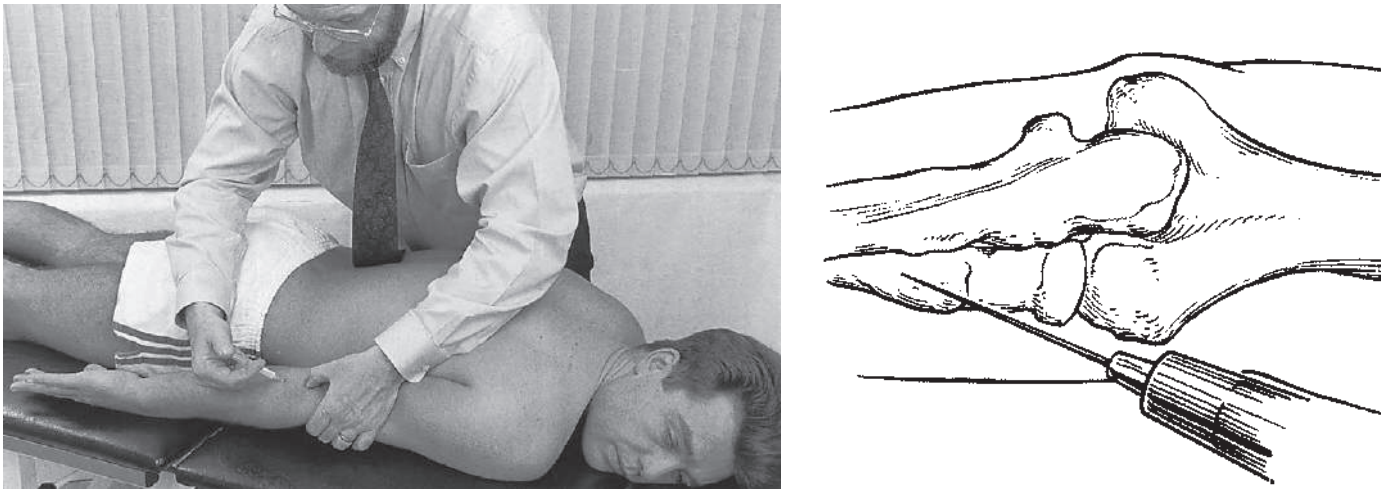

Fig 19.3 • Infiltration of the distal insertion of the biceps.

The alternative treatment is deep transverse friction. Cure takes about 2 weeks, and the treatment is quite painful, in that the lesion lies deeply and is difficult to reach.

Technique: infiltration of the distal insertion of the biceps

The patient lies prone on the couch. The upper arm is passively held in external rotation by the side. The forearm is put in full pronation, which turns the radius so that the radial tuberosity, where the insertion lies, points upwards.

The joint line between humerus and radius is palpated. The posterior edge of the ulna is easily felt. A point is chosen 2–3 cm further distally from the joint line and just laterally to the ulna. A 2 mL syringe is filled with triamcinolone and a thin needle, 2 cm long, is fitted. The needle is inserted at the chosen point and pushed vertically downwards until it hits the shaft of the radius, either directly or through a tendinous structure (Fig. 19.3). In the former case, the needle has to be partly withdrawn and reinserted in a slightly different direction in order to feel the tendinous resistance. Then a series of droplets is infiltrated at the tendinous insertion according to the usual infiltration technique.

The patient should be warned of moderate after-pain and to avoid flexion and supination movements for a week. Follow-up is after 2 weeks and, if the tests are not completely negative, a second infiltration is given. In most cases, one or two infiltrations suffice.

Fig 19.4 • Deep friction to the distal insertion of the biceps.

Technique: friction to the distal insertion of the biceps

The patient sits on the couch with the elbow bent at a right angle and supinated. The therapist sits and with the contralateral hand palpates for the radial tuberosity, searching the radiohumeral joint line and descending 2 cm along the shaft of the radius. At that level the thumb is moved anteriorly to identify the tuberosity deeply under the muscles of the forearm. The thumb is held well flexed and placed medially to the biceps tendon. The fingers apply counterpressure at the dorsal aspect of the elbow.

The ipsilateral hand, which grasps the patient's forearm about the wrist, is used to perform a pronation movement. The forearm is pronated until the biceps tendon passes under the therapist's thumb. The tendon now lies medial to it. Friction is thus performed by this indirect movement. During this part of the movement, the pressure on the tendon is augmented (active phase). The forearm is then brought back to the supinated position, while the pressure is released (passive phase). These repeated movements result in a transverse friction (Fig. 19.4), which is continued for 15 minutes.

The therapist must make sure that neither the median nerve nor the brachial or radial arteries are compressed during the manœuvres.

Brachialis muscle

Resisted flexion of the elbow is painful, certainly with the forearm in pronation, the position in which the biceps does not work. Resisted supination is negative.

Again, the tender area is difficult to find but usually lies in the distal third of the muscle belly, just dorsal to the bicipital tendon. It is therefore not impossible for passive flexion to hurt too because this pinches the injured part of the muscle. Diagnostic infiltration may prove necessary.

Treatment consists of 2 or 3 weeks' deep transverse friction.

Technique: deep friction

The same technique is used as for the brachial biceps muscle. The distal part of the brachialis muscle can be palpated just dorsally to the bicipital tendon. The muscle is well relaxed and friction performed with a pinching grip.

During treatment, the therapist should make sure that no nervous (paraesthesia) or arterial (paleness of fingers) symptoms arise, which would indicate that either the ulnar nerve or the brachial artery is being contacted. In such a case, the position of the hand must be altered.

The brachialis muscle and heterotopic ossification

Myositis ossificans is a benign condition, characterized by heterotopic bone formation, which occurs after injury to muscle fibres, connective tissue, blood vessels and underlying periosteum.[9] It occurs most often in males aged between 15 and 30 years and presents with the following triad of symptoms: pain in the affected muscle, a palpable mass and a flexion contracture.[10] The history of severe contusion is helpful in the early evaluation of these patients, before radiographic changes are evident.[11]

When, after an injury, usually fracture,[12] pain in the elbow region increases and the range of movement gradually decreases,[13] this may indicate the development of myositis ossificans. An increasing firm mass in the brachialis muscle is mostly palpable in the middle or distal segment of the arm and becomes visible on the radiograph in the course of a few weeks.[14] A technetium bone scan is clearly positive.[15] When myositis ossificans has fully developed, only a little movement to either side of the right angle is possible and even rotations are markedly limited.

Warning

Osteogenic sarcoma may also present with the formation of a mass invading the muscle.[16] The characteristic radiographic appearance of the sarcoma (presence of periosteal elevation and cortical destruction) provides the diagnosis.

Myositis ossificans does not respond to conservative treatment and may disappear spontaneously over the course of 2 years. Lipscomb *et al*[17] have stated that myositis ossificans in the upper extremity is very likely to resorb completely. If not, surgical excision may be performed, but only when the lesion is completely ossified, because removal of immature bone may cause extensive local recurrence.[18]

Because some authors attribute the occurrence of myositis to previous treatments, massage and mobilization to the brachialis muscle should only be given when there is a full passive range of movement at the elbow joint and radiographic evaluation shows no heterotopic bone formation.

Brachioradialis muscle

We have never encountered a lesion of the brachioradialis muscle but a case has been described by Barbaix.[19] The patient, following exertion, experienced supracondylar pain at the radial aspect of the elbow occurring during activities which included elbow flexion and simultaneous rotations. The pain could be elicited on passive extension, which was slightly limited, and on resisted flexion of the elbow. Accessory examination showed resisted supination with the forearm in full pronation more painful with a flexed elbow than with an extended one. Diagnosis was confirmed with echography and the patient responded well to infiltration with triamcinolone acetonide.

These clinical findings are compatible with an earlier electromyographic study showing electrical activity with flexion, especially with the forearm rotated in pronation.[20]

Weakness

Neurological conditions

Weakness of elbow flexion usually results from a cervical root palsy, either C5 or C6. In palsy of the fifth cervical root, resisted abduction and external rotation of the shoulder are also weak. In sixth cervical root palsy, resisted extension of the wrist is also weak.

Rupture

A distal biceps tendon rupture is usually at the tendinous insertion and sometimes accompanies an avulsion of the radial tuberosity.[21] The lesion is reported increasingly in the current literature.[22–26] The mechanism of injury is most commonly an eccentric load applied to a flexed elbow. On physical examination there may be swelling, haematoma and a 'Popeye' deformity of the upper arm. However, the normal contour of the distal biceps may still appear to be intact if the lacertus fibrosus is not torn.[27] Range of motion is usually full unless there is severe swelling. Strength testing reveals weakness in forearm supination and, to a lesser extent, elbow flexion. The biceps squeeze test and the hook test are two physical examination manœuvres that have been shown to be sensitive and specific in diagnosing distal biceps tendon ruptures. The biceps squeeze test involves compression of the biceps muscle belly, which results in forearm supination if the tendon is intact.[28] In the hook test, with the elbow actively flexed and supinated, an index finger should be able to 'hook' under a cord like structure in the antecubital fossa if the tendon is intact.[29]

The treatment of choice is surgery: anatomic repair of distal biceps tendon rupture provides consistently good results and early anatomic reconstruction can restore strength and endurance to the elbow.[30–32]

Resisted extension of the elbow

Pain

Triceps muscle

Lesions of the triceps muscle are rare. Three possible localizations can be differentiated by palpation (Fig. 19.5): the musculotendinous junction, which is the most common site; the body of the tendon; and the tenoperiosteal junction at the olecranon.

For all the sites, treatment consists of deep transverse friction. The tenoperiosteal junction responds equally to deep transverse friction and infiltration.

Technique: infiltration at the tenoperiosteal junction

The patient lies prone with the arm slightly flexed by the side. A small pillow is placed under the elbow.

A 1 mL syringe is filled with triamcinolone acetonide and a 2 cm needle is fitted. The tip of the olecranon is palpated and the tender point located. The needle is inserted 1 cm proximal to it and directed towards the olecranon (Fig. 19.6). Tendinous resistance should be felt before hitting bone. Infiltration is then carefully performed by several withdrawals and reinsertions of the needle and maintaining bony contact.

Technique: friction to the musculotendinous junction, body of tendon and tenoperiosteal junction

The patient sits next to the couch with the arm rested, the elbow held in 90° flexion. The therapist sits at a right angle to the patient's arm. With the contralateral hand the patient's elbow is grasped, while the other hand stabilizes the patient's forearm. The tender spot in the triceps tendon is palpated and then the index finger, reinforced by the middle finger, is placed at the medial side of the tendon. Counterpressure with the thumb is then applied at the lateral aspect of the proximal part of the forearm (Fig. 19.7). The therapist abducts the arm and then brings it back into the side. This is the active phase and is followed by relaxation while bringing the arm back into abduction. Such repeated movement results in a transverse friction to and fro over the lesion.

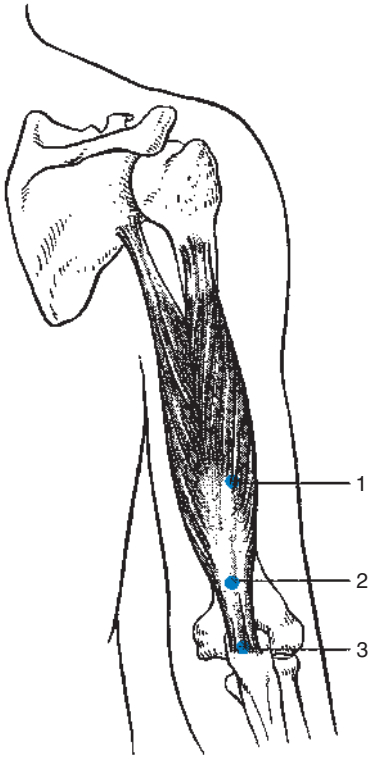

Fig 19.5 • Sites of lesions of the triceps: 1, musculotendinous junction; 2, body of the tendon; 3, tenoperiosteal insertion.

Resisted extension of the elbow and painful arc

Another possibility is that resisted extension of the elbow elicits pain at the shoulder in the C5 distribution. This has the same significance as a painful arc at the shoulder. As a result of contraction of the triceps muscle, the humerus is pulled upwards towards the acromion. A tender structure, lying between the head of the humerus and the roof of the joint, especially an inflamed subacromial bursa, may be painfully squeezed by this movement.

Anconeus compartment syndrome

Abrahamsson *et al*[33] reported a case of lateral elbow pain caused by a chronic compartment syndrome of the anconeus muscle. The symptoms were lateral elbow pain and muscular dysfunction during heavy work. The pain was reproduced by repeated extension of the elbow and pronation of the forearm. There was a slightly bulging mass and pronounced tenderness of the anconeus muscle, which were successfully treated by fasciotomy.

Weakness

Painful weakness

Total or partial rupture of the triceps tendon

This has been reported as a rare injury.[34,35] The most common form is an avulsion from the osseous tendon insertion.[36] Injury

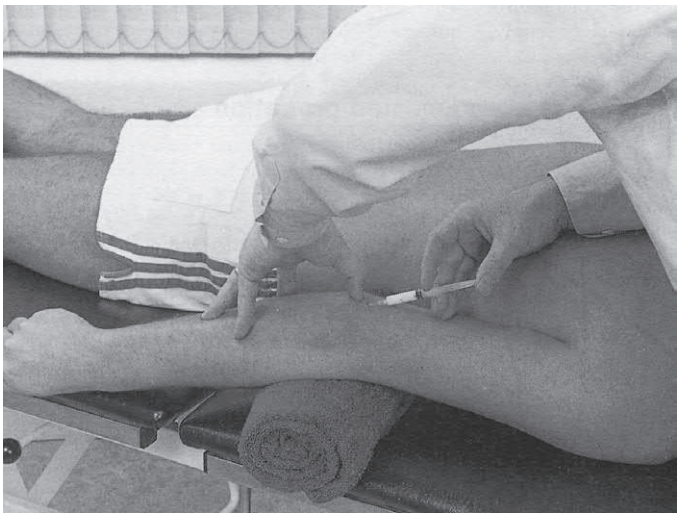

Fig 19.6 • Infiltration at the tenoperiosteal junction of the triceps.

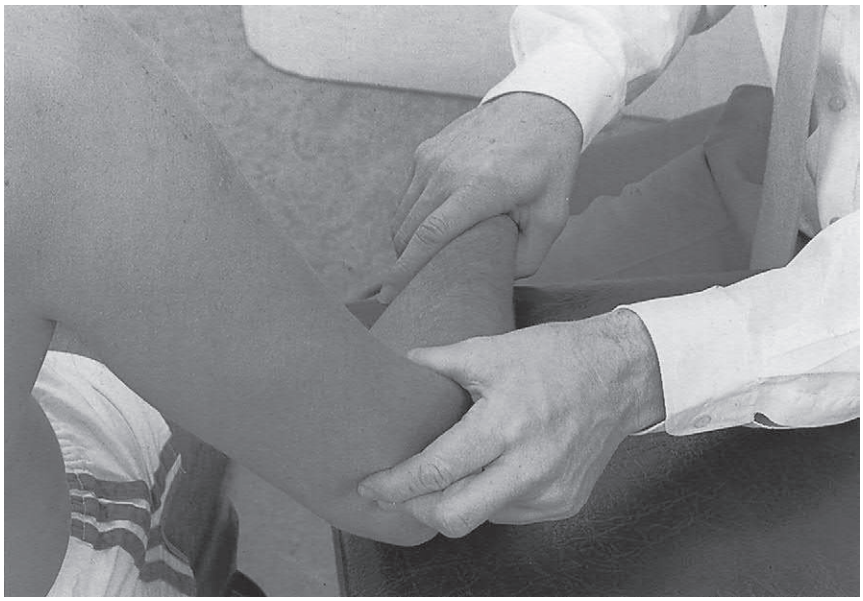

Fig 19.7 • Deep friction to the triceps.

at the musculotendinous junction occurs less often.[37] The most common mechanism of injury is a deceleration stress superimposed on a contracted triceps muscle.[38] A palpable gap, with complete weakness of arm extension, is pathognomonic of triceps rupture. In many cases, however, the palpable defect is not noted initially because of swelling and ecchymosis.[39] Early surgical repair of the injury is the treatment of choice and gives predictably good results.[40,41] Sometimes the same mechanism of injury causes a triceps avulsion fracture. Apart from the same symptoms and signs, the lateral radiograph will show the presence of flecks of avulsed osseous material from the olecranon ('flake sign'), which is almost pathognomonic of this lesion.[42]

Fracture of the olecranon

If the pain is the result of an injury and resisted extension of the elbow is painful and weak, the possibility of a fracture of the olecranon must be considered. Local tenderness and marked articular signs at the elbow joint will also be present: warmth, swelling and limitation of passive movements in the capsular pattern. In most cases, conservative treatment is sufficient.[43]

Painless weakness

A radial palsy and a C7 root palsy are the most common of the other neurological disorders.

Radial palsy

Apart from known traumatic causes, a radial palsy is quite often the result of pressure from a crutch or sleeping with the inner side of the arm pressed against a hard edge ('Saturday-night paralysis'). In this case, resisted extension of the wrist is also very weak and may even result in wrist-drop. The condition is painless and recovers spontaneously over the course of 3–6 months. Some severe cases require neurosurgical repair (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

C7 root palsy

This is the most common cause of a weakness of elbow extension and usually results from a C6 disc protrusion, compressing the C7 nerve root. The history points towards a neck problem, and cervical examination is positive. The triceps muscle may be found to be weak in isolation or in conjunction with weakness of the flexor muscles of the wrist and, in severe cases, the adductors of the shoulder.

Resisted supination

Painful resisted supination usually occurs in conjunction with pain on resisted flexion, in which case the lesion lies in the biceps muscle. If resisted flexion is not positive, the supinator brevis muscle must be at fault. The latter condition is quite rare.

To confirm the diagnosis, the test is repeated with the elbow held actively in full extension – a position which inhibits the function of the biceps. The muscle is not found to be particularly tender and therefore an infiltration with a local anaesthetic should be given (Fig. 19.8). This may effect a cure, but treatment with deep transverse friction (Fig. 19.9) is usually necessary. It is successful in 1 or 2 weeks.

Technique: friction to the supinator brevis

The patient sits beside the couch. The elbow is bent at a right angle, pronated and placed on the couch. The therapist sits at a right angle to the patient's arm and palpates for the shafts of radius and ulna. The tender spot is found in between the two bones. The supinator, being a flat muscle, cannot be felt on palpation, so anatomical knowledge is required to be able to palpate in that region. The therapist then places the thumb on the most tender area and applies counterpressure with the fingers at the medial aspect of the forearm. The friction is performed by an oblique movement perpendicular to the course of the muscular fibres, a movement that starts proximally on the radius and ends more distally on the ulna.

Fig 19.8 • Infiltration of the supinator brevis.

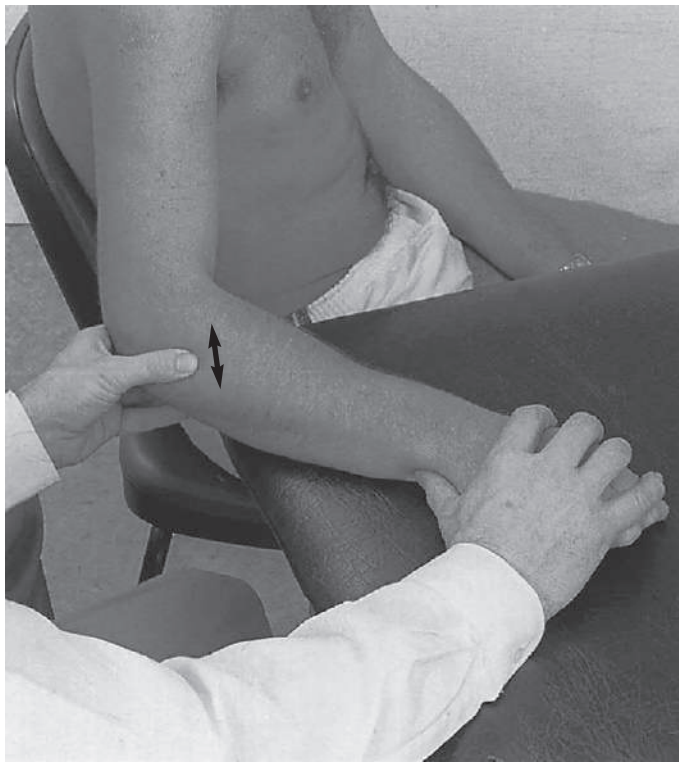

Fig 19.9 • Deep friction to the supinator brevis.

Resisted pronation

Pain on resisted pronation usually indicates golfer's elbow – a lesion in the common flexor tendon – in which case, resisted flexion of the wrist must also be painful. The fact that the pronator teres muscle partly originates from this tendinous complex at the medial epicondyle explains why resisted pronation may be positive (see golfer's elbow).

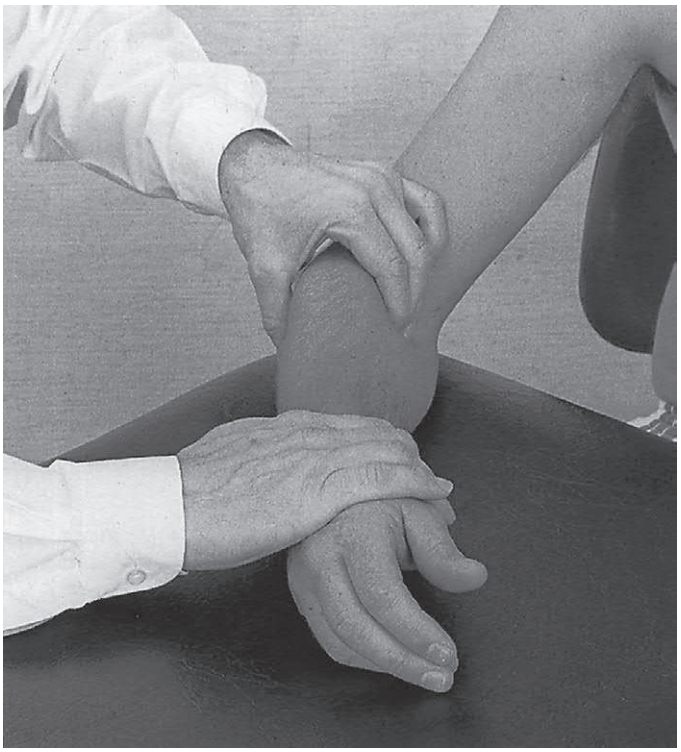

Fig 19.10 • Deep friction to the pronator teres.

Very occasionally, the lesion lies in the pronator teres muscle itself. Palpation discloses tenderness in the muscle belly, usually at its midpoint. In this unusual lesion, treatment consists of a few sessions of deep transverse friction.

Technique: friction to the pronator teres muscle

The patient sits with the arm rested on the couch. The therapist sits at a right angle to the patient's arm. The elbow is held in 90° flexion and the forearm in neutral position between pronation and supination. The therapist palpates at the anterior aspect of the forearm for the muscle belly, which may be facilitated by an active contraction by the patient. The fingertips of two or three fingers of the contralateral hand are then placed on the tender area and counterpressure is applied with the thumb at the lateral aspect of the forearm. The forearm is stabilized with the other hand (Fig. 19.10). The friction movement is begun underneath the muscle and the fingers are pulled over the muscle towards the therapist. This is the active phase. The fingers are then brought back to the previous position (passive phase). The sequence is repeated.

Pain on resisted extension of the wrist

Tennis elbow

The term 'tennis elbow' has been used to describe a multiplicity of conditions of the elbow.

Renton,[44] in 1830, was the first to describe a patient with pain along the outer forearm which increased on using the

hand. In 1873, Runge, a German physician, wrote an article on 'writer's cramp'. He distinguished the condition from a case of 2 years' inability to write, associated with tenderness on the lateral condyle of the humerus. Rest and electrotherapy had no effect and he then cauterized the skin over the tender area, after which the patient became well. He thought the cramp was the result of traumatic inflammation of the periosteum in this location, originally caused by a forcible supination effort and made chronic by the continual pull of the extensor muscles attached to the lateral condyle.[45] Morris (1882)[46] compared a condition named 'lawn-tennis arm' to rider's sprain – a lesion of the adductor longus muscle at the hip – and Major also called the condition 'lawn-tennis elbow'.[47] An annotation in *The Lancet* (1885) drew attention to the number of people suffering from 'tennis elbow', whose plaintive letters had recently appeared in the lay press. From then on, the term 'tennis elbow' has been used to describe symptoms at the outer aspect of the elbow. Remak (1894)[48] and Bernhardt (1896)[49] agreed that it was a periosteal tear from occupational overuse of the extensor muscles that arise from the lateral condyle. Couderé (1896)[50] called it a 'ruptured epicondylar tendon', Féré (1897)[51] 'épicondylalgie', Franke (1910)[52] 'epicondylitis'. In 1921, Schmidt[53] suggested superficial epicondylar bursitis, thereby incriminating the bursa described by Schreger in 1825.[54] In 1922, Osgood[55] and, in 1932, Carp[56] believed the lesion to lie in the radiohumeral bursa, and extra-articular bursa under the extensor tendons, which was first described by Monro in 1788.[57]

In 1936, Cyriax[58] compiled a list of no fewer than 26 different types of lesion to which the name tennis elbow had been given by 91 authors during the previous 63 years. He presented a synopsis of opinion as to the cause of tennis elbow and stated that a condition, the symptoms and signs of which are as constant as those of tennis elbow, may well be supposed to have but one background and, as a corollary, but one type of treatment.

An enormous number of articles on tennis elbow have been published in the ensuing years, describing different pathological entities such as radiohumeral bursitis, radiohumeral synovitis, irritation of the synovial fringe, degeneration of the annular and collateral ligaments, fibrillation of the articular cartilage, osteoarthrosis of the radiohumeral joint, osteochondritis dissecans, aseptic necrosis of the radial head, stenosis of the orbicular ligament, chondromalacia of the radial head and capitellum, calcific tendinitis of the extensor muscles, myofasciitis, traumatic periostitis of the lateral epicondyle, and enthesopathy of the lateral epicondyle of the humerus, among others.[59–68]

A new concept was introduced in 1972 when Roles and Maudsley described the 'radial tunnel syndrome'[69] (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

The most encompassing classification is perhaps that of O'Neill *et al*,[70] who state that 'tennis elbow or lateral epicondylitis consists clinically of pain localized in the region of the lateral aspect of the elbow with tenderness in the vicinity of the lateral epicondyle'. This vague description illustrates how unsure most authors are about the pathogenesis of tennis elbow.

Most authors consider tennis elbow as a local condition in relation to the lateral epicondyle of the humerus. However, some authors have described this condition as resulting from a cervical problem and they claim curative results with treatment to the neck. Gunn *et al*[71] considered a tennis elbow to be caused by a reflex localization of pain from radiculopathy at the cervical spine. Several authors agreed with this point of view.[72–74] Weh[75] believes that the idea of a local clinical assessment of tennis elbow should be broadened to an overall vision of a functional chain consisting of cervical spine, shoulder and elbow, in which local reflex inhibition of muscles innervated by the seventh nerve root and a limitation of movement of the cervical spine are causative elements. It is quite certain that elbow pain may have a cervical origin. This should not be designated 'tennis elbow' but instead 'referred elbow pain' from the cervical spine. If clinical examination shows the elbow pain to be evoked by movements at the elbow, then the lesion must be sought there. In contrast, if cervical examination is positive, this means that cervical movements must be the cause of pain in the elbow region.

We agree with those who consider tennis elbow as a lesion in the radial wrist extensors at the elbow. This is a logical deduction from what is found at clinical examination of the elbow, the primary sign being pain on resisted extension of the wrist.

Tennis elbow is characterized by pain on resisted extension of the wrist.

Terminology

'Tennis elbow' is technically a misnomer, since it most often occurs in non-tennis players: less than 5% of the patients play tennis.[76–78] Even in a population of 500 tennis players complaining of lateral elbow pain, Grachaw and Pelletier found tennis elbow present in only 39.7%.[79] This accords with Krämer's findings.[80] Neither is the term 'epicondylitis' right: at least 10% of the lesions do not lie at the epicondyle itself. Furthermore, the suffix '-itis' indicates an inflammatory process, but histological analysis shows only disruption of the collagen bundles with vascular and fibroblast proliferation and without inflammation. Therefore the term 'tendinosis' should be preferred over 'tendinitis'.[81]

Of all the patients seen in a general medical practice, 0.5% suffer from 'tennis elbow'.[82] The condition is therefore important enough to try to define it properly. The lesion lies at the elbow, in the structures controlling wrist extension and radial deviation (extensores carpi radiales). Theoretically, the lesion could also lie in the ulnar deviators or in the extensors of the fingers but this is much less common and should be separately named: for example, lesion of the extensor carpi ulnaris muscle, lesions of the extensor digitorum muscle.

Pathological features

It is generally believed that tennis elbow is an overuse phenomenon caused by repeated contractions of the radial extensors

of the wrist,[61,83] and especially of the extensor carpi radialis brevis.[84] Post-traumatic causes have also been described.[85] In the early stages, when the tissue attempts repair, and often just as the tear begins to unite, continued muscular contraction pulls the healing surfaces apart once more. This results in the formation of a painful scar with self-perpetuating inflammation (Cyriax[86]: p. 178). Cyriax's view was confirmed by Coonrad and Hooper in 1973.[76]

More recent observations during surgery have led Nirschl to classify this condition mostly under the heading 'tendinosis' rather than tendinitis: surgical inspection shows a typically 'grayish color and homogenous and generally edematous and friable tissue' indicating angiofibroblastic invasion – fibroblasts and vascular granulation-like tissue.[87–89] Inflammatory cells are not usually found.[90]

History

The patient is usually between 30 and 60 years,[91,92] and seldom under 20 or over 70. As the lesion is the result of overuse, the patient does not notice the pain the moment a tennis elbow develops but rather a few days later. A pain is described starting at the outer aspect of the elbow and radiating down the posterior aspect of the forearm, very often as far as the dorsum of the hand. Pain may be felt in the long and ring fingers. It is evoked by grasping, pinching and lifting – the movements that involve extension of the wrist and in which the wrist extensors merely act as stabilizers of the joint.

In a few weeks, the symptoms develop to the point that even light objects are dropped as the result of sudden painful twinges. Patients may be encountered who have constant pain, which may be worst at night and followed by waking in the morning with the elbow feeling stiff.

Functional examination

Nine out of the 10 tests of the elbow are negative and one is positive: resisted extension of the wrist. It should be remembered that the elbow must be held in full extension in order to avoid a false-negative result.

Tennis elbow = 9 tests negative + 1 test (resisted extension of the wrist) positive.

Our experience has shown that, if resisted extension of the wrist causes such a sharp twinge that the patient has to drop the hand, this points to a lesion at the tenoperiosteal junction. Resisted extension of the wrist, with and without the fingers held actively flexed, is then compared. Active flexion of the fingers inhibits the action of the finger extensors. In most instances both versions will be equally positive, which shows the wrist extensors to be at fault. Rarely, resisted extension of the wrist with the fingers held actively flexed will be negative, which implicates the finger extensors. If one or more finger extensors are strained, resisted extension of the different fingers will show which tendon is involved.

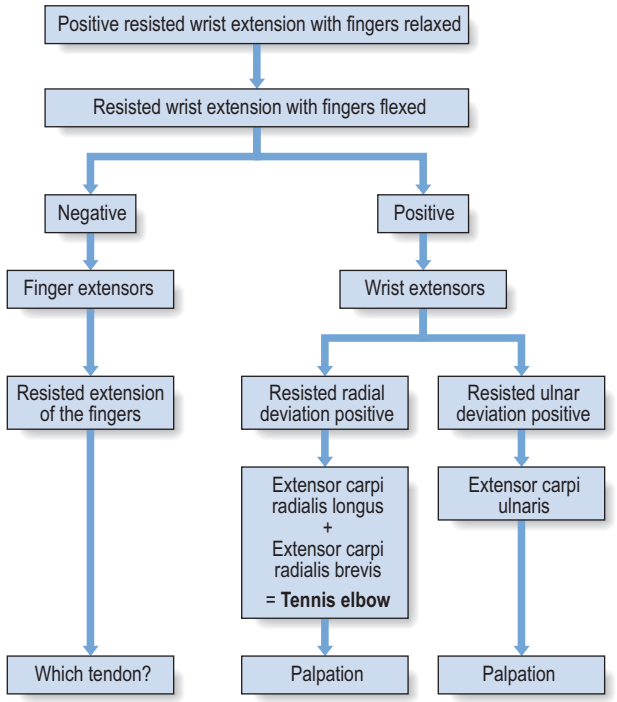

Fig 19.11 • Clinical examination of tennis elbow.

The next approach is to differentiate the radial extensors from the ulnar extensor using two accessory tests. Resisted radial deviation is compared with resisted ulnar deviation, the wrist being held in the neutral position between flexion and extension. In the rare circumstance that resisted ulnar deviation is painful, the lesion lies in the extensor carpi ulnaris muscle. Much more frequently, resisted radial deviation is painful, which indicates a lesion in either the extensor carpi radialis longus or the extensor carpi radialis brevis – the structures involved in tennis elbow (Fig. 19.11).

Palpation

The exact location is revealed by palpation. The palpatory manœuvres must be confined to the structures at fault: the extensor carpi radialis longus and brevis. In that the lateral aspect of the elbow is very often tender to the touch, even in those without a lesion, palpation is sometimes misleading. One elbow should be compared with the other, as should possible locations. In corpulent women, it may be difficult to define the lateral epicondyle. The palpation techniques are identical to the friction techniques (see Treatment, below) although it might sometimes be necessary to put the elbow further into extension to be able to reach the tender spot.

Practice shows that a tennis elbow has four different localizations (Fig. 19.12). Double lesions, however, are not at all uncommon. On palpation from proximal to distal, a tender spot can be found at one of the following places:

- *just proximal to the epicondyle* along the supracondylar ridge at the anterior aspect – i.e. the origin of the extensor carpi radialis longus. This structure feels like a muscular rather than a tendinous tissue (type I).

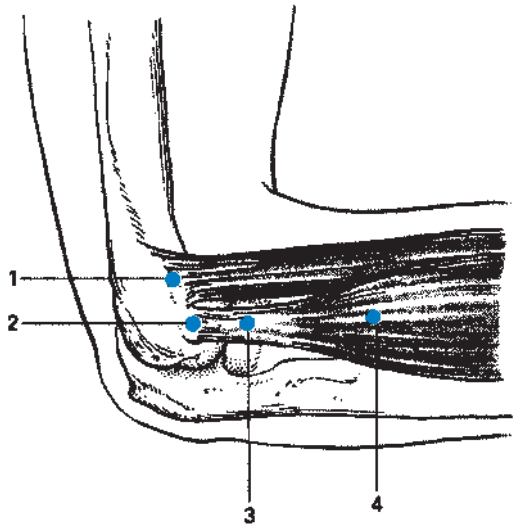

Fig 19.12 • Localizations of tennis elbow: 1, supracondylar (type I); 2, tenoperiosteal (type II); 3, tendinous (type III); 4, muscular (type IV).

- *at the anterior aspect of the lateral epicondyle* – the tenoperiosteal origin of the extensor carpi radialis brevis. In this instance palpation must be precisely at the origin of the tendon itself. Palpation of the lateral or posterior aspect of the epicondyle may also be positive, which is merely 'associated' tenderness. This disappears as soon as the lesion is cured. The tenoperiosteal variety at the epicondyle itself is by far the most common localization of tennis elbow (type II).
- *level with the radiohumeral joint line* and over the head of the radius – the body of the tendon of the extensor carpi radialis brevis, lying in between other tendinous structures (type III).
- *level with the neck of the radius* and a few centimetres distally – the upper part of the muscle bellies of extensor carpi radialis longus and brevis (type IV).

Experience shows that type I occurs in 1% of cases, type II in 90%, type III in 1% and type IV in 8% (Cyriax[86]: p. 178).

Treatment of type I (supracondylar) tennis elbow

Treatment of this type is quite simple. It responds very well to deep transverse friction and should be cured in 3–6 treatments, performed two or three times a week. Infiltrations are futile.

Technique: deep friction

The patient sits with the arm resting on the couch. The elbow is held in 90° flexion and in supination. The therapist sits lateral to the patient and uses the contralateral hand, with the tip of the thumb placed on the anterior aspect of the humerus just proximally to the lateral epicondyle. The thumb is kept well flexed and is held perpendicular to the shaft of the humerus.

The fingers apply counterpressure at the posterior aspect of the arm (Fig. 19.13).

Friction is imparted by an up-and-down movement of the entire hand, resulting in a movement of the thumb parallel to the axis of the humerus. The manœuvre has two phases: an active phase during the downwards movement and a passive phase when the hand is brought upwards again.

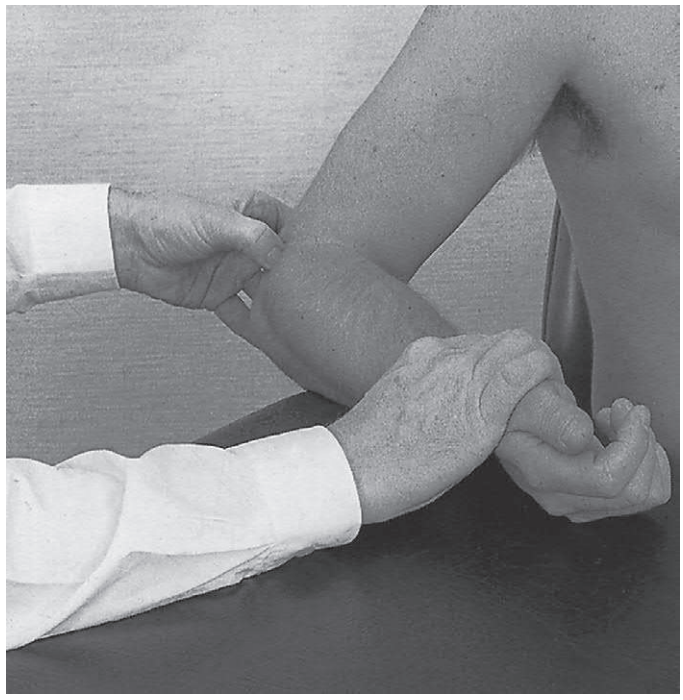

Fig 19.13 • Deep friction in supracondylar tennis elbow.

Treatment of type II (tenoperiosteal) tennis elbow

Treatment of the tenoperiosteal type of tennis elbow varies from very easy to very complicated. The choice of treatment depends on different factors, such as age, activities and duration of the symptoms. As the condition tends to resolve spontaneously, this possibility should be presented to the patient. Active treatment consists of infiltration with triamcinolone and Mills's manipulation. Recurrent or refractory cases may need other approaches, including infiltration with a sclerosant solution, percutaneous tenotomy and partial immobilization – taping and bracing (see Treatment procedures, p. 312).

Natural evolution

The tenoperiosteal variety is the only type of tennis elbow that has a tendency to spontaneous cure[93] (Fig. 19.14); this may take a year in patients under 60 and up to 2 years when the patient is older than this. After full spontaneous recovery, a second attack is rare. However, infiltration of any steroid solution inhibits the mechanism of spontaneous cure. The patient should be told about the possibility of spontaneous recovery, certainly if symptoms have been present for some time. Waiting, meanwhile sparing the elbow as much as possible, may be the preferred option. Cyriax[86] (his p. 179) explains the mechanism of spontaneous recovery as follows: as the result of the many contractions of the extensors of the wrist, which put tension on the healing breach, the gap between the two edges gradually widens. Finally the two surfaces cease to lie in apposition and the tension on the scar ceases. The gap now fills with

fibrous tissue. The painful scar is now embedded and heals with permanent lengthening of some tendinous fibres. In consequence, the strain no longer falls on that part of the tendon. Recurrence is prevented by this structural alteration. Because several muscles are attached here, slight permanent lengthening of the section of tendon relevant to only one muscle does not weaken the power to control the wrist.

Infiltration with triamcinolone suspension

Until 1952 there was no alternative to deep transverse friction in the treatment of tendinous lesions. For many years a means of reducing a localized area of unwanted traumatic inflammation had been sought. In 1952, Cyriax and Troisier[94] suggested the use of steroid infiltration as a treatment for tennis elbow. After the infiltration, the scar remains in place but the inflammation ceases. Because the steroid is a suspension of insoluble particles, its action is confined to the structure which is infiltrated without much effect on or spread to the adjacent structures.

In the following decades, steroid infiltration gained a bad reputation. Some authors therefore advise that the injection be given in such a way that the solution will bathe the underlying tendon rather than being injected into the tendon itself.[95] This technique may easily lead to the development of lipoatrophy and depigmentation of the skin. All these side effects can be avoided by using the smallest possible amount of weak steroid and precise infiltration into the tendon itself.

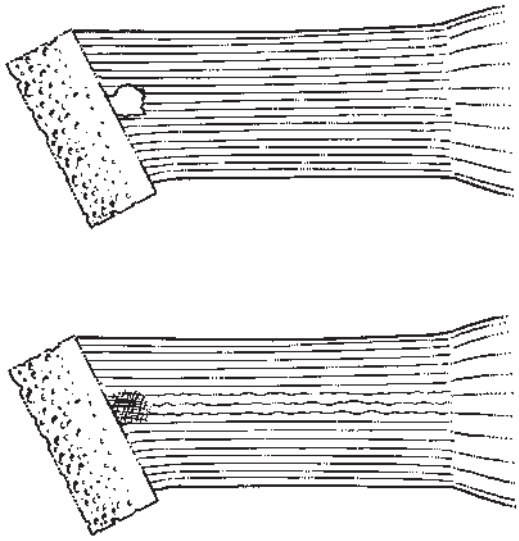

Fig 19.14 • Mechanism of spontaneous cure of tenoperiosteal tennis elbow.

Technique: infiltration

The patient sits with the elbow resting on the couch. The joint is flexed at a right angle and held in full supination. The boundaries of the lesion are now meticulously defined by palpation.

A 1 mL tuberculin syringe is filled with triamcinolone suspension and fitted with a thin needle 2 cm in length. The thumb is placed at the tender spot. The needle is thrust in vertically until it pierces the tendinous insertion and hits bone (Fig. 19.15). As one droplet is infiltrated, the appearance of a tiny bulge is felt for with the palpating thumb, confirming that the correct spot has been found. By half-withdrawing and reinserting the needle at slightly different angles, the entire lesion, which must be envisaged as a three-dimensional object, is infiltrated. Each time a droplet is injected, its exact position should be determined using the thumb. Considerable pressure sometimes has to be exerted on the syringe.

The patient is warned against possible severe discomfort for 24 hours, which may be possible to reduce by the application

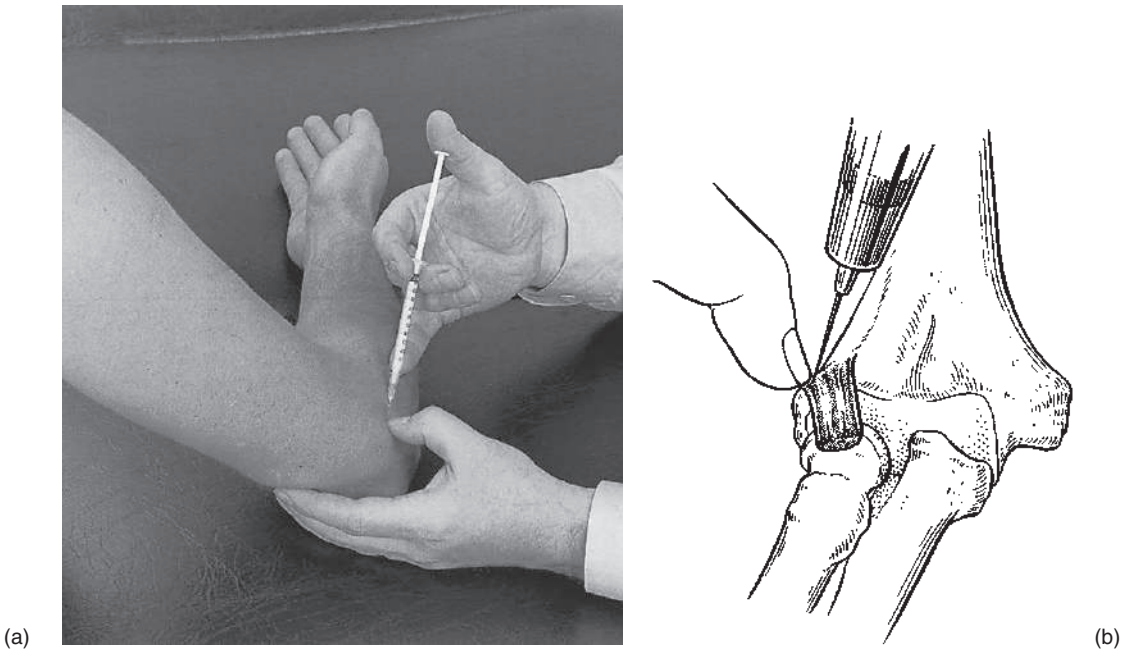

Fig 19.15 • Infiltration in tenoperiosteal tennis elbow. Viewed (a) from behind and (b) from the front.

of ice. Complete rest should be taken for a week and relative rest for another week. Follow-up is after 2 weeks with careful retesting, even if cure appears to have been achieved. If the examination is negative, no more need be done. If the elbow still aches or if the clinical examination is not 100% negative, infiltration should be repeated.

Results

Our personal experience is that 1–3 steroid infiltrations give full relief in all cases of uncomplicated tennis elbow. However, only two-thirds of patients remain asymptomatic. The rest will relapse within 2–6 months. Although renewed infiltrations may be of most benefit, there will remain some refractory cases that are difficult to treat (see p. 310). The prerequisites for success are: accurate diagnosis and localization of the lesion, correct infiltration technique, and a completely negative test on re-examination. A similar success rate was found by Troisier in 1991[96]: in a series of 257 patients, infiltration with corticosteroids gave full relief in all cases but the recurrence rate was 66.7%, although 67% of these recurred only once or twice.

Over the last few decades the effectiveness of steroid infiltration has been investigated via multiple controlled trials. All showed that steroid injections produced quick and significant pain relief in the short term, but that long-term outcomes are less clear. Hay *et al* performed a multicentre pragmatic randomized controlled trial of local corticosteroid injection and naproxen in 164 patients. They came to the conclusion that early local corticosteroid injection is much more effective in the first weeks than treatment with naproxen or placebo, but that the outcome at 1 year was the same in all groups.[97] This confirms the findings of Assendelft *et al*[98] and Verhaar *et al*.[99]

In another randomized clinical trial, Smidt *et al* claimed that the long-term outcomes of steroid injections might be poor due to the high number of relapses.[100] The study by Tonks *et al* was very positive for steroid injections but did not follow up the patients beyond 7 weeks,[101] while Altay *et al* reported that local steroid injection produced excellent pain relief at 1 year.[102] In a prospective randomized study Dogramaci *et al* compared three different methods of injection: a local injection of triamcinolone, a peppering infiltration of local anaesthetic and a peppering infiltration of triamcinolone. The peppering infiltrations with triamcinolone produced superior clinical results with cure in 84% of cases, whereas corticosteroid injection was only effective in 36% and peppering with lidocaine alone gave good results in 48%.[103]

Mills's manipulation

Several authors, such as Cyriax, Mills, Mennell, Stoddard and Kaltenborn, have proposed manipulation as a treatment for tennis elbow.[58,104–108] Although it is based on different pathological premises, they found that manipulative treatment could lead to good results. Manipulation, preceded by deep transverse friction, was Cyriax's treatment of choice before infiltration with steroids was found to be effective in 1952. He intended to stretch the extensor carpi radialis brevis tendon maximally in order to try to pull apart the two surfaces of the painful scar. This would thus imitate and speed up the mechanism of spontaneous recovery (see p. 307).

Several manipulations have been compared and it seems that Mills's manipulation, as described by Cyriax and for the indications which he describes, has the greatest potential to stretch the affected tendon with the least potential for harm to the joint.[109] Mills was an orthopaedic surgeon who described his manipulation technique in 1928 with the intention of re-aligning a torn section of the annular ligament, which he regarded as out of place.[104] Cyriax later discontinued the use of his own initial manipulation method and advocated the use of his modification of Mills's manœuvre.

The manipulation is preceded by deep transverse friction because of its desensitizing and softening effect, which makes the actual manœuvre less painful and therefore more tolerable. Friction alone is ineffective. This second type of tennis elbow is the only tenoperiosteal tear in the body that is not treated by deep transverse friction alone, and the only one for which manipulation has any effect. Some authors claim good results with stretching of the wrist extensors as home exercise following the treatment.[110]

Contraindication

Mills's manipulation should not be performed when extension of the elbow is limited, either as the result of an existing capsular pattern (arthritis or arthrosis) or as the result of a limitation of extension in a non-capsular pattern (loose body disorder), because of the danger of provoking a traumatic arthritis. If the extension seems limited but is so because of pain alone, a careful manipulation may be tried and, if this does not set off an irritation or reaction of the joint, there is no danger in doing this at each treatment session.

Technique: preparative deep friction

The patient sits with the elbow flexed to 90° and in full supination. The therapist sits facing the patient's arm and grasps the elbow with the contralateral hand. The fingers apply counter-pressure at the medial aspect of the elbow.

The thumb is well flexed and the thumb tip placed on the tender spot at the lateral edge of the epicondyle. The thumb is then brought over the anterior aspect of the epicondyle and imparts friction by moving medially over the bone (Fig. 19.16). The amplitude of the friction is only a few millimetres. Pressure is exerted vertically downwards. The therapist should start gently, because of the painfulness of the condition, and gradually increase the pressure.

After 10–15 minutes' friction the manipulation follows.

Technique: manipulation

The patient sits on a chair and the therapist stands behind. The patient's arm is abducted and also put in internal rotation. The forearm is then fully pronated and the wrist flexed. The patient's hand is grasped with the ipsilateral hand by bringing the thumb between the patient's thumb and index finger, so that the therapist's thumb is on the patient's palm. Consequently the fingers come to lie at the dorsum of the hand. This position enables the therapist to maintain full flexion at the patient's wrist at the moment of manipulation. The contralateral hand is then placed on top of the olecranon (Fig. 19.17). By moving both hands in opposite directions, the elbow is extended and the extensor muscles are thus stretched.

The therapist focuses attention on the patient's hand, which should be forced into full flexion. As the manœuvre proceeds,

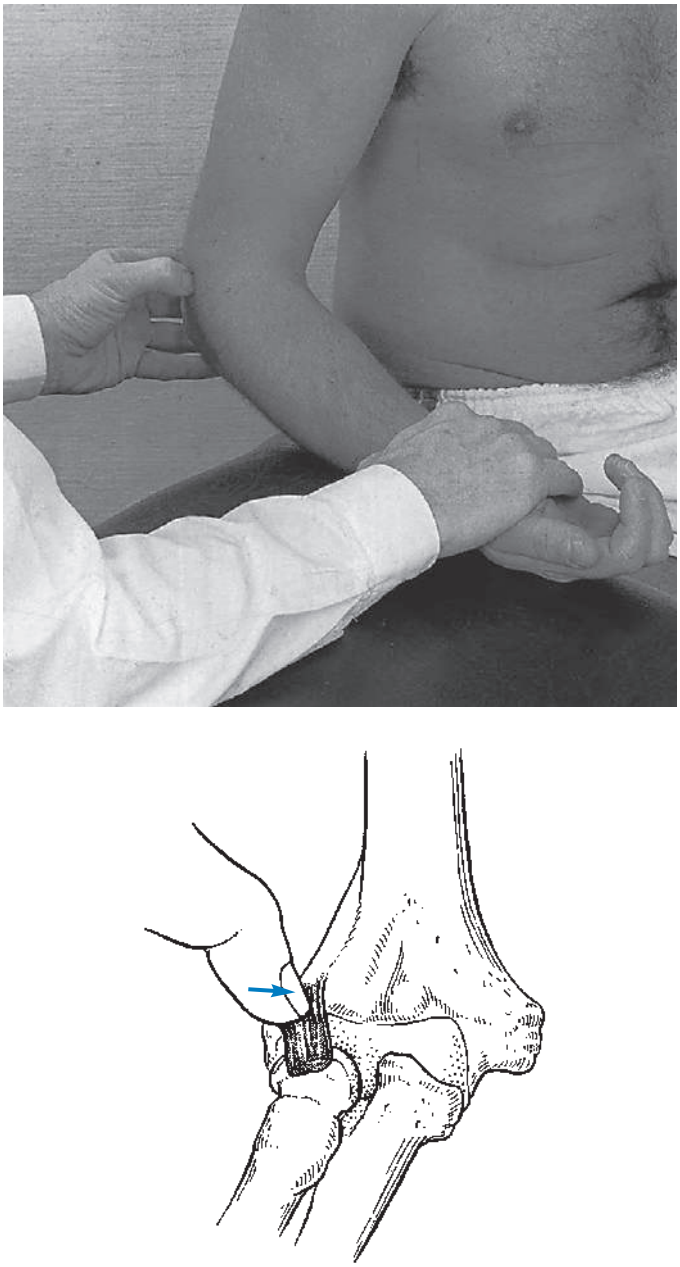

Fig 19.16 • Preparative friction prior to Mills's manipulation.

the body weight is brought to the other leg, so that the body moves away from the elbow. In this position the therapist is able to keep the patient's elbow and wrist in the required position.

A quick thrust towards elbow extension (Fig. 19.18) is then performed by moving both hands in opposite directions. A crack is very often heard, indicating the rupturing of some tendinous fibres. This manipulation is carried out once at each attendance. It usually takes 8–15 sessions for the patient to be cured but some cases require 20–30 treatments and not every tenoperiosteal tennis elbow responds well.

Troisier[96] reported a series of 131 cases in which good and excellent results were achieved in 63% by deep transverse friction and manipulation. A recent randomized clinical trial compared the effectiveness of deep transverse friction massage with Mills's manipulation versus phonophoresis with supervised exercise. Whereas both groups improved significantly from the initiation of treatment, a between-group comparison revealed significantly greater improvements regarding pain, pain-free grip and functional status for the experimental group compared to the control group.[111]

Refractory tennis elbow

The great majority of patients with the commonest variety of tennis elbow can be cured by the two procedures described. If the lesion seems refractory or if it frequently recurs, less usual measures can be used.

Infiltration with a sclerosant solution

The intention is no longer to reduce inflammation of the scar but to provoke the formation of dense adhesive scarring, which engulfs the original scar, using the irritant effect of hypertonic dextrose. The beneficial result may also stem from the powerful destructive effect of phenol on the small unmyelinated pain fibres.[112]

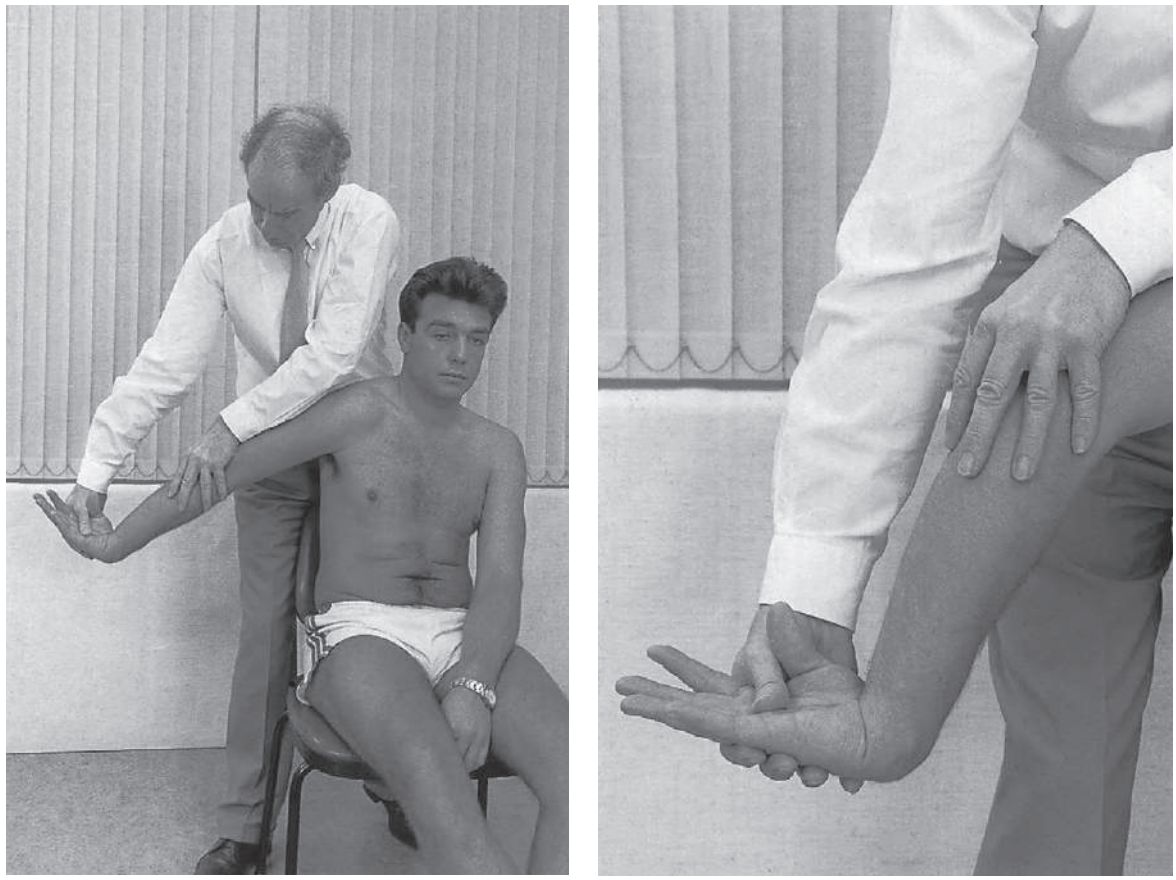
After-pain is considerable and may last several days, after which the condition gradually improves. The effect may only be expected after 2–3 weeks. Symptoms should disappear after one infiltration; if not, a second is unlikely to help.

Recent studies have demonstrated that 1–2 injections with a sclerosant solution effectively decreased elbow pain and improved strength testing in subjects with refractory tennis elbow compared to control injections.[113,114]

Tenotomy

If all other means have been tried without lasting effect, percutaneous tenotomy under local anaesthesia is worth consideration. This is a very simple operation, performed on an ambulant patient. The extensor carpi radialis brevis tendon at the anterior aspect of the lateral epicondyle is divided across its whole width. It is immediately followed by Mills's manipulation to ensure complete separation of the two cut ends. This treatment again imitates the mechanism of spontaneous cure. A study by Daubinet of 18 tennis elbow patients who did not respond to conservative treatment showed the effectiveness of insertion–tenotomy of the extensor carpi radialis brevis.[115] A prospective long-term follow-up study by Verhaar *et al* claims gratifying results and a low rate of complications with lateral extensor release as a simple outpatient procedure. They consider it to be the operation of choice for the treatment of long-standing tennis elbow.[116] Dunkow *et al* conducted a prospective randomized controlled trial of 47 patients with tennis elbow, who underwent either a formal open release or a percutaneous tenotomy. They concluded that the percutaneous procedure is a quicker and simpler procedure to undertake and produces significantly better results.[117] Other authors also claim good to excellent results with percutaneous release of the common extensor origin for long-standing symptoms.[118–122]

If tenotomy fails, one unexpected outcome is that treatment can be started again from the very beginning. The lesion, which hitherto showed no lasting response to infiltration with triamcinolone, may become amenable and will be helped with one or two further infiltrations.



(a) (b)

Fig 19.17 • (a) Mills's manipulation for tenoperiosteal tennis elbow. (b) Detail of hand position.

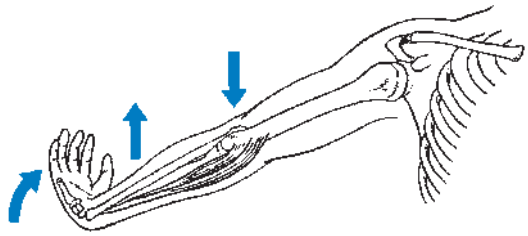


Fig 19.18 • Mills's manipulation for tenoperiosteal tennis elbow.

Technique: tenotomy[123]

The exact spot is palpated. Using the same infiltration technique as for treatment with steroids, the whole tender area is infiltrated with 1 mL of a 2% xylocaine solution. Some of the fluid is reserved to inject subcutaneously in order to render the skin anaesthetic. After a minute, resisted extension of the wrist is retested. If the correct spot has been chosen, this movement should be completely painless.

A small, thin, double-edged tenotome is then thrust through the skin into the dense tendinous tissue in the same way the needle was introduced – vertically. The tenotome is moved further down until it touches bone (Fig. 19.19). By moving the tip of the tenotome up and down along the bone of the epicondyle in a perpendicular way, the tendon of the extensor carpi radialis brevis is divided transversely across its entire width. The small lancet is then removed and the bleeding, if present, stopped by pressure.

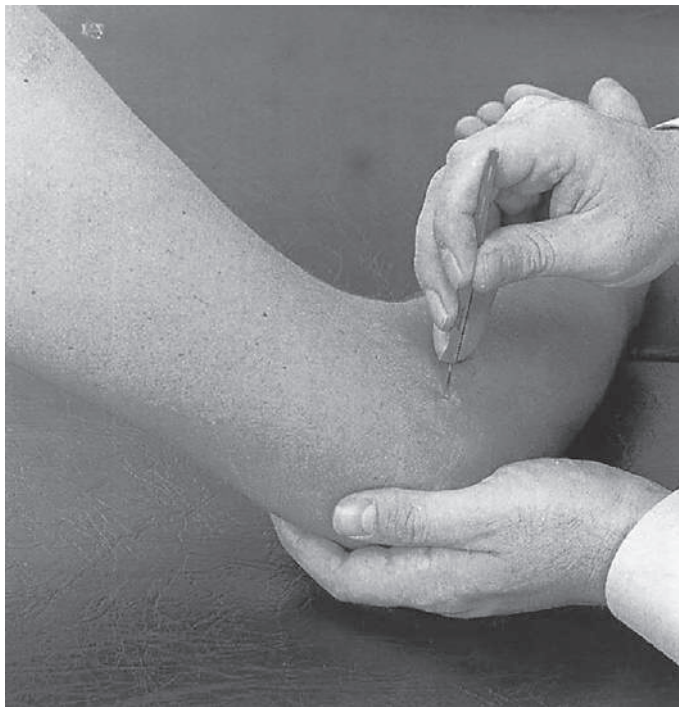
Mills's manipulation is then carried out to ensure complete separation of the two cut ends. No further treatment is needed. Suture is not necessary as the opening in the skin is only a few millimetres long.

The patient should be warned of serious after-pain, which may last for a few days. The elbow should not be exerted for a week and follow-up is after 2 weeks. Most of the traumatic arthritis, which sometimes results after a tenotomy, will have disappeared by then. If this is not the case, an intra-articular injection with 20 mg of triamcinolone acetonide should be given.

If the operation is not successful and resisted extension of the wrist remains painful after, say, a month, a further infiltration with 10 mg of triamcinolone acetonide should be given at the tender spot, which is usually localized at both cut ends.

Extracorporeal shock wave therapy

Attempts are made with extracorporeal shock wave therapy (ESWT) to treat resistant cases. The patient receives 500–3000 shock waves of 0.08–0.12 mJ/mm^2 three times at weekly intervals. Some authors consider this a useful conservative alternative in the treatment of tennis elbow.[124–126] However, more recent randomized clinical studies comparing different



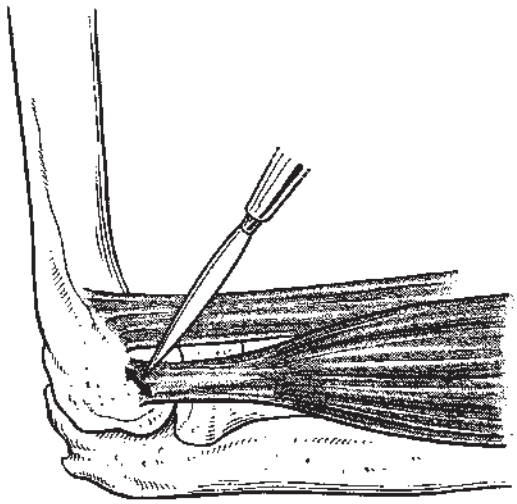


Fig 19.19 • Tenotomy.

extracorporeal shock wave regimens with placebo did not show strong statistical evidence in favour of ESWT.[127–129]

Bracing and taping

Through the years, tape and braces have been used to treat injuries suffered by athletes. In the early stages of the use of external support systems, physicians and certified athletic trainers used mostly trial and error and intuition to provide support for the injured area. Nowadays, interest in this aspect of preventive sports medicine has increased, and sound scientific principles have been used to improve the design and effectiveness of external support systems.[130,131]

At the elbow, a constricting band can be applied to the proximal part of the forearm (Fig. 19.20). It acts as a

Fig 19.20 • Counterforce brace for tennis elbow.

counterforce brace, constraining full muscular expansion and therefore decreasing intrinsic muscular force to the sensitive area in the forearm extensors. The intent is to cause the extensor mechanism on the lateral side of the elbow to work at the point where the band is attached, rather than at its point of origin on the lateral condyle. We consider the use of a counterbrace to be a valuable method for preventing recurrence because it causes improvement in wrist extension and grip strength with positive biomechanical effects.[132–135]

Special circumstances

There are two rare types of lateral elbow pain that are worth considering here.

Tenoperiosteal lesion of the extensor carpi radialis brevis with limitation of movement

This is encountered from time to time. If the limitation is in the capsular pattern, involvement of the capsule is suggested. This possibility will have been confirmed recently by arthroscopic examination.[136] If this is the case, the capsule should be treated first. If the limitation follows a non-capsular pattern, it may be caused either by a loose body limiting mostly extension, or by a cyst. The loose body can be manipulated. A cyst gives rise to a few degrees' limitation of passive extension of the elbow. The end-feel is softish, sometimes even a bit springy. Palpation usually reveals a cystic swelling under the origin of the tendon.

This type of tennis elbow has been shown to be refractory to any of the treatments described above. When a thick needle is thrust in, cystic fluid can be aspirated. Immediately afterwards, passive extension becomes full-range. A triamcinolone solution is now infiltrated, 1 mL at the origin of the tendon and 1 mL at a deeper site where the cyst has been detected. The patient is seen again after 2 weeks and, if necessary, treatment is repeated.

Radial tunnel syndrome

Some authors consider the so-called radial tunnel syndrome to be a type of tennis elbow (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Treatment procedure for type II tennis elbow

There are three therapeutic options for a type II tennis elbow (Fig. 19.21):

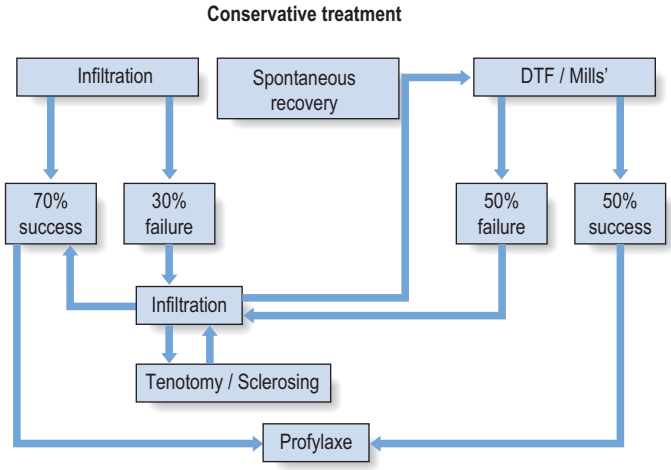

Fig 19.21 • Treatment procedure for type II tennis elbow.

1. *Waiting for spontaneous cure*. Tennis elbow is a self-limiting disorder that is usually spontaneously cured in 1–2 years. Therefore, in a mild case of lateral epicondylitis that is present for several months, it is worthwhile waiting before giving active treatment, and advising the patient to wear a counterbrace during activities.[137]
2. *Treatment with triamcinolone infiltrations*. Immediate relief is always obtained, provided the diagnosis and the applied technique are correct. However, this does not mean that all cured patients with type II tennis elbow remain well. The recurrence rate is high if the procedure (repeated reassessment and treatment), together with good secondary prophylaxis, is not properly followed. With a good infiltration technique and consequent procedure, complete and lasting cure is obtained in more than 70% of cases. If the condition recurs a few months after complete cure, triamcinolone infiltrations can be applied again. If relapses are very frequent, the case must be regarded as refractory and another treatment form should be considered: sclerosing injections or tenotomy.
3. *Mills's manipulation*. This form of treatment has a success rate of about 50%. However, there are no recurrences after complete cure. Mills's manipulation and triamcinolone infiltrations are interchangeable but are never applied at the same time.

Treatment of type III (tendinous) tennis elbow

Deep transverse friction is the better treatment in this case and should be successful in six sessions, performed 2–3 times a week.

Technique: deep friction

The patient sits at the couch with the arm resting on it. The elbow is held in 135° extension and in nearly full pronation by the ipsilateral hand. The tendon of extensor carpi radialis brevis now overlies the head of the radius.

The therapist takes hold of the patient's elbow with the contralateral hand. Counterpressure is applied at the medial aspect of the elbow with the fingers. With the flexed thumb, palpation is carried out at the tender spot. The therapist starts with the thumb at the medial aspect of the tendon and the friction is applied by pulling the thumb towards him, so that it slips over the tendon (Fig. 19.22). The thumb is then relaxed and the same movement started again.

The therapist must make sure that the amplitude of the friction movement is not diminished or stopped by the hand coming in contact with the couch. The patient's forearm is therefore best supported with a cushion, which leaves the elbow free.

Treatment of type IV (muscular) tennis elbow

The treatment of choice is infiltration with 10 mL of a local anaesthetic in the upper part of the belly of the extensor carpi radialis muscles. Two to four weekly infiltrations usually give lasting relief (Fig. 19.23).

Deep transverse friction is an alternative treatment; it is difficult, painful and not always curative. It is performed with a pinching grip (Fig. 19.24).

Technique: infiltration of the extensor carpi radialis muscle belly

The patient sits with the elbow resting on the couch. The elbow is flexed at a right angle and supinated. A 10 mL syringe is filled with 0.5% procaine and a 5 cm, thin needle is fitted. The tender spot is held pinched up by the therapist's thumb and index finger. The needle is inserted obliquely through the belly of the brachioradialis muscle until the point strikes the radius. It is then slightly withdrawn to lie between the fingertips (see Fig. 19.23). The solution is now infiltrated fanwise with different withdrawals and reinsertions so that the entire lesion is covered.

After 5 minutes, resisted extension of the wrist is retested. This movement should no longer hurt; if it does, the lesion was not entirely reached. Infiltration should be repeated at the patient's next appointment and concentrated on the areas that were missed.

The patient must be warned that a temporary weakness of hand extension is possible because infiltration of a local anaesthetic may paralyse the deep branches of the posterior interosseous nerve.

Lesion of the extensor carpi ulnaris muscle

Occasionally, resisted extension and resisted ulnar deviation of the wrist are painful at the outer aspect of the elbow. This indicates a lesion of the extensor carpi ulnaris muscle, usually at its tenoperiosteal origin at the posterior aspect of the lateral epicondyle of the humerus (Fig. 19.25) or, more rarely, at the olecranon. Palpation will, of course, disclose the exact site of the lesion.

Treatment consists of either infiltration with triamcinolone suspension or deep transverse friction.

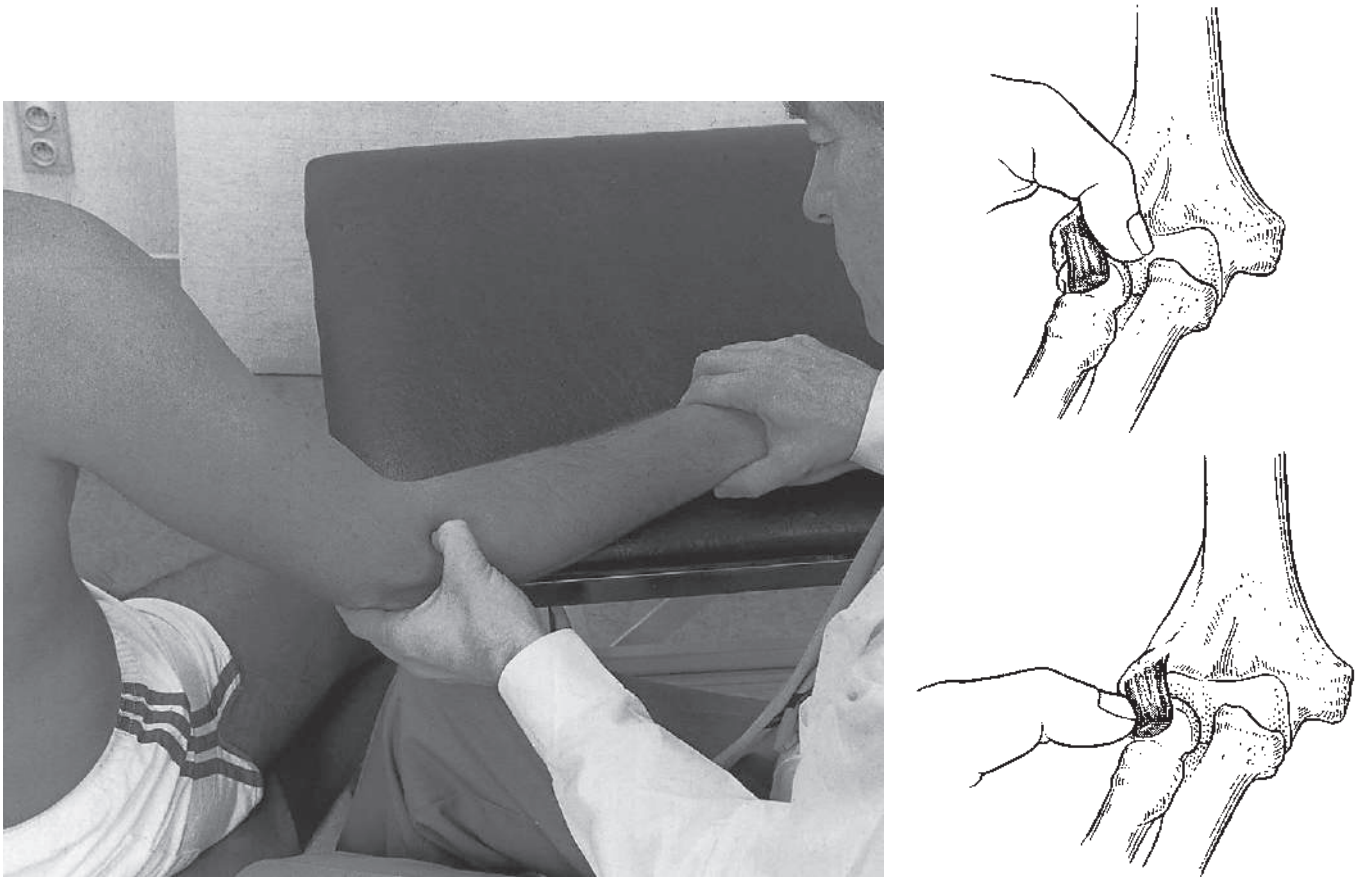

Fig 19.22 • Deep friction in tendinous tennis elbow: (a) starting position; (b) end position.

Lesion of an extensor digitorum muscle

Lesions of the extensors of the fingers do occur but are quite uncommon. The diagnosis is made too often and is probably the result of a misinterpretation of the clinical examination – resisted extension of the fingers, and especially of the middle finger, is often found to be positive in tennis elbow and apparently is a consequence of the close relationship of the extensors of wrist and fingers in the region of the elbow. When a lesion of the extensor digitorum does occur, resisted extension of the wrist with the fingers held actively flexed should be negative.

Treatment consists of either infiltration with triamcinolone (origin) or deep transverse friction.

Weakness on resisted extension of the wrist

Painless weakness of extension of the wrist can be the result of a radial palsy, a C5 disc protrusion compressing the C6 nerve root or, rarely, a C6 disc protrusion compressing the C7 nerve root.

Painful weakness also occurs at the moment that a painful twinge is elicited in type II tennis elbow.

Resisted flexion of the wrist

Pain

Resisted flexion of the wrist (with the elbow held in extension) causing pain at the medial aspect of the elbow indicates a lesion of the common flexor tendon, which originates mainly from the medial epicondyle. The lesion is known as medial epicondylitis or *golfer's elbow*. The disorder is diagnosed 7–10 times less often than lateral epicondylitis.[138] Although golfer's elbow may affect patients from 12 to 80 years of age, it is most commonly seen in the 40–50-year age group.[78] The condition has been attributed to repetitive forearm pronation and wrist flexion.[139,140] As in tennis elbow, it follows a series of repeated (often occupational) strains,[141] rather than a single injury. Histological analysis shows pathological changes in the common flexor tendon: micro-tearing with disruption of the collagen bundles, vascular and fibroblast proliferation, focal hyaline degeneration and an incomplete reparative process. As in tennis elbow, these changes have been called 'angiofibroblastic hyperplasia' and, as there is no evidence of any inflammatory process, the term 'tendinosis' is preferred over 'tendinitis'.[142]

Fig 19.24 • Deep friction to the extensor carpi radialis muscle bellies.

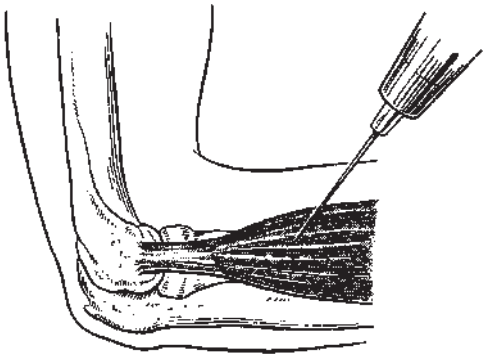

Fig 19.23 • Infiltration of the extensor carpi radialis muscle bellies.

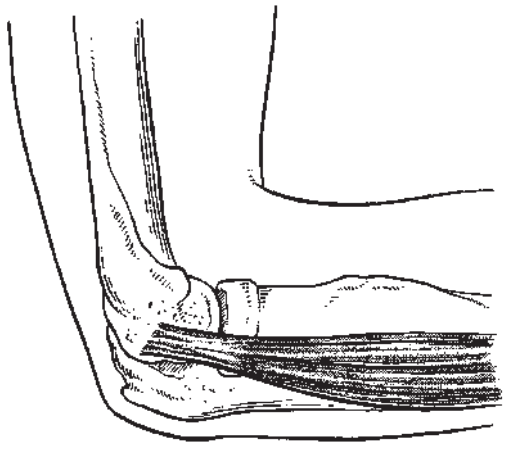

Fig 19.25 • The extensor carpi ulnaris muscle.

The patient, aged between 40 and 60 years, describes pain at the medial aspect of the elbow that may radiate down the upper part of the forearm at the ulnar side. The pain is provoked by palmar flexion of wrist and/or fingers. Resisted pronation of the elbow is often positive as well, because the pronator teres muscle partly originates from the common flexor tendon. Rarely, pain is only evoked by resisted pronation and/or resisted flexion of one or two fingers. This may occur in very localized lesions and depends on which part of common flexor tendon is affected.

Palpation of the medial epicondyle is necessary to find the exact spot, which is usually very localized. There are two possible sites (Fig. 19.26):

- *The tenoperiosteal variety*: the tender spot is found at the anterior aspect of the medial epicondyle of the humerus at the origin of the common flexor tendon.
- *The musculotendinous variety*: the tender spot is 5 mm farther down, level with the inferior edge of the epicondyle. This is the musculotendinous junction (the common tendon diverging immediately below its origin into the muscle belly).

Occasionally, and only in long-standing cases, calcification may be seen on radiography. As this is merely a radiological finding without clinical significance, it may be ignored and does not influence the therapeutic approach.

Treatment

Tenoperiosteal junction

The treatment of choice is one or two infiltrations with 1 mL of triamcinolone suspension (Fig. 19.27). The alternative is deep transverse friction (Fig. 19.28). Very often, 6–12 sessions, 2–3 times a week, are needed. The results of surgical treatment are poor.[143,144]

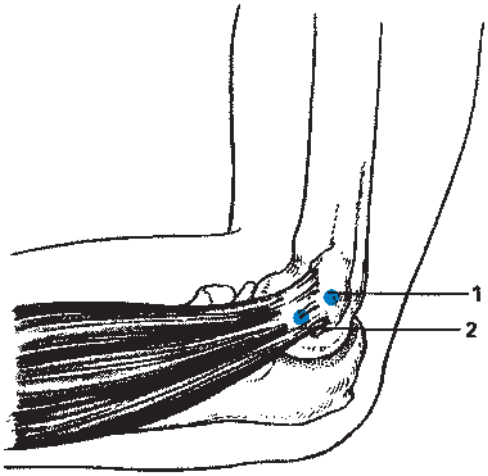

Fig 19.26 • Sites of lesions in the common flexor tendon: 1, tenoperiosteal; 2, musculotendinous.

Technique: infiltration

The patient lies on the couch with the upper arm abducted and externally rotated so that the elbow lies on the lap of the therapist, who sits next to the patient. The elbow is held in almost full extension and in full supination. The tender spot is sought at the anterior aspect of the medial epicondyle. A 1 mL tuberculin syringe is fitted with a fine 2 cm needle. The needle is thrust vertically downwards until the resistance of the tendon is felt and bony contact made. The whole of the affected area is infiltrated by means of a series of withdrawals and reinsertions so as to fill a three-dimensional area. The thumb continuously palpates to make sure that the whole area has been covered.

Technique: deep friction

The patient lies in the same position as for the infiltration, again with the elbow held in full extension and supination by the therapist's ipsilateral arm and hand, of which the thumb palpates for the most prominent point at the medial side. This

Fig 19.27 • Infiltration of the tenoperiosteal junction.

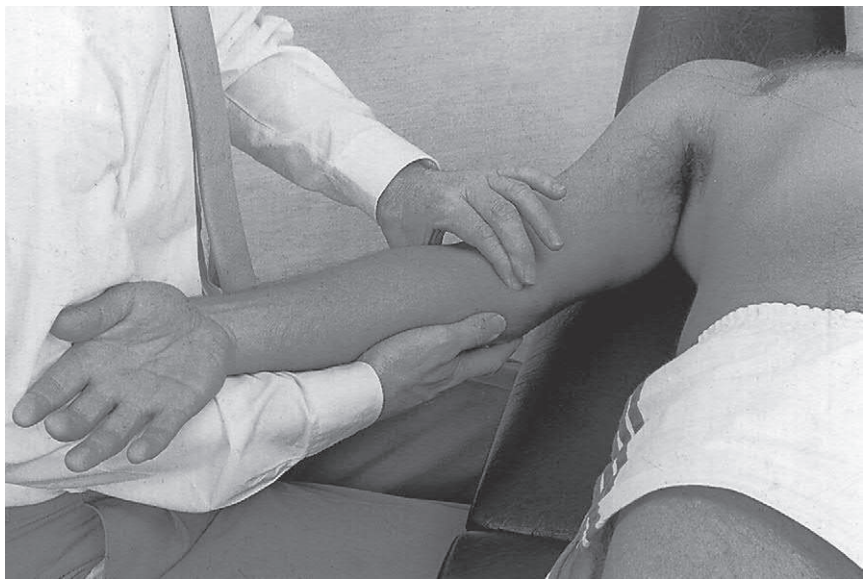

Fig 19.28 • Deep friction to the tenoperiosteal junction.

is the medial epicondyle. At its anterior aspect the origin of the common flexor tendon can be found.

Transverse friction is performed with the index finger of the other hand, reinforced with the middle finger. Counterpressure is applied with the thumb at the lateral aspect of the elbow. Friction is produced by movement of the entire arm, which results in a flexion–extension movement at the wrist.

Musculotendinous junction

Deep transverse friction is performed 2–3 times a week. It is the only successful treatment and usually leads to recovery in 4–8 sessions.

Technique: deep friction

When the tenoperiosteal junction is found on palpation, the finger is then moved 5 mm distally. The ulnar border of the index finger now lies in contact with the distal border of the epicondyle. The structure feels like a soft, muscular and round mass. The index finger now moves to the medial aspect of the muscle and the transverse friction movement is performed by pulling the hand towards the therapist's body.

The elbow may be slightly flexed. This relaxes the musculotendinous junction, which can be penetrated more deeply.

Refractory golfer's elbow

Sclerosant infiltration

Medial epicondylitis that does not respond properly to the usual approach can be infiltrated with sclerosant solution (PDG) in order to create dense scarring which engulfs the original scar so that muscular contraction force is no longer transmitted.

Counterforce brace

A medial counterforce brace can be applied. It helps to diminish the forces acting on the origin of the common flexor tendon.

Weakness

Weakness of flexion of the wrist is usually the result of a C6 disc protrusion, compressing the C7 nerve root, and occurs in combination with weakness of extension of the elbow and occasionally of adduction of the shoulder.

Examination of the fingers . . . 325
Passive movements . . . 325
Resisted movements . . . 325
Palpation . . . 325

Referred pain

When a patient refers to the wrist as the site of symptoms, an area is indicated in which there are many structures that could be responsible. The region that patients call the wrist contains:

- The distal radioulnar joint
- The wrist joint
- The tendons that control the wrist
- The trapezium–first metacarpal joint
- The tendons that control the thumb
- The tendons that control the fingers
- The intrinsic muscles of the hand.

When a patient feels pain proximal to the distal radioulnar joint, this is usually described as being in the forearm. The same applies distally, where pain is described as being in the fingers.

Pain is usually the result of a local lesion, although more proximal causes, such as cervical, shoulder girdle and shoulder disorders, as well as problems at the elbow, may refer pain to the distal part of the upper limb. However, in a lesion in the distal part of the limb, the patient is able to point accurately to the exact site of the lesion and it is only when the clinical examination of the wrist and hand is negative that the lesion should be sought more proximally.

Paraesthesia, being a 'nerve symptom', may result either from lesions higher up in the segment (e. g. cervical spine or thoracic outlet) or from local lesions (e. g. ulnar nerve problem or carpal tunnel syndrome).

History

The history is seldom distinctive and therefore examination must be relied on for diagnosis. However, some questions are important.

- *What is the problem?* The patient describes the symptoms that are experienced in the wrist, thumb, hand or fingers. They are variable and may include pain, paraesthesia, numbness and weakness.
- *How did it start? Was there an injury?* Especially when a capsular pattern is found during the examination, the possibility of a fracture must be considered.
- *Or did it start after particular exertion?* Most ligamentous, muscular or tendinous lesions result from overuse. The symptoms may have started *spontaneously*, as usually happens in arthrotic or arthritic disorders.
- *How has the problem developed?* Because of the distal localization of the lesion, its evolution can only be judged in terms of the intensity of the symptoms, or by their appearance or disappearance, but not by reference of the symptoms.

Inspection

The typical articular deformities of arthrotic or arthritic changes in the joints are well known.

Local swelling may be found. In dorsal subluxation of a carpal bone, the bony projection is visible when the wrist is held in flexion. A cyst on the dorsal aspect may mimic such a subluxation. The same applies to mal-united fractures, where bony outcrops may be visible on inspection. Palpation or disappearance of a fluid collection after puncture will help to reveal the difference.

Another important aspect is generalized swelling. Swelling coming on quite soon after a trauma – for example, a fall – is highly suggestive of fracture of a carpal bone. Spontaneous swelling occurs in rheumatoid arthritis and is quite often bilateral. In long-standing rheumatoid arthritis, multiple large ganglia may also occur.

In arthrosis at the trapezium–first metacarpal joint, the thumb is often visibly fixed in adduction; osteophytes can be seen and felt.

There may be changes in the colour of the hands, which may suggest a circulatory disorder – for example, Raynaud's syndrome, or a cervical rib pressing on the subclavian artery or vein.

Functional examination

Many different structures – inert and contractile – lie close together and have to be examined. It should be clear that by passive testing, which is meant to examine the inert structures, either stretching or pinching may elicit symptoms. In some instances, painful movement of a contractile structure is provoked – for example, of a tendon within its sheath.

The wrist, thumb and hand are examined using 21 tests (Box 20.1).

The distal radioulnar joint

The two movements described below test the integrity of the distal radioulnar joint. Painful supination is also a localizing sign in tendinitis of the extensor carpi ulnaris in the groove at the distal part of the ulna. The normal end-feel of both movements is capsular (elastic).

Passive pronation

The patient holds the elbow in 90° flexion. The examiner grasps the patient's forearm just proximally to the wrist with both hands. The heel of the contralateral hand is placed on the palmar aspect of the ulna, the fingers of the other hand at the dorsal aspect of the radius. Pronation is performed by a simultaneous movement of both hands (Fig. 20.1a).

Box 20.1

Tests for the wrist, thumb and hand

The distal radioulnar joint
- 2 passive movements

The wrist
- 4 passive movements
- 4 resisted movements

The thumb
- 1 passive movement
- 4 resisted movements

The hand
- 6 resisted movements of the fingers

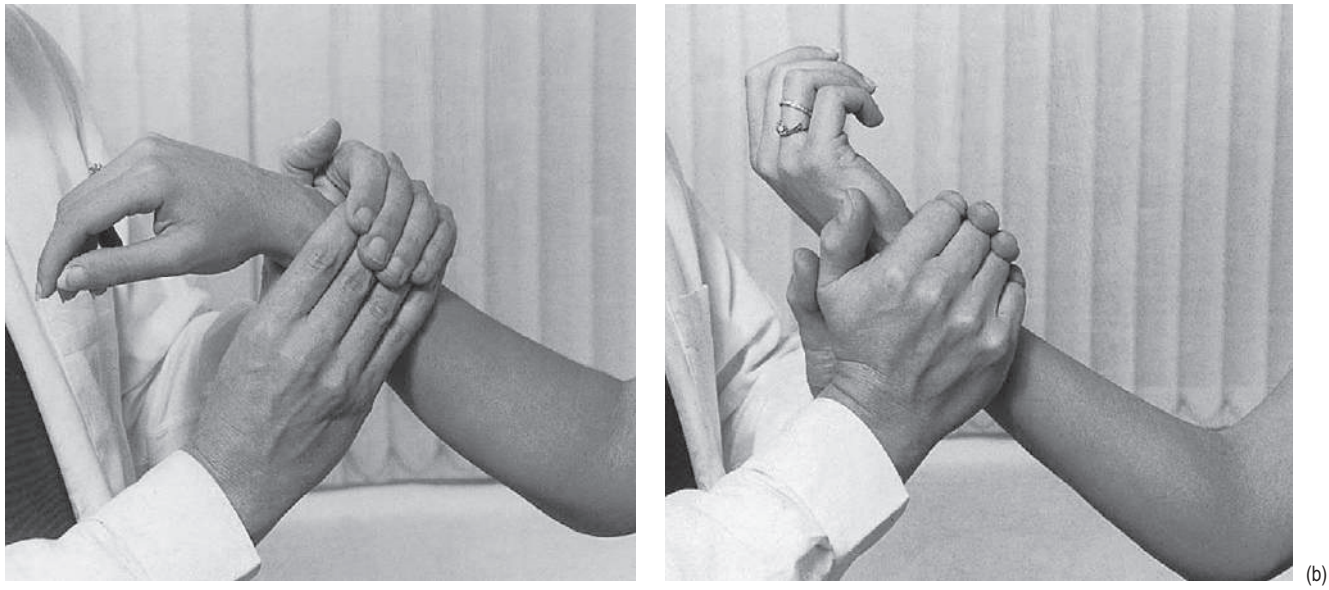

Fig 20.1 • Passive pronation (a) and supination (b).

Passive supination

The examiner changes hand position and puts the fingers of the contralateral hand on to the palmar aspect of the radius and the heel of the other hand on the dorsal aspect of the ulna. Supination is again performed by a movement of both hands (Fig. 20.1b).

The wrist

Passive movements (Fig. 20.2)

The normal end-feel of flexion and extension is capsular (elastic). If these movements are positive, the examiner must be able to tell whether the condition is of the capsular or the non-capsular type (see Ch. 23).

Passive flexion

The patient holds the elbow flexed at a right angle. The examiner takes hold of the patient's forearm with the contralateral hand, in order to achieve good fixation. With the other hand, the patient's hand is grasped and the wrist is flexed to the end of its range. The movement stretches the structures on the dorsal aspect of the wrist (ligaments, tendons) and pinches some structures on the palmar aspect (Fig. 20.2a).

Passive extension

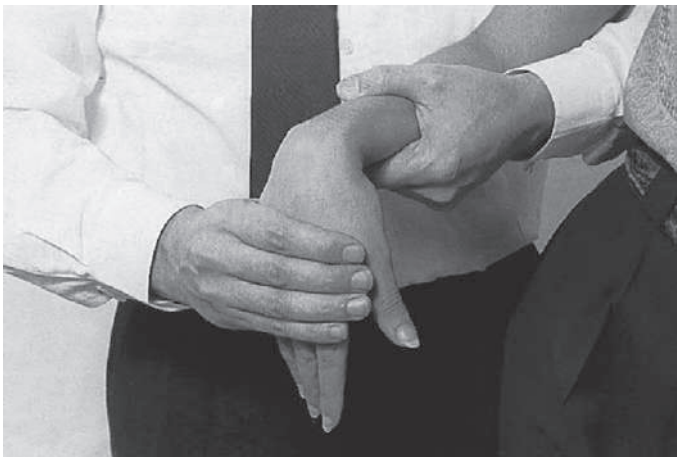
Using the same grip, the examiner can bring the wrist into extension. Extension stretches the palmar tissues and pinches other tissues dorsally (Fig. 20.2b).

Passive radial deviation

The examiner brings the patient's hand into radial deviation, which stretches the structures at the ulnar side of the wrist – the ulnar collateral ligament and the extensor carpi ulnaris (Fig. 20.2c).

Passive ulnar deviation

The examiner brings the patient's hand into ulnar deviation, stretching the structures at the radial side of the wrist – the radial collateral ligament and the tendons in the first tunnel (the extensor pollicis brevis and abductor pollicis longus) (Fig. 20.2d).



(a)

(b)

(c)

(d)

Fig 20.2 • Passive movements of the wrist: (a) flexion; (b) extension; (c) radial deviation; (d) ulnar deviation.

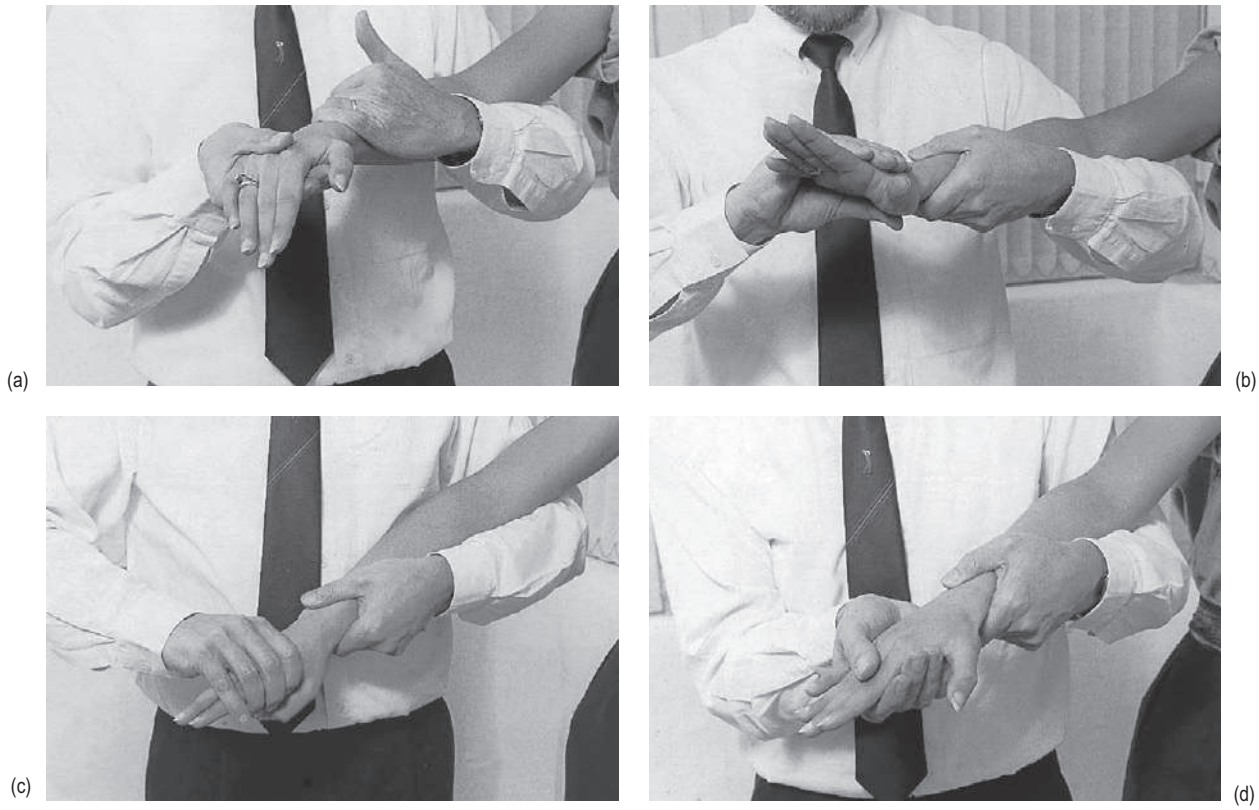


Fig 20.3 • Resisted movements of the wrist: (a) flexion; (b) extension; (c) radial deviation; (d) ulnar deviation.

Resisted movements

For the resisted tests (Fig. 20.3) the patient's elbow is kept in extension. This puts more stress on the contractile structures of the wrist and makes it possible to detect even the slightest tendinous and muscular lesions.

Resisted flexion

The patient's hand is held in the neutral position. The examiner's contralateral arm is passed under the patient's in order to hold the patient's elbow in extension and fixes the forearm with the hand. The other hand is placed under the patient's hand and creates resistance at the palmar aspect.

This test examines the flexors of the wrist and fingers – the flexor carpi radialis, flexor carpi ulnaris, flexor digitorum superficialis and profundus (Fig. 20.3a).

Resisted extension

Fixation of the patient's forearm is as in the previous test. The examiner creates resistance at the dorsal aspect of the patient's hand.

This tests the extensors of the wrist and fingers – the extensor carpi radialis longus, extensor carpi radialis brevis, extensor carpi ulnaris, extensor digitorum communis, extensor indicis proprius and extensor digiti minimi (Fig. 20.3b).

Resisted radial deviation

Resistance is applied at the radial aspect of the patient's hand – the thumb is not involved – and tests the radial deviators of the wrist – the extensor carpi radialis longus and brevis and flexor carpi radialis (Fig. 20.3c).

Resisted ulnar deviation

Resistance to ulnar deviation is applied at the ulnar aspect of the hand and tests the ulnar deviators of the wrist – the extensor carpi ulnaris and flexor carpi ulnaris (Fig. 20.3d).

The thumb

Passive movement

Backwards movement during extension

The patient flexes the elbow to a right angle and presents the hand with the palm upwards. The examiner takes hold of it with the ipsilateral hand and fixes it. With the other hand the thumb is brought into extension. Then the thumb is moved backwards so as to stretch the anterior part of the capsule of the trapezium–first metacarpal joint (Fig. 20.4).

Resisted movements (Fig. 20.5)

Resisted extension

The patient presents the hand with the thumb upwards and it is fixed by the examiner's contralateral hand. Resistance is then applied with the thumb of the other hand at the dorsal aspect of the distal phalanx. Extension tests the extensors of the

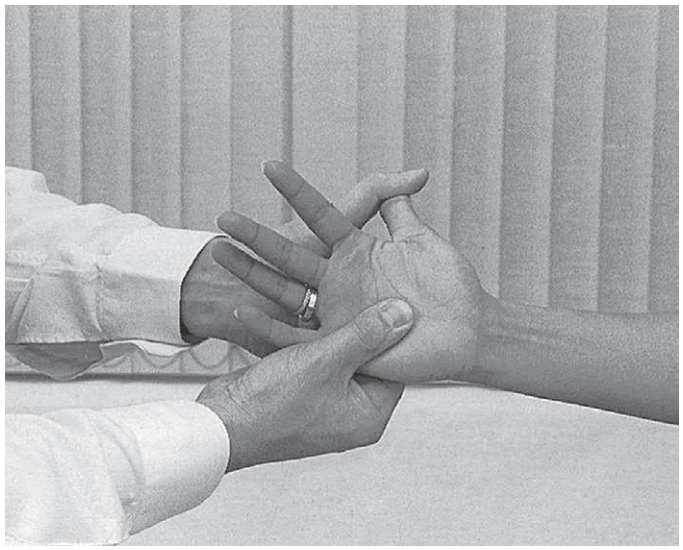

Fig 20.4 • Passive movement of the thumb.

thumb – the extensor pollicis longus and extensor pollicis brevis (Fig. 20.5a).

Resisted flexion

Resistance is applied to the palmar aspect of the distal phalanx of the patient's thumb and tests the flexors of the thumb – the flexor pollicis longus and brevis (Fig. 20.5b).

Resisted abduction

Resistance is applied to the distal part of the first metacarpal bone and tests the abductors of the thumb – the abductor pollicis longus and brevis (Fig. 20.5c).

Resisted adduction

This movement tests the adductor of the thumb – the adductor pollicis (Fig. 20.5d).

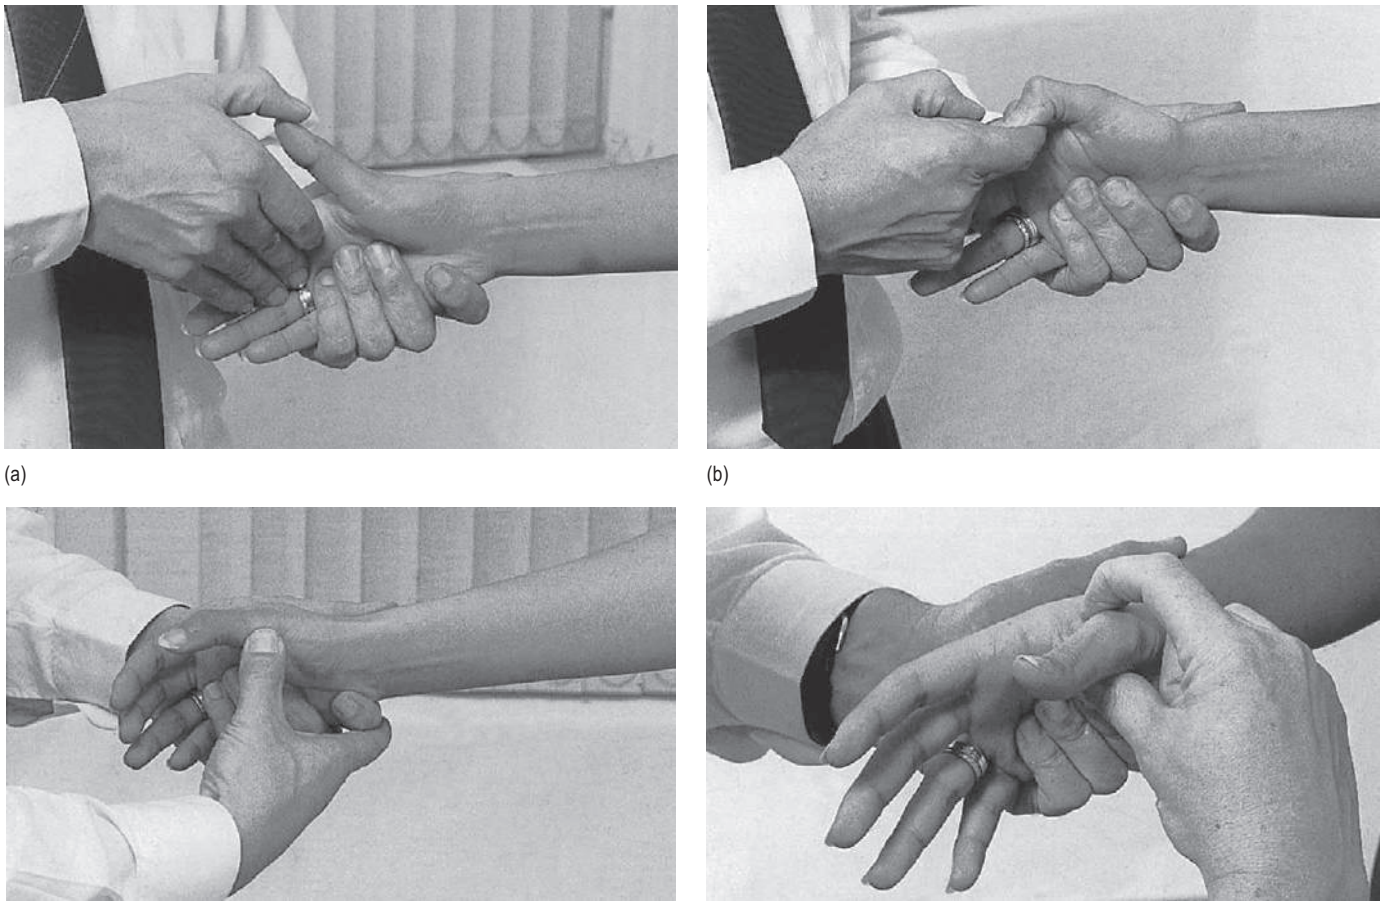

Fig 20.5 • Resisted movements of the thumb: (a) extension; (b) flexion; (c) abduction; (d) adduction.

The intrinsic muscles of the hand: dorsal and palmar interossei

Squeezing with the index and middle fingers

The patient presents the hand in the horizontal position with the dorsal aspect upwards. The examiner puts an index finger between the patient's index (II) and middle (III) fingers and asks the patient to squeeze it, so testing the palmar interosseus of the index finger and the dorsal radial interosseus of the middle finger (Fig. 20.6a).

Squeezing with the middle and ring fingers

The examiner's finger is squeezed between the patient's middle (III) and ring (IV) fingers. The examiner carries out the test as before, with the finger between the patient's middle and ring fingers, so testing the dorsal ulnar interosseus of the middle finger and the palmar interosseus of the ring finger (Fig. 20.6b).

Squeezing with the ring and little fingers

The examiner's finger is squeezed between the patient's ring (IV) and little (V) fingers. The dorsal interosseus of the ring finger and the palmar interosseus of the little finger are tested (Fig. 20.6c).

Resisted separation of the index and middle fingers

The examiner resists the separation of the patient's fingers at the distal phalanges, which tests the dorsal interosseus of the index finger and the dorsal ulnar interosseus of the middle finger (Fig. 20.7a).

Resisted separation of the middle and ring fingers

This assesses the dorsal radial interosseus of the middle finger and the dorsal interosseus of the ring finger (Fig. 20.7b).

Resisted separation of the ring and little fingers

This tests the palmar interosseus of the ring finger and the abductor of the little finger in the hypothenar, abductor digiti minimi (Fig. 20.7c).

Palpation

Palpation with the joints at rest helps to find the exact localization of lesions in ligaments, tendons or muscles. Palpation is also performed for warmth, swelling and synovial thickening.

Palpation during movement may reveal crepitus. Fine creaking during movement of a tendon in its sheath indicates roughening of the gliding surfaces, the result of overuse. This is quite common in the tendons or muscle bellies of the structures that pass through the first and third tunnels: namely, the abductor and extensors of the wrist. Coarser crepitus can indicate tuberculosis or advanced rheumatoid disease.

Accessory tests

These tests (Fig. 20.8) are not part of the standard examination. They are only done when there is a need for more information about the patient's problem.

(a)

(b)

(c)

Fig 20.6 • Squeezing the fingers: (a) II–III; (b) III–IV; (c) IV–V.

Resisted extension of the wrist with the fingers held actively flexed

The patient is asked to flex the fingers and to press the fingertips in the palm of the hand. In this position resisted extension of the wrist is repeated (Fig. 20.8a).

Resisted extension of each finger separately

Resistance is applied at the distal phalanx (Fig. 20.8b).

(a) (b) (c)

Fig 20.7 • Resisted separation of the fingers: (a) II–III; (b) III–IV; (c) IV–V.

Resisted flexion of each finger separately

Resistance is applied at the distal phalanx (Fig. 20.8c).

Tests for carpal tunnel syndrome

These are described in the online chapter *Nerve lesions and entrapment neuropathies of the upper limb*.

The clinical examination of the wrist, thumb and hand is summarized in Box 20.2.

Examination of the fingers

This examination (summarized in Box 20.3) is performed only when the patient clearly presents with a problem in the fingers.

Passive movements

Passive movements are performed at the metacarpophalangeal joints of thumb and fingers, at the interphalangeal joint of the thumb, and at the proximal and distal interphalangeal joints of the fingers. There are four tests for each joint:

- *Flexion*: with one hand the examiner fixes the proximal bone and with the other at the distal bone the joint is brought into flexion.
- *Extension*: with one hand the examiner fixes the proximal bone and with the other at the distal bone the joint is brought back to the starting position. Extension is usually not possible, except in very mobile or hypermobile individuals.
- *Rotation in one direction*: with one hand the examiner fixes the proximal bone. The other takes hold of the distal bone, brings the joint into slight flexion and rotates it in one direction. Very little movement is possible.
- *Rotation in the opposite direction*: the same manœuvre is performed but this time the rotation goes in the opposite direction.

There are two tests for the collateral ligaments:

- *Radial deviation*: the proximal bone is fixed with one hand; with the other the joint is kept in extension and forced into radial deviation, thereby using the distal bone as a lever.
- *Ulnar deviation:* the same technique is used but now the joint is forced into ulnar deviation.

Resisted movements

Resisted movements test the tendinous structures in the fingers – the long flexor and extensor tendons. There are two tests; in both, resistance is applied at the distal phalanx.

- *Flexion*: with one hand the examiner takes hold of the patient's wrist and hand; the other is used to supply resistance against the patient's attempt to flex the finger. Resistance is supplied at the palmar aspect of the distal phalanx.
- *Extension*: the examiner again fixes the patient's wrist and hand. With the other hand at the distal phalanx the patient's attempt to extend the finger is resisted.

Palpation

Palpation can be done at the level of the different joints and seeks to detect:

- *Fluid* which may be found in joint or ligamentous disorders.
- *Synovial thickening* which accompanies rheumatoid-type arthritis. It is best palpated at the level of the collateral ligaments.

Disorders of the contractile structures 331

Disorders of the inert structures

Pain felt at the wrist during pronation and supination movements of the forearm inculpates the distal radioulnar joint. The source can be the joint capsule,[1] the ligaments[2–4] or the articular disc.

Capsular pattern

The capsular pattern of the lower radioulnar joint presents with pain at the end of range of the two movements (pronation and supination, Fig. 22.1) and indicates arthritis. Usually there is only pain at end-range but sometimes there may be equal limitation, or slightly more limitation of supination than of pronation.

Traumatic arthritis

Traumatic arthritis is usually not the result of a single injury but of repeated and excessive pronation/supination movements. There is constant pain, aggravated by movement. Swelling may be seen at the ulnar side of the distal forearm. Treatment consists of one or two intra-articular injections of 10 mg of triamcinolone acetonide.

Arthrosis

When a fracture of the distal part of the radius fails to unite properly, arthrosis at the distal radioulnar joint may follow. Mal-union of the distal part of the ulna does not give rise to persistent problems[5] and painless ulnar styloid non-union is a frequent incidental radiographic finding.[6]

The patient feels discomfort with movement of the joint. On examination, the extremes of both rotations are uncomfortable. The condition may be helped by strapping the distal part of the forearm; if this does not help, intra-articular triamcinolone may be tried.

Monoarticular steroid-sensitive arthritis

Arthritis may develop without a provable cause such as rheumatoid or traumatic arthritis. Furthermore, the condition will worsen when attempts are made to mobilize the joint. Such a condition responds particularly well to intra-articular triamcinolone.[7]

Rheumatoid arthritis

Rheumatoid arthritis (RA) involves the wrist in up to 95% of cases. The distal radioulnar joint is affected in 31–75% of these patients and is frequently the first compartment of the wrist involved,[8] often bilaterally.[9] Triamcinolone suspension injected intra-articularly once or twice a year may keep the joint free from symptoms.[10]

Long-standing rheumatoid arthritis results in ligamentous laxity. At the distal radioulnar joint this leads to the so-called

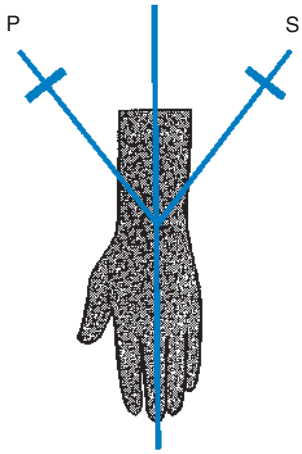

Fig 22.1 • The capsular pattern of the lower radioulnar joint.

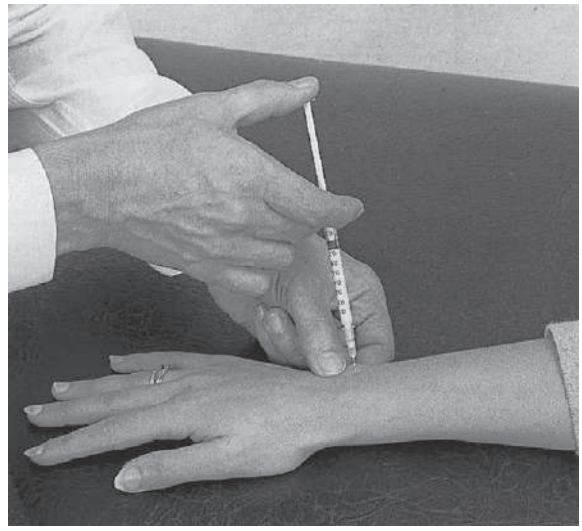
'caput ulnae syndrome': dorsal subluxation of the distal part of the ulna, supination of the carpus on the forearm, and palmar dislocation of the tendon of the extensor carpi ulnaris.[11–14]

Technique: intra-articular injection

The patient sits at the couch with the arm lying in pronation. A 1 mL syringe filled with triamcinolone acetonide and fitted with a 2 cm needle is used. The joint line, which is very short, is identified just radially to the head of the ulna. Gliding movements between the ulna and radius may help to find it. As the extensor digiti minimi tendon lies just dorsal to the joint line, care must be taken to avoid puncturing it (Fig. 22.2).

The needle is inserted vertically downwards at the midpoint of the joint line, about 5 mm proximal to the lower edge of the ulna. It is thrust down and will hit bone at about 1.5 cm. It is then manœuvred in an oblique direction towards the radius, until it slips beyond it without resistance. The injection is then carried out.



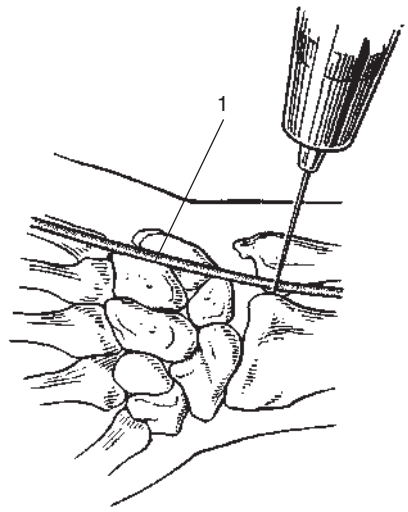


Fig 22.2 • Injection of the radioulnar joint: 1, extensor digiti minimi.

Non-capsular pattern

Limited supination

After a mal-united Colles' fracture, shortening of the radius may be responsible for an irreversible limitation of supination only, with the end-feel of a bony block.[15,16] The movement may be painful in recent cases but should become painless in due course.

A dorsal dislocation of the ulna also presents with a block to supination and a visible dorsoulnar prominence. The mechanism for dorsal subluxation and dislocation is extreme pronation and extension, which pull the ulnar head out through the dorsal capsule. Triangular fibrocartilage complex avulsion and attenuation of the palmar radioulnar ligament will allow this dislocation.[17]

Painful supination

In tenosynovitis of the extensor carpi ulnaris, passive supination may be painful at the end of the range. This is a localizing sign, indicating that the lesion lies in the groove at the base of the ulna. The tenosynovitis will, of course, be diagnosed by interpreting resisted movements at the wrist (see p. 345).

Limited pronation

A block to pronation is present in palmar dislocations of the ulna. On inspection–palpation there will be a volar–ulnar prominence and a palpable radial sigmoid notch.[18]

Disorders of the triangular fibrocartilage complex

During the last few decades it has become obvious that triangular fibrocartilage complex (TFCC) tears are a common source of ulnar-sided wrist pain. The TFCC plays an important role in load bearing across the wrist, as well as in distal radioulnar joint stabilization.

Palmer devised a classification system of TFCC tears in 1989.[19] The main division is between traumatic type I and atraumatic (degenerative) type II tears. The traumatic conditions (type I) follow hyperpronation or axial load-and-distraction injury to the ulnar part of the wrist (e.g. fall on an outstretched extremity[20]) and include perforation and avulsion[21] with or without fracture.[22] Type IA (***A***vascular articular disc) tears are the most common. The other type I tears are peripheral in nature: type IB (***B***ase of the styloid) tears; type IC (**C**arpal detachment) tears; type ID (detachment from the ra***D***ius). The degenerative disorders (type II) result from chronic injuries after repetitive loading on the ulnar side of the wrist.[23] They vary from triangular fibrocartilage wearing to chondromalacia and ligament perforation.[24] Degenerative changes in the TFCC often accompany those in the distal radioulnar joint.[25]

TFCC disorders result in ulnar-sided wrist pain.[26] Uncomplicated cases show a capsular pattern at the radioulnar joint. Complicated cases may present with some subluxation of the joint (limitation of pronation or supination). A provocative test for TFCC lesions, the ulnar grind test, has been described. It involves dorsiflexion of the wrist, axial load, and ulnar deviation or rotation. If this manœuvre reproduces the patient's pain, a TFCC tear should be suspected.[27] Another quick and highly sensitive test to evaluate tears of the TFCC is the 'press test', which axially loads the wrist in ulnar deviation as the patient pushes him- or herself up from a seated position.[28] The best place to palpate the TFCC is between the tendons of the extensor and flexor carpi ulnaris, distal to the styloid and proximal to the pisiform. In this soft spot of the wrist, there are no other structures than the TFCC.[29] Acceptable methods to confirm the clinical diagnosis are magnetic resonance imaging (MRI)[30] and high-resolution ultrasonography.[31]

The treatment depends on type and degree of the lesion. Most symptomatic lesions respond very well to relative rest and one or two intra-articular injections into the distal radioulnar joint. Surgery is the treatment of choice when gross instability occurs. Instability is found when the ligamentous components of the TFCC proper – the dorsal and palmar radioulnar ligaments – are torn.[32] Early surgery is then preferred.[33,34] Chronic disorders of the TFCC, often combined with instability, require arthroscopic[35–37] or open repair,[38] including ulnar shortening.[39,40] The results are good.[41]

Disorders of the contractile structures

Resisted pronation and supination are not tested in the standard functional examination, because they are not relevant at this level. However, resisted pronation can be performed as an accessory test in order to examine the pronator quadratus muscle. This being said, a lesion of this structure has never been described and does not seem to exist. Resisted pronation movement also tests the common flexor tendon (in the case of golfer's elbow) and the pronator teres muscle, but in lesions of these two structures, pain is felt near the elbow (see Ch. 19).

Resisted supination does not test any structure in the wrist region, only those at the elbow – the brachial biceps and supinator brevis.

Lesions at the wrist often have a traumatic cause – either a single injury or overuse – and are localized. Usually the patient can locate the lesion precisely because wrist and hand disorders seldom cause referred pain. If the symptoms appear spontaneously and are diffuse over the entire wrist, arthritis, usually of the rheumatoid type, is very likely. Further data obtained from the history include pain at rest, pins and needles, twinges and functional loss. The interpretation of the functional examination is classic and encompasses inert structures (capsular, non-capsular and ligamentous lesions) and contractile structures.

Disorders of the inert structures

Limited range: capsular pattern

The capsular pattern is an equal degree of limitation of flexion and extension (Fig. 23.1). In advanced arthritis, fixation of the wrist in the neutral position takes place.

Traumatic arthritis

The discovery of a capsular pattern following a trauma should always induce further examination. Uncomplicated traumatic arthritis is rare and the finding of a post-traumatic capsular pattern is highly suggestive of a fracture. The radiographic picture is unreliable because it may take up to several weeks for radiological evidence of a fracture to be conclusive.[1] This delay may be responsible for serious complications because failure to diagnose and immobilize carpal fractures often leads to non-union and avascular necrosis.[2,3] However, the clinical picture is so evident that the diagnosis should not be missed: any case of traumatic arthritis of the wrist lasting for longer than 2 days should be considered as a fracture.

Warning

A capsular pattern lasting for more than 2 days after trauma makes fracture, either of a carpal bone or of the epiphysis of the radius, a strong possibility.

History and examination

The history is that of an injury, varying from a simple thrust to a fall onto the outstretched and dorsiflexed hand. There is

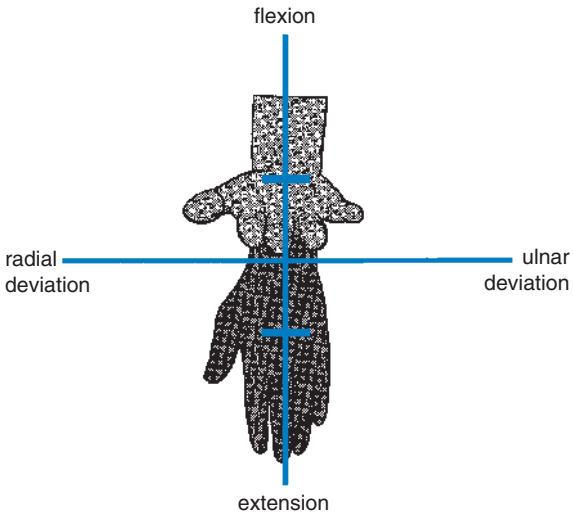

Fig 23.1 • The capsular pattern at the wrist.

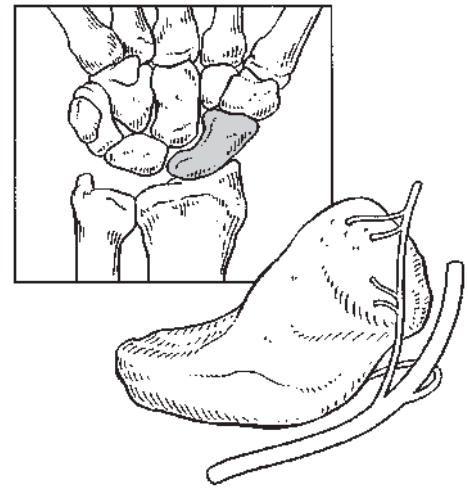

Fig 23.2 • Vascular supply to the scaphoid.

instant and severe pain that prevents hand movement. Initially the pain is localized but spreads over the entire wrist later on.

Inspection shows swelling of the wrist. On examination, a capsular pattern is found: passive flexion and extension are very painful and limited. The end-feel is that of a vibrant twang caused by a protective muscle spasm. Passive deviation of the wrist towards the painful side also increases the pain – a compression phenomenon that provides further evidence of a bony lesion. Careful palpation of the bones reveals localized tenderness. Most often the scaphoid bone is involved.[4] In this case, tenderness will be elicited in the anatomical snuffbox.[5] This is often described as a classic sign of scaphoid fracture and has a reported sensitivity of 90% but a low specificity of 40%.[6] The scaphoid compression test also has a high sensitivity but a better specificity for scaphoid fractures. This test is performed by grasping the thumb and applying an axially directed compressive force along the line of the thumb metacarpal; wrist pain indicates a positive result.[7]

The scaphoid bone spans the joint between the proximal and distal rows of carpal bones and is most vulnerable: scaphoid fracture comprises between 51 and 78% of all carpal fractures.[8–11] Young males and persons between 10 and 19 years of age are at highest risk for scaphoid fracture.[12–14]

Scaphoid fractures occur most easily during loading of a hyperextended wrist, possibly in combination with ulnar deviation. This movement tightens the palmar ligaments (the radiocapitate and radioscaphoid ligaments), so stabilizing the scaphoid against the radius. As the proximal pole is strongly stabilized, further loading and extension of the wrist causes bending forces on the distal pole, which may result in fracture.[15,16]

Fractures may occur at any level in the scaphoid but the more proximal the fracture, the greater the chance of avascular necrosis of the proximal fragment.[17,18] The main reason for this is the special nature of the scaphoid's blood supply.[19] The blood supply to the scaphoid can be divided into extraosseous and intraosseous sources. The extraosseous blood supply is primarily derived from a branch of the radial artery, the artery to the distal ridge of the scaphoid.[20] The branches of this vessel enter the scaphoid through a foramen at the dorsal ridge at the level of the wrist (Fig. 23.2). These vessels then run proximally and palmarly within the medullary chamber, forming the intraosseous supply to the proximal pole.[21] Since vascularity of the proximal pole is limited and dependent on intraosseous flow, acute proximal pole fractures have a potentially prolonged healing period, averaging 3–6 months, and there is higher incidence of non-union.

Because of the danger of avascular necrosis developing, it is important to recognize a scaphoid fracture as quickly as possible. Acute scaphoid fractures are often missed on initial plain radiographs. Therefore an initial negative radiograph does not alter the clinical diagnosis. When clinical suspicion of a scaphoid fracture is high and plain films are negative, the traditional recommendation is for these patients to be immobilized in a thumb spica splint or cast, with repeat radiographs after about 2 weeks.[22]

Warning

It is important to diagnose a scaphoid fracture as soon as possible in order to avoid avascular necrosis. In post-traumatic arthritis lasting longer than 24 hours, the condition should be regarded as a fracture until the contrary has been established.

Alternative imaging modalities for diagnosis include bone scans and magnetic resonance imaging (MRI). A bone scan reportedly shows focally increased uptake within 72 hours and is very sensitive for detecting a fracture, but may not be extremely specific.[23–25] MRI has been reported to have 95–100% sensitivity and almost 100% specificity for scaphoid fractures.[26–28] Additional advantages of MRI include its potential to assess vascularity of the proximal scaphoid pole when a fracture is present.[29]

Treatment

Treatment consists of immediate immobilization of the wrist, which is protective and can decrease the incidence of non-union and avascular necrosis.[30] The best position remains unclear. Several dissection studies have come to different conclusions.[31–34] Immobilization seems to be best performed with a thumb–spica cast, holding the thumb in the palmar abducted position and the wrist in the mid-position but with an element of deviation towards the site of the fracture, which, for the scaphoid, would be radial deviation. This helps to press the fractured surfaces together and stimulates the healing process.[15] The time needed for a scaphoid fracture to heal is variable, from a minimum of 6 weeks to as long as 9 months,[35] but 90% of fresh fractures heal with adequate treatment.[30]

Fractures of the other carpal bones can occur. Frequently, multiple radiographic views and/or follow-up studies with tomograms or bone scans may be necessary for a definitive diagnosis.[36] Displaced fractures may require open reduction and internal fixation.[37,38]

Rheumatoid arthritis

The wrist can become affected by any type of rheumatic disorder, such as systemic lupus erythematosus, progressive systemic sclerosis, psoriatic arthritis, gout and pseudogout, ankylosing spondylitis and sarcoidosis, but rheumatoid arthritis is one of the commonest, frequently affecting both wrists[39] and often following involvement of the fingers. In the acute stage a capsular pattern is found on examination, together with swelling, warmth and synovial thickening. At this stage MRI can be a useful technique for reaching a diagnosis.[40] Recently joint ultrasound has also proved to be an important tool to evaluate synovitis of the wrist.[41] In addition to pain, the more chronic cases present with gross limitation of movement. At this stage, there is no longer any warmth and even the swelling has diminished; diagnosis is easily made on conventional radiographs.

In the acute stage, the patient can be treated locally by immobilization of the wrist for some weeks. In the subacute and chronic stages, triamcinolone is a much better approach. One infiltration of 20 mg of triamcinolone acetonide is given at all the different areas of synovial thickening and/or tenderness, which are first precisely identified by palpation. Although treatment is very painful, the results are spectacular and symptoms at the wrist tend not to recur.

Arthrosis

Arthrosis may come on spontaneously as age advances or may be secondary to severe injury or overuse of the wrist (e.g. professional causes).

The patient complains of stiffness and of some discomfort on certain activities. On examination a moderate capsular pattern is found, with a hard end-feel and crepitus on passive testing.

The radiograph shows osteophytes, sclerosis of the bony margins and diminished joint spaces. It is important to realize that minor arthrosis, visible on radiograph, does not always interfere with the function of the wrist.

Because the disability is usually minor in arthrosis, treatment is seldom necessary. In rare instances where fairly heavy loads are imposed on the joint, arthrodesis may be warranted.[42]

Limited range: non-capsular pattern

Carpal subluxation

Subluxation of a carpal bone, most often the capitate, occurs quite frequently. The diagnosis is purely clinical and, once the condition is recognized, it can be dealt with successfully by conservative management. Recurrence is not at all uncommon and may ultimately cause problems.

History and examination

The patient complains of pain on certain movements at the dorsal aspect of the wrist, especially when weight is put on an extended wrist. The symptoms may come on spontaneously or as the result of a minor injury in flexion.

On examination, signs of internal derangement are found (Fig. 23.3): one movement, most often extension, is limited with – certainly in acute cases – an end-feel of muscle spasm. Other movements are full-range, although often painful – the result of overstretching the irritated ligaments (see p. 34). The bony subluxation may be visible and palpable if the wrist is held in flexion. There is local tenderness in the ligaments.

The radiograph is negative: the edge of the subluxated bone appears merged with the others and cannot be visualized separately on the radiograph, nor can its position be measured against the superimposed margins of the other bones (Cyriax:[43] p. 184).

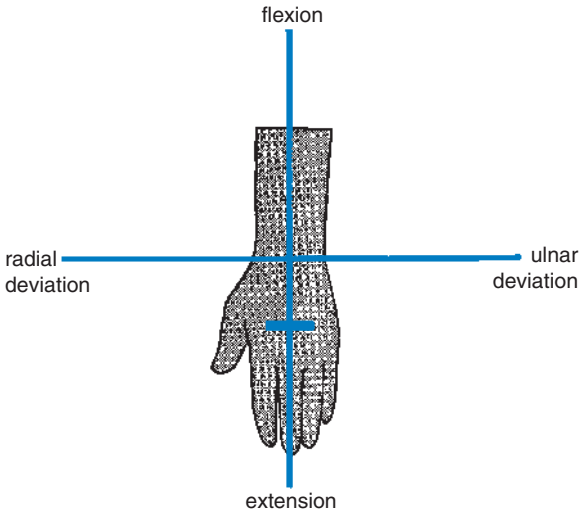

Fig 23.3 • The non-capsular pattern in carpal subluxation.

The clinical examination supplies the diagnosis: the joint is blocked in one direction only, (which is typical of internal derangement) and there is a visible displacement on inspection. Instant reduction during manipulation confirms the tentative diagnosis.

Palmar subluxation, mostly of the lunate bone, is very exceptional. It gives rise to (slight) limitation of flexion and may compress a palmar branch of the median nerve, causing paraesthesia in the corresponding territory (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Differential diagnosis

Limitation of wrist extension does not necessarily indicate carpal subluxation and differential diagnosis should be made from the following disorders:

- *A ganglion* at the dorsum of the wrist usually feels softer on palpation. It does not respond to manipulative treatment but can be diagnosed and treated by puncture.
- *Kienböck's disease, un-united fracture and isolated arthrosis* have a different history and can easily be detected on radiography (see p. 337).
- *A carpal boss* (see p. 338).

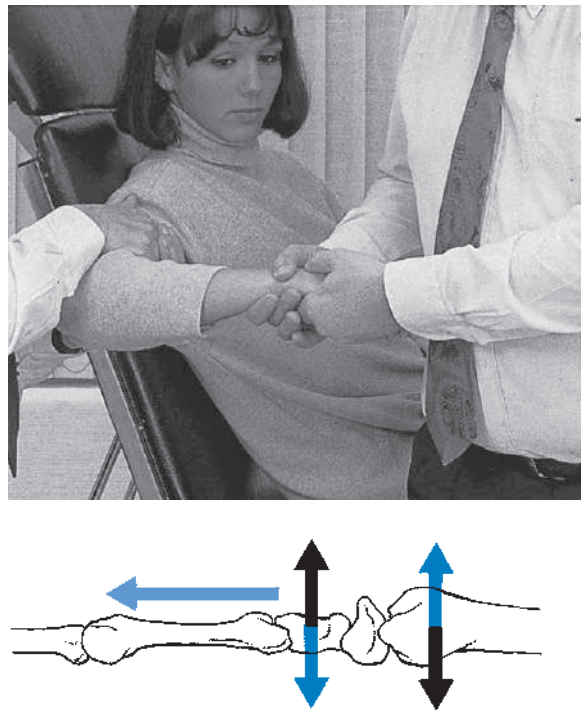

Fig 23.4 • Basic manipulation for carpal subluxation.

Treatment

Treatment consists of manipulative reduction, which restores extension. Because of the accompanying sprain of the dorsal ligaments, flexion often remains painful. A few sessions of deep transverse friction will resolve this problem. If the condition recurs, manipulation is repeated. Frequent recurrences indicate instability and should be treated with infiltration of a sclerosant solution into the ligaments attached to the subluxated bone.

Basic technique: manipulation for carpal subluxation

The patient sits on a couch, the arm held in abduction against the back of the couch. An assistant grasps the patient's upper arm just proximally to the elbow and holds it firmly against the couch. One foot is placed forwards for the manipulator's benefit: the latter will place a foot against it.

The manipulator stands level with the patient's hip, between the couch and the patient's arm, and places the ipsilateral foot against the assistant's foot; later, this will enable the manipulator to lean sideways and use the body weight for the pull required to obtain traction on the wrist joint. With the ipsilateral hand, the patient's forearm is grasped just proximally to the radiocarpal joint, with the thumb on the dorsal aspect of the forearm. With the contralateral hand, the patient's wrist is held with the thumb dorsally on the subluxated bone.

The aim of the manipulation is to perform a gliding movement between the rows of carpal bones during traction. The technique is executed as follows. The manipulator leans sideways but makes sure that the pull is only carried out with the distal hand, so as to obtain traction on the wrist. After the slack has been taken up, both hands are moved vertically up and down in opposite directions (Fig. 23.4). The little finger of the contralateral hand is kept in the palm of the patient's hand to control movement; the manœuvre should result in a pure gliding movement and flexion–extension should be avoided.

This gliding movement is performed several times in one manœuvre. The movements of the wrist are then re-examined and the manipulation repeated until a full range of extension has been restored or until no further benefit results. If there is no immediate result, the attempt should not be abandoned too quickly. It may sometimes help to slightly change the position of the patient's hand during the manœuvre and to build in a bit more flexion, extension or radial or ulnar deviation.

When this technique does not lead to full recovery, the next manœuvre is tried.

Second technique: manipulation for carpal subluxation

This technique is never used first but is introduced only when the bone is partially reduced. The aim is to perform a squeezing of the wrist during traction.

The patient, assistant and manipulator maintain the same positions as in the previous technique. The manipulator's distal hand is now moved slightly downwards, so that it grasps the patient's hand at the level of the bases of the metacarpal bones. Using the other hand, the patient's wrist is approached from above and encircled with thumb and index finger. The metacarpophalangeal joint of the index finger is placed on the subluxated bone. The manipulator's forearm is held vertically (Fig. 23.5). The manipulator leans sideways, applying traction with the distal hand and, having taken up the slack, executes a short, sharp squeezing manœuvre.

Although the manipulative thrust is a pure squeezing, there is an involuntary downwards movement of the hand, which helps reduction. This technique can be repeated several times.

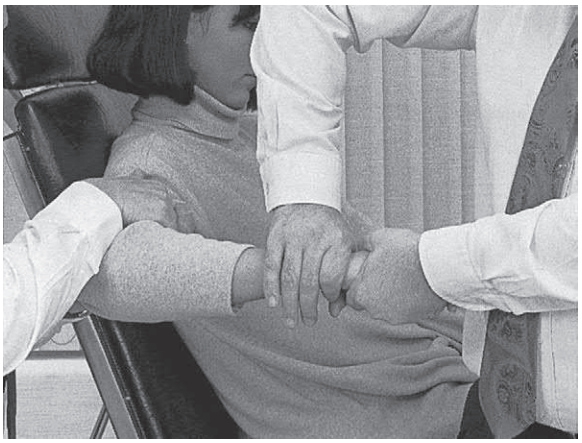

Fig 23.5 • Second manipulative technique for carpal subluxation.

Fig 23.6 • Alternative manipulation for carpal subluxation.

Alternative technique: manipulation for carpal subluxation

The patient stands next to the couch, with the forearm, stabilized by the other hand, placed on the couch, the distal part level with the edge. The manipulator stands in front of the patient and grasps the hand in such a way that one thumb, reinforced with the other, is placed dorsally on the subluxated bone, while one index finger, reinforced by the other, is placed on the palmar aspect of it. The little fingers are placed in the palm of the patient's hand, in order to prevent flexion–extension movements during the manipulation (Fig. 23.6).

Traction is applied with both hands and, after having taken up the slack, an anteroposterior glide is performed with emphasis on downward movement. Several movements are performed and the patient is re-examined after each manœuvre.

Other joint problems

The four following disorders, all visible on radiograph, give rise to limited extension only.

Aseptic necrosis of the lunate bone (Kienböck's disease)

Avascular necrosis of the lunate was first described by Peste in 1843.[44] The condition was then forgotten until 1910, when Kienböck recorded lunatomalacia, which he assumed had a vascular traumatic aetiology.[45] Despite recognition of this disease entity for the past 100 years, its cause is still debated. Some investigators relate it to a stress fracture that leads to devascularization of the major segment of the lunate. Other authors consider the avascular necrosis to be the result of interruption of the vascularization of the lunate bone following excessive shear forces caused by acute trauma or repeated microtrauma.[46] This would happen more easily in those lunate bones that are supplied by a single volar or dorsal blood vessel.[47] Others suggest that a vascular non-traumatic process, with a minor infarction pattern in the proximal subchondral area, may be nearer to the truth.[48]

Avascular necrosis usually affects the dominant hands of males between 20 and 40 years of age.[49,50] The symptoms come on spontaneously or as the result of minor injury, and usually interfere very significantly with work-related activities. The initial symptoms are pain and stiffness, which may vary from moderate to severe and incapacitating. The patient may also mention reduced strength in the hand.[51]

Clinical examination in the initial stage shows a capsular pattern with muscle spasm, due to the accompanying synovitis. Later, painful limitation of passive dorsiflexion becomes obvious, together with pain at the end of range of the other movements – a clear non-capsular pattern.

The classification of Kienböck's disease is based on its roentgenological appearance.[52,49,53]:

- Stage 1 consists of small fracture lines – bone scintigraphy[54] or MRI[55] will be required for diagnosis.
- Stage 2 is rarification along the fracture line, usually on the volar pole.
- Stage 3 shows sclerosis of the bone dorsal to the fracture site.
- Stage 4 shows sclerosis of the bone dorsal to the fracture site, and collapse and secondary fracture with loss of architectural integrity of the lunate.
- Stage 5 shows secondary arthritic changes of the radius.

Treatment methods extend from immobilization to revascularization surgery on the affected bone. However, there is still no gold standard for the treatment of Kienböck's disease.[56] A recent systematic review showed that, to date, there are insufficient data to determine whether the outcomes of any intervention are superior to placebo or the natural history of the disease.[57]

Avascular necrosis in other carpal bones has been described but is rare.[58,59]

Un-united fracture

This leads to pseudoarthrosis and also gives rise to limitation of extension.

Isolated arthrosis

This comes on some years after an un-united fracture, especially of the scaphoid bone. The projecting osteophytes can be seen and felt. Extension is very limited but the condition is not necessarily painful.

Carpal boss

This bony prominence at the base of the second and third metacarpals adjacent to the capitate and trapezoid bones may represent degenerative osteophyte formation and/or the presence of an os styloideum, an accessory ossification centre that occurs during embryonic development. The symptoms of a carpal boss may result from an overlying ganglion or bursitis, an exterior tendon slipping over this bony prominence, or from osteoarthritic changes at this site. Diagnosis is by X-ray.[60]

Full range

Although passive movements of the wrist show a full range of movement, they can be painful at the end of range, showing that a structure is either stretched (ligament) or pinched (impaction syndromes).

Ligamentous lesions

Ligamentous injuries range from minor sprains with no instability (which are discussed here) to complete rupture with gross instability (see p. 341).[61]

Sprain of the ulnar collateral ligament

This disorder is the result of an injury causing a fracture, either a Colles' fracture or fracture of the styloid process of the ulna. The fracture has healed but pain remains at the ulnar aspect of the wrist. On inspection, the deformity of the radius is visible and passive radial deviation causes pain at the ulnar aspect of the wrist. The symptoms can be quickly relieved by an infiltration of triamcinolone.

Technique: infiltration

A 1 mL syringe, filled with 10 mg of triamcinolone acetonide, and a 2 cm needle are used. The patient's arm rests in pronation on the couch. The hand is brought into slight radial deviation. The tender spot is identified, and the infiltration given with bony contact and ligamentous resistance (Fig. 23.7).

Sprain of the radial collateral ligament

This rare disorder results in pain felt at the radial aspect of the wrist during passive ulnar deviation. A more common cause of these symptoms is a tendinous lesion in the extensor pollicis brevis and abductor pollicis longus tendons (see p. 354). Differential diagnosis is easy because, in tendinitis, resisted movements are also positive.

Radial collateral sprain responds well to treatment with either one infiltration of triamcinolone or several sessions of deep transverse friction.

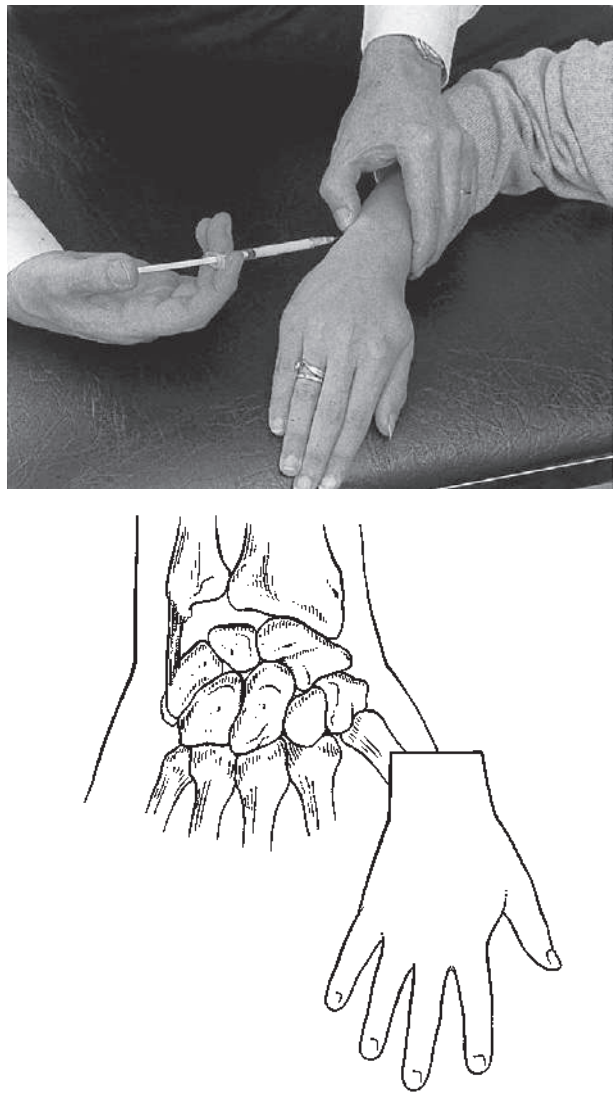

Fig 23.7 • Infiltration of the ulnar collateral ligament.

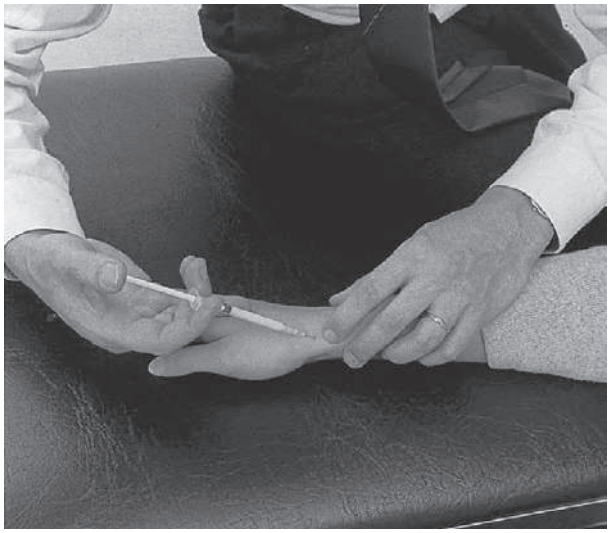
Technique: infiltration

The patient sits with the forearm in the neutral position and the hand on the couch. The wrist is brought into slight ulnar deviation. The tender spot is palpated and 10 mg of triamcinolone acetonide is infiltrated using a 2 cm needle (Fig. 23.8). During infiltration, ligamentous resistance and bony contact should be felt. Care must be taken to avoid puncture of the radial artery.

Sprain of the dorsal ligaments

The most common minor lesions are usually the result of overuse but may also occur when long-standing carpal subluxation causes irritation of the overstretched ligaments.

Pain is felt at the dorsal aspect of the wrist on full passive flexion. Other tests are negative. Careful palpation reveals the exact site of the lesion. Most of the lesions are found in the lunate–capitate ligament but occasionally also in the radiolunate, capitate–third metacarpal or ulnar–triquetral ligament.



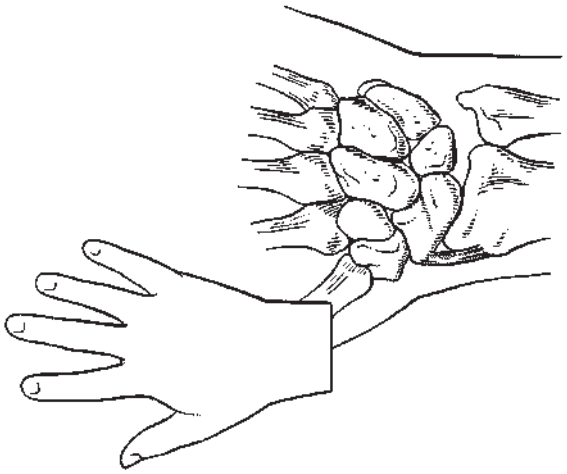


Fig 23.8 • Infiltration of the radial collateral ligament: (a) the intercarpal ligaments; (b) the radiocarpal or carpometacarpal ligaments.

Treatment consists of several sessions of deep transverse friction, which should lead to complete cure, independently of how long symptoms have been present. In the rare case in which it is not clear whether the symptoms are caused by a pure ligamentous sprain or by irritation of the ligaments from carpal subluxation, manipulation may be tried. If it proves ineffective, deep transverse friction is substituted. Even in the chronic stage of a dorsal ligamentous lesion at the wrist, the only effective treatment is deep transverse friction. Other treatments, such as steroid injections, immobilization or operation, are of no use. In order to avoid permanent problems, and because these lesions are often multiple, friction must be given to all the sprained ligaments. Palpation should therefore be performed carefully until all the tender spots have been found.

Technique: deep transverse friction

The patient sits with the hand over the edge of the couch. The therapist sits facing the patient's wrist, which is flexed with one hand within the limits of pain. Friction is imparted with the other hand. The direction depends on the course of the ligamentous fibres: the radiocarpal and carpometacarpal ligaments are aligned in the same longitudinal axis as the forearm, while the intercarpal ligaments have a more or less transverse direction (Fig. 23.9). For a radiocarpal or carpometacarpal ligament, the direction of the friction is transverse on the ulnar–radial axis. Friction is given with either the index finger, reinforced with the middle finger (Fig. 23.10), or with the thumb. As the lesion is very localized, the therapist must make

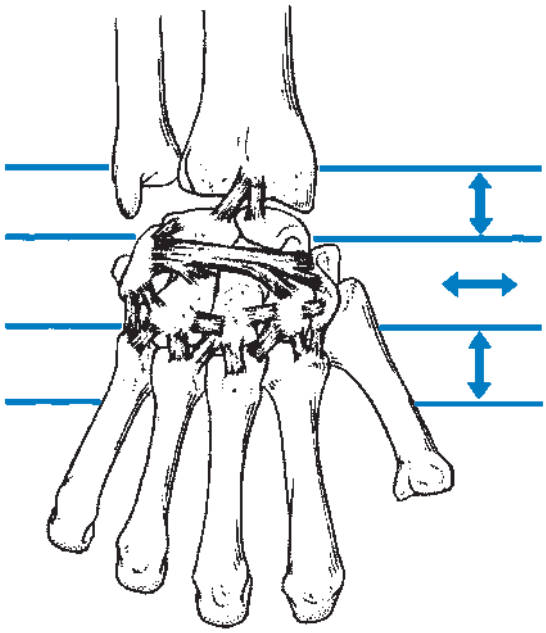

Fig 23.9 • The dorsal ligaments. The arrows emphasize the direction of the ligamentous fibres at the joint lines.

sure that the finger remains deep between the extensor tendons and does not pass over them.

An intercarpal ligament is given friction with the thumb and in a proximo–distal direction (see Fig. 23.9).

Wrist impaction syndromes

Dorsal and/or ulnar-sided wrist pain may be caused by periosteal bruising that results from impaction between the carpus and the radioulnar border.

Ulnar impaction syndrome

Ulnar impaction syndrome, also known as ulnar abutment or ulnocarpal loading, is a degenerative condition characterized by ulnar wrist pain related to excessive load bearing across the ulnar aspect of the wrist. Chronic impaction between the ulnar head and ulnar carpus results in periostitis and degeneration of the lunate bone, triquetral bone and distal ulnar head, and degenerative tears of the triangular fibrocartilage complex (Fig. 23.11).[62]

The clinical manifestation of ulnar impaction syndrome generally consists of chronic or subacute ulnar wrist pain, often exacerbated by activity such as loading in extension and relieved by rest. Functional examination shows dorsal pain on passive extension. If the triangular fibrocartilage complex is involved, there will also be pain on forearm rotations.

Radiographic changes include subchondral sclerosis and cystic changes in the ulnar head, ulnar aspect of the proximal lunate bone, and proximal radial aspect of the triquetral bone. MRI is helpful in detecting occult disease in the early stage.[63]

Treatment will depend on the severity of the lesions. Periostitis responds well to local infiltration with 10 mg of triamcinolone acetonide, provided that further irritation is avoided. This can be done by avoiding the extremes of wrist movement in the loaded position or by the application of a splint or a cast. In more advanced cases or in lesions of the triangular fibrocartilage complex, arthroscopy and surgery will be needed.[64,65]

Ulnar styloid impaction syndrome

This ulnar-sided wrist pain is caused by impaction between an excessively long ulnar styloid process and the triquetral bone.[66] The ulnar styloid process is a continuation of the prominent subcutaneous ridge of the shaft of the ulna, which projects distally towards the triquetral bone for a variable distance (2–6 mm).[67] A single or repetitive impaction between the tip of the ulnar styloid process and the triquetral bone results in contusion, which leads to periostitis of the opposing surfaces. If a single-event trauma is forceful enough, fracture of the dorsal triquetral bone may occur.[68]

The diagnosis of this condition is made on the basis of pinching pain during ulnar deviation and radiographic evidence of an excessively long ulnar styloid process. MRI may show chondromalacia of the ulnar styloid process and proximal triquetral bone (Fig. 23.12).[69]

Treatment consists of a local infiltration with 10 mg of triamcinolone. In advanced cases, resection of all but the two most proximal millimetres of the styloid process is the treatment of choice.

Radial impaction syndrome

Pain at the dorsal aspect of the wrist may occur as the result of repetitive extension movements during weight bearing, as frequently happens in gymnastics or other high-energy sports; this may lead to periostitis at the distal epiphysis of the radius or the proximal carpal bones,[70,71] described as 'wrist impingement' syndrome[72] or 'stress reaction'.[73] The pain is elicited each time the patient puts weight on an extended wrist.

On examination, passive extension of the wrist is found to be full but painful, all other movements being negative. Careful

palpation shows the lesion to lie at the inferior border of the radius or at the scaphoid and lunate bones.

Periostitis responds well to local infiltration with 10 mg of triamcinolone acetonide, provided that further irritation is avoided. This can be done by avoiding the extremes of wrist movement in the loaded position or by the application of a splint or a cast, if necessary. Surgery can be performed in recurrent cases or to avoid long-term complications.[74]

Repetitive compressive loading may result in stress fractures of the distal part of the radius, the scaphoid and the capitate bones. Scintigraphy and MRI are diagnostic and immobilization in a cast is therapeutic.[75,76]

Ganglion

A ganglion is a fluid-filled cavity that originates from the joint capsule or tendon sheath. It is very common at the wrist. It occurs dorsally, most often over the scapholunate joint, as well as at the palmar aspect, usually at the trapezioscaphoid joint.[77] Its aetiology has been debated for many years and various hypotheses have been presented: retention cyst, herniation of tendon or capsular synovia, bursal transformation, neoplasia, or mucinous degeneration of fibrous tissue, the last of these being the most widely accepted theory.[78]

The main complaint is the presence of a swelling that was not there before. It may sometimes be painful either at rest or during movement. The size may vary and so does its consistency: it can be either very soft or quite hard, giving the impression of a bony structure. When the ganglion grows, the neighbouring tissues may become compressed and there may be pressure on nervous tissue as well (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Many techniques have been used to treat this condition, varying from crushing the ganglion (e.g. pressure with the thumbs or a firm slap with a book) to aspiration and infiltration with a steroid or sclerosant solution. These measures usually lead to temporary cure but recurrences are frequent because the cause has not been treated. More consistent results are obtained by surgical removal, although the risks associated with surgery may be more undesirable than the minor symptoms associated with the presence of a ganglion.[79]

Excessive range

Ligamentous instability

According to Ekenstam, instability of the wrist is 'a condition of altered joint kinematics in which one or several carpal bones are permitted abnormal patterns of motion as a result of bony abnormalities, ligamentous lesions or joint laxity'.[80]

Carpal instability remains a very controversial topic. Since 1943, when Gilford *et al*[81] first mentioned instability of the wrist, many authors have worked on the subject. They have developed several hypotheses and proposed different methods of classification. This variability indicates the difficulty in reaching a consensus on such a vague topic as 'instability' in the complex area that is the wrist. There is still a lack of standardization in evaluation methods and in the findings and radiographic criteria. Arthroscopy, however, has helped to provide a clearer picture of the possible underlying mechanisms.[82]

Aetiology

Wrist instability is generally believed to be caused by post-traumatic stretching or rupture of one or several radiocarpal or intercarpal ligaments. The injury is usually hyperextension combined with radial or ulnar deviation and/or pronation or supination.[83]According to some authors, however, it can also be the result of anatomical changes and malalignment subsequent to radial or carpal fracture. Other possible causes of ligamentous laxity are degenerative and inflammatory conditions (i.e. crystal synovitis, rheumatoid arthritis), as well as iatrogenic causes.[84]

Epidemiology and classification

Epidemiological data on carpal instability are still not available, although wrist injuries occur in 28.6% of all accidents.[85] Several methods of classification have been described.[86]

Taleisnik[87,88] has proposed a theory based on the columnar concept of Navarro.[89] This concept recognizes three vertical columns in the wrist: (a) the central (flexion/extension) column contains two blocks – one on the lunate bone and one on the trapezium, trapezoid, capitate and hamate bones; (b) the radial column comprising the mobile scaphoid bone; and (c) the ulnar (rotating) column ,which includes the triquetral bone and the pisiform. Taleisnik therefore classifies wrist instability as being radial, ulnar or proximal.[90]

This concept does not mention the transverse or perilunar patterns (stages I–IV), which were later described by Mayfield *et al*,[91] or the more recently discussed mid-carpal instability, proximal row instability and miscellaneous instability.

The Mayo Clinic proposes a classification, based on the work of Amadio, Cooney, Dobyns and Linscheid.[92–96]

The Lichtman classification[97] deviates from the columnar wrist concept and the consequent longitudinal classification system. It is based on the 'carpal ring concept' – the distal and proximal rows are joined by two links: on the radial side the mobile scaphotrapezial joint and on the ulnar side the rotatory triquetrohamate joint. This concept includes the perilunate and mid-carpal instabilities.

Other classification systems – for example, the Barton classification – have also been proposed.

We consider Saffar's classification[86] to be a clinical and useful approach.

1. Static or dynamic instabilities

   Dynamic instability only shows when, during movement of the wrist or under specific loading, symptoms can be elicited. Static instability is fixed, cannot be corrected by the patient and shows an abnormal position of the bone.

2. Location of instability

   Proximal row instability is the most frequent type of instability:

(a) Scapholunate: there is a malalignment between the scaphoid and the lunate. This condition may lead to arthrotic changes.

(b) Triquetrolunate is the result of a complete or partial rupture of the triquetrolunate ligament.

(c) Or both.

Mid-carpal instability:

(a) Ligament attenuation or tear after light trauma in hyperlax persons: this results in a malalignment between the proximal and middle row of carpal bones.

(b) Ligament tear after rotational injury: there is a rupture or elongation of the ligaments that stabilize the mid-carpal joint.

Proximal instability (radiocarpal) with the two Taleisnik stages:

(a) Stage 1: ulnar gliding of the entire carpus

(b) Stage 2: ulnar gliding of the entire carpus with scapholunate separation.

Clinical diagnosis

Although post-traumatic wrist pain occurs frequently, instability does not. The patient is examined thoroughly, and only when the history and the physical findings are compatible with carpal instability should the diagnosis be made.

The patient has a history of past trauma with or without fracture or of past inflammatory disease. There is wrist pain mostly during or after activity, which may be accompanied by a feeling of weakness or of snapping during movement. Information about the type of injury should be obtained but the patient often does not recall such features.[98] The localization of the pain is also very informative and points towards specific possibilities. The passive movements are full or even excessive in range and, although they are performed very gently, they may cause pain at the end of the movement.

Provocative tests can be performed:[99]

1. For scapholunate instability

- The scaphoid bell sign: the examiner grasps the patient's scaphoid bone between thumb and index finger and controls its movement while the patient is actively moving from radial to ulnar deviation. The movement of the scaphoid should be smooth. If this is not the case, the test is considered positive.
- Watson's test:[100,101] the examiner puts the patient's hand in ulnar deviation. With the other hand the scaphoid bone is grasped between thumb (on the tubercle) and index finger. The hand is then brought into radial deviation and resists flexion movement of the scaphoid by the thumb. In instability this results in the proximal pole shifting backwards, which can be felt at the dorsal aspect (Fig. 23.13).
- Lane's test (the scaphoid shift test):[102] the examiner assesses the anteroposterior gliding of the scaphoid.

2. For triquetrolunate instability

- Kleinman's shear test:[103] the examiner grasps the patient's distal forearm and puts the fingers on the most distal and dorsal aspect of the ulna. The thumb is placed on the pisiform bone. The ulna is so stabilized and a posterior pressure exerted on the pisiform. Pain may be produced (Fig. 23.14).
- Linscheid's test:[104] the examiner grasps the patient's distal forearm and puts the finger on the most distal and radial aspect of the radius. The thumb is placed at the ulnar aspect on the triquetral bone (Fig. 23.15).

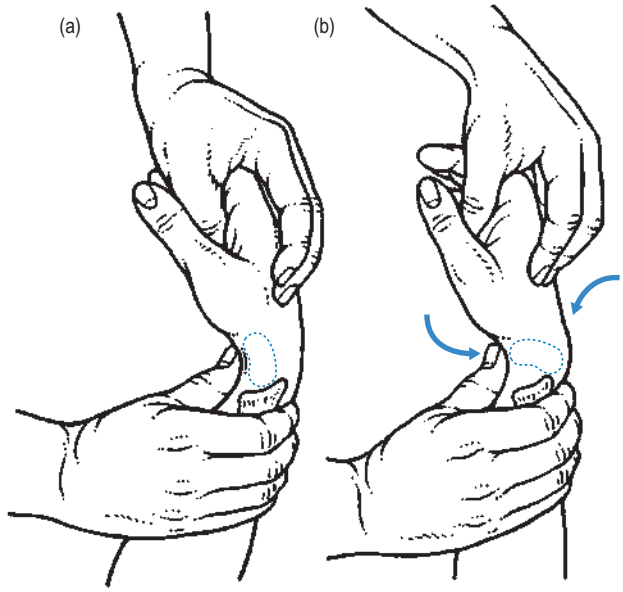

Fig 23.13 • Watson's instability test: pressure is exerted on the palmar aspect of the scaphoid during movement from ulnar to radial deviation.

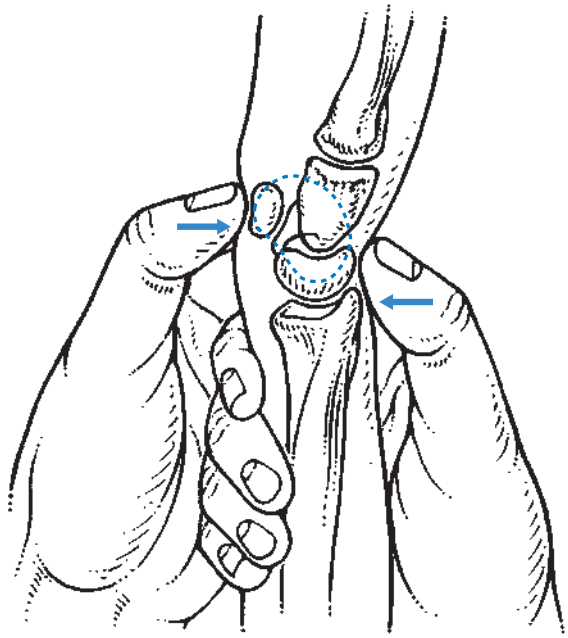

Fig 23.14 • Kleinman's test: the dorsal aspect of the wrist is stabilized and pressure exerted on the pisiform bone in a dorsal direction.

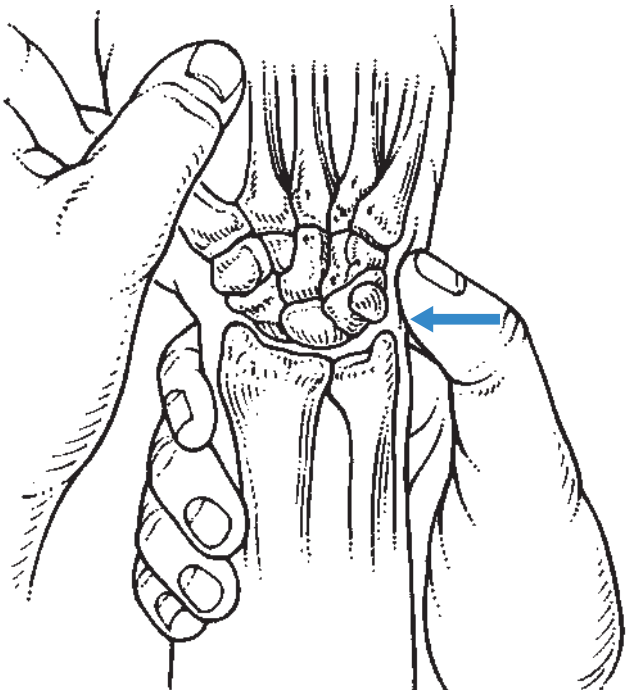

Fig 23.15 • Linscheid's test: the radius is stabilized and pressure is exerted on the triquetral bone in a radial direction.

The radius is stabilized and pressure exerted laterally on the triquetrum. Pain may be produced.

3. For mid-carpal instability
   - Mid-carpal shift test:[105] the examiner exerts axial compression on the wrist via the hand and asks the patient to move the wrist actively. A painful click may be produced. The click will not be present when pressure is brought to bear on the pisiform or during active contraction of the hypothenar muscles.
   - Apprehension test:[106] when the capitate bone is glided in a posterior direction, pain and/or apprehension are produced.
   - Metacarpal gliding:[107] the wrist is placed in ulnar deviation and the metacarpals glided in a palmar direction. Pain may be elicited.
4. For radiocarpal instability
   - Medial radiocarpal drawer test:[108] pressure is exerted on the posterior aspect of the triquetral bone and counterpressure is on the radius. The test is positive when painful.
   - Ulnar sag: the ulnocarpal sag has increased.

Technical investigations may include arthrography, arthroscopy, computed tomography (CT), MRI and scintigraphy.

Treatment

Treatment is still controversial and is very much surgeon-, physician- or therapist-related. Therapy varies from conservative treatment to a range of different surgical techniques. Asymptomatic or slightly symptomatic cases are usually treated conservatively, including immobilization, anti-inflammatory drugs and gradual physiotherapy. Clearly symptomatic, persistent or recurrent cases are often treated surgically. Therapeutic evidence should be looked for in the years to come.

The disorders of the inert structures of the wrist are summarized in Box 23.1.

Box 23.1

Summary of disorders of the inert structures of the wrist

Limited range

Capsular pattern
- Traumatic arthritis
- Rheumatoid arthritis
- Arthrosis

Non-capsular patterns
- Carpal subluxation
- Other joint problems

Full range
- Ligamentous lesions
- Impaction syndromes
- Ganglion

Excessive range
- Ligamentous instability

Disorders of the contractile structures

Tendinitis and tenosynovitis of the wrist are often encountered. Their frequency is the consequence of the long course of the tendons over the wrist, the role played by these tendons in the mobilization and stabilization of the wrist, and overuse of the hand in daily life, as well as in professional and sporting activities.

Resisted extension

Pain

Pain on resisted extension indicates a lesion of either the wrist or the finger extensors. The movement hurts near the wrist, which shows that the distal part of either muscle group is implicated.

Differentiation between wrist and finger extensors can be made by testing extension first with the fingers relaxed and then actively flexed, which inhibits the action of the finger extensors. When an extensor of the wrist is at fault, it is possible to differentiate between the radial extensors and the ulnar extensor by testing resisted radial and ulnar deviation (Fig. 23.16).

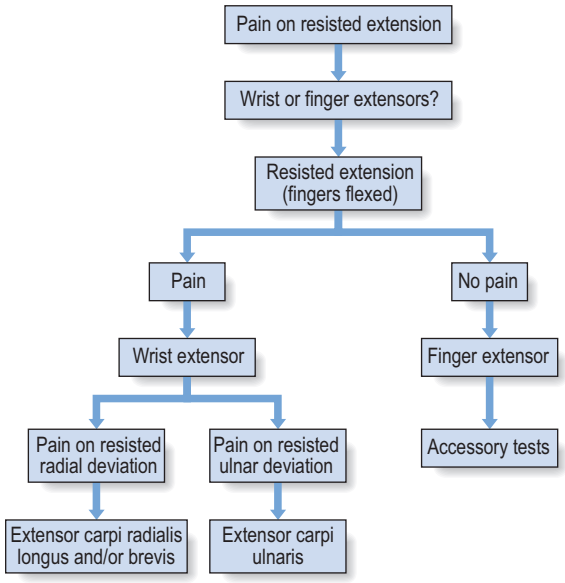

Fig 23.16 • Differentiation between the wrist and finger extensors.

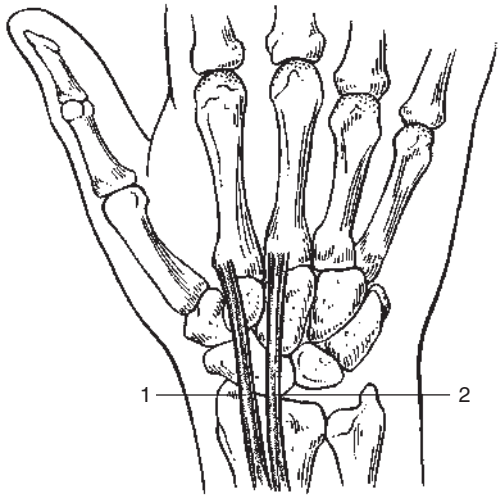

Fig 23.17 • The extensor carpi radialis longus (1) and brevis (2).

Extensor carpi radialis longus and/or brevis

A lesion of the extensor carpi radialis longus and/or brevis (Fig. 23.17) is usually the result of overuse.[109,110] The patient complains of local pain during activity.

Resisted extension and radial deviation of the wrist are painful at the dorsal and radial aspect of the joint. Full passive flexion may also cause pain but is usually negative.

On palpation (in full flexion) two different localizations can be found. Tenderness is elicited at the insertion of the tendons at the base of the second (longus) and/or third (brevis) metacarpal bones. Sometimes the lesion lies in the distal part of the tendon(s), level with the carpus.

Treatment consists of either deep transverse friction three times a week, in which case full recovery should be obtained within 2 weeks, or one or two infiltrations with triamcinolone suspension, provided the lesion is at the tenoperiosteal junction.

For the duration of treatment, the patient should avoid exertion that causes pain. Exercises, passive movements, immobilization and surgery are not indicated.

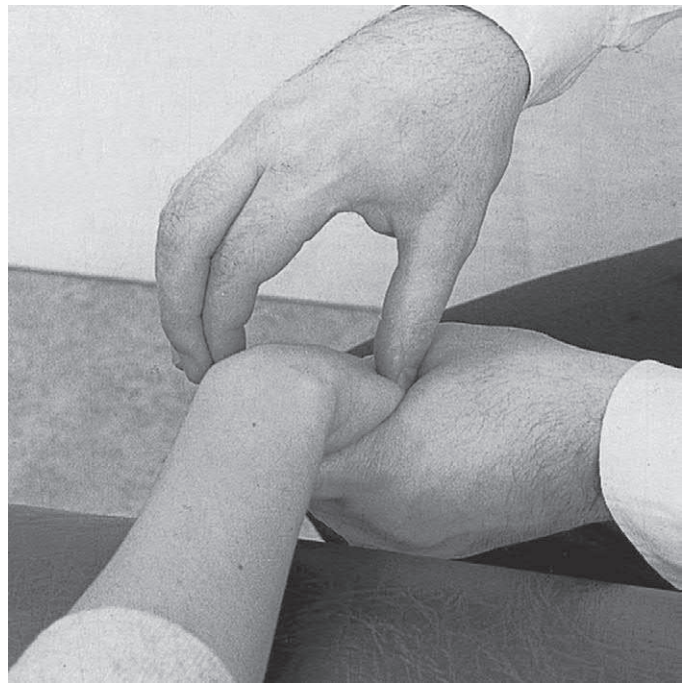

Fig 23.18 • Friction to the extensor carpi radialis longus and brevis.

Technique: deep transverse friction

The patient sits with the arm resting on the couch, the hand lying over its edge. The therapist sits lateral to the patient's hand. To stretch the tendon, the patient's wrist is flexed but this should not provoke pain. The index finger of the other hand, reinforced with the middle finger, is placed on the tender spot. Counterpressure is applied with the thumb at the ulnar aspect of the wrist (Fig. 23.18). The friction starts at the radial side of the tendon and, when the finger has passed over the tendon, the movement restarts. This results in a to-and-fro movement, the active phase being the movement towards the therapist.

Technique: infiltration

This treatment is only applied to insertion tendinitis on the base of the second and/or third metacarpal bones. Ten milligrams of triamcinolone acetonide are infiltrated at the tender area, using a 2 cm needle. The infiltration is given when tendinous resistance is felt and the needle is in contact with the bone. If the palpating finger is kept on the tender spot during the whole procedure (Fig. 23.19), the exact location of the infiltration can be confirmed.

Extensor carpi ulnaris

The tendon is the second most common site of tendinitis in the upper limb.[111,112] A tendinitis of the extensor carpi ulnaris

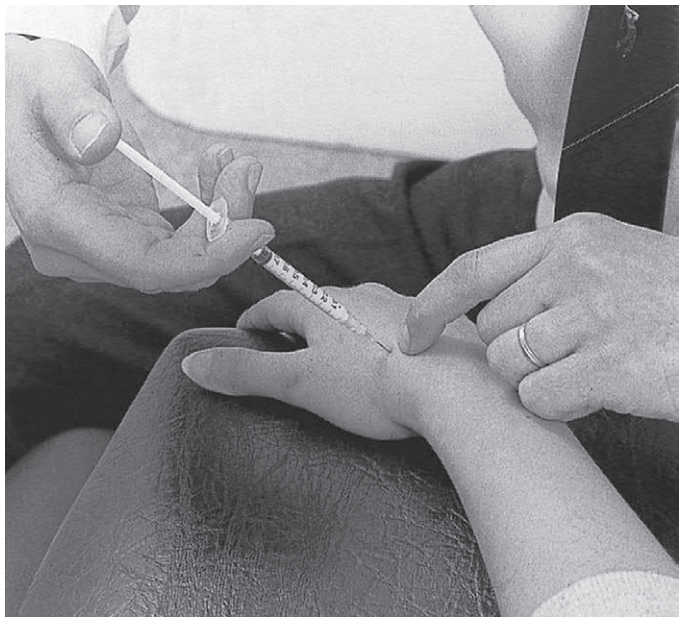

Fig 23.19 • Infiltration of the extensor carpi radialis longus and brevis.

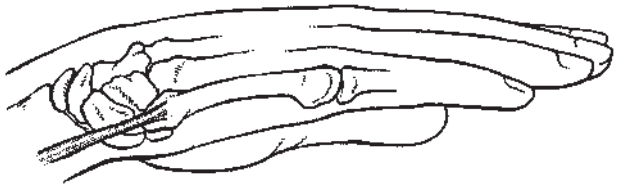

Fig 23.20 • The extensor carpi ulnaris.

(Fig. 23.20) usually develops after a strain or overuse. A tenosynovitis is a rheumatoid manifestation.

On examination, pain at the dorsal and ulnar aspect of the wrist is elicited by testing resisted extension and resisted ulnar deviation. Passive radial deviation may also cause pain at the ulnar side. Palpation is performed with the hand in radial deviation. In rheumatoid tenosynovitis the structure is warm to the touch and swollen or nodular. In an overuse disorder three possible localizations can be palpated. They are (in order of frequency): the tenoperiosteal junction at the base of the fifth metacarpal; the tendon body between the triquetral and the head of the ulna; and the tendon at the groove of the ulna. In the latter, pain is also elicited at the extreme of passive supination. This puzzling localizing sign is explained by Bowers as follows:

> 'The arrangement of the fibrous septa about the ECU [extensor carpi ulnaris] creates an angular approach of the tendon to its insertion in the position of full supination. This angle results in an ulnar translocation stress on the tendon sheath during ECU contraction, particularly with the forearm in supination and the wrist ulnarly deviated.'[113]

Fig 23.21 • Friction to the extensor carpi ulnaris.

In mechanical tendinitis, either 2 weeks of deep transverse friction or one or two infiltrations with triamcinolone suspension will effect a cure. Infiltration is performed at the tenoperiosteal junction or between tendon and sheath. Mobilization, exercises or immobilization do not afford any help. Surgery is seldom necessary. Rheumatoid tenosynovitis is treated by infiltration of a steroid suspension between the tendon and its sheath.

Post-traumatic rupture of the subsheath or of the extensor retinaculum may result in recurrent subluxation of the tendon. The patient feels a sudden snap on certain movements – for example, active supination with the wrist slightly flexed.[114] During the clinical examination, an attempt can be made to reproduce the instability using isometric stress in supination. Treatment is surgical reconstruction.[115]

Technique: deep transverse friction

The patient's pronated arm rests on the couch. The therapist, sitting at the medial aspect of the patient's arm, stretches the tendon by bringing the patient's hand into radial deviation. Depending on the extent of the tenderness, friction is applied with the fingertips of one, two or three fingers, or the index finger is reinforced by the middle finger (Fig. 23.21). Counterpressure is applied to the radial and distal aspect of the forearm. The finger is placed at the palmar aspect of the tendon and then moved upwards over the tendon. Repetition of this movement results in up-and-down friction.

Technique: infiltration at the tenoperiosteal junction

The patient's forearm rests on the couch in the same position as for friction. Ten milligrams of triamcinolone acetonide are infiltrated with a 2 cm needle at the insertion of tendon at the fifth metacarpal bone, while one finger of the other hand ensures that the agent is placed at the correct spot (Fig. 23.22).

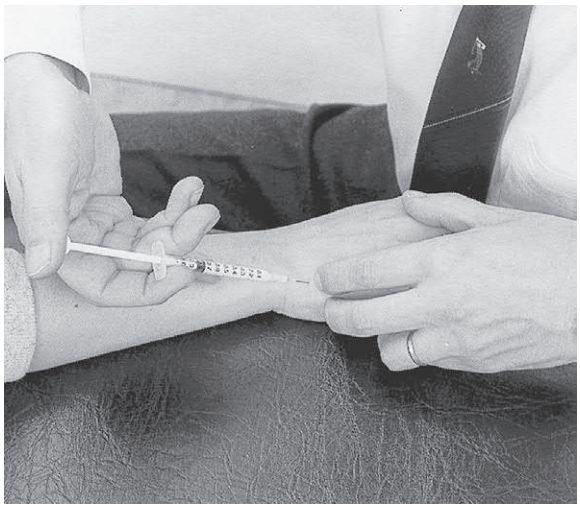

Fig 23.22 • Infiltration of the extensor carpi ulnaris.

The extensor carpi ulnaris and its related structures

This structure is closely connected to the distal radioulnar joint (DRUJ) and to the triangular fibrocartilage complex (TFCC). The distinct subsheath blends proximally with the capsule of the DRUJ and distally with the TFCC, and explains the phenomenon of 'transmitted stress' which is particularly present at this level. Resisted extension and ulnar deviation of the wrist may be positive in lesions of the inert structures (DRUJ and TFCC). The reverse also holds: passive supination may hurt in a lesion of the extensor carpi ulnaris (see p. 345). The phenomenon can be reduced to a minimum by making sure that all examination tests are performed in a starting position which is technically correct (see Ch. 20).

Extensor indicis proprius

Lesions of the extensor indicis proprius are rare and result from overuse.

Pain at the dorsal and radial aspect of the wrist is felt on resisted extension with the fingers relaxed but disappears when the fingers are held actively flexed. The lesion becomes obvious when each finger is separately extended against resistance. Palpation shows the lesion to lie at the carpal extent of the tendon. Crepitus during movement is occasionally felt.

A few sessions of deep transverse friction are curative.

Extensor digitorum

Tenosynovitis, either mechanical or rheumatoid, may occur at the level of the carpus – where the tendons lie in a common sheath – and gives rise to pain felt locally at the dorsum of the wrist. Resisted extension of the fingers provokes this symptom, as does passive flexion, which stretches the tendon. Rheumatoid tenosynovitis is characterized by a discrepancy between (pronounced) symptoms and (moderate) signs. Palpation shows the exact location and, in rheumatoid conditions, reveals swelling as well. Crepitus accompanies mechanical tenosynovitis.

The mechanical type responds to either infiltration with 10 mg of triamcinolone acetonide between the tendon and tendon sheath, or a number of sessions of deep transverse friction. In the rheumatoid type, triamcinolone injection is the only effective treatment.

Weakness

Painless weakness on resisted extension of the wrist should lead to a full neurological examination of the upper limbs. Combination with weakness of other muscle groups helps to determine the causative lesion. Although other conditions may cause painless weakness, those described below are the most common.

Bilateral weakness

If examination shows that only wrist extension is weak, lead poisoning is a possibility. Involvement of motor function in the peripheral nervous system is one of the main features, in addition to those arising from haematopoietic, central nervous, gastrointestinal and renal involvement.[116]

If lead poisoning is not the cause, either carcinoma of the bronchus or one of the general neurological diseases should be suspected.

Unilateral weakness

Unilateral weakness of wrist extension may result from a lesion of either a nerve root or a peripheral nerve. Combination with weakness of other muscles provides more information: the cause lies at the C6–C8 nerve roots or at the radial nerve.

- C6 *root palsy*: in a C6 root palsy, flexion of the elbow is weak as well.
- C7 *root palsy*: weakness of extension of the wrist is exceptional in C7 root palsy but extension of the elbow and flexion of the wrist are normally found to be weak.
- C8 *root palsy*: this is suspected when the extensor carpi ulnaris and flexor carpi ulnaris are weak. Consequently, the hand deviates radially when resisted extension of the wrist is tested. Extension and adduction of the thumb are also weak.
- *Radial palsy*: pressure on the radial nerve in the arm gives rise to radial palsy. The causes may be pressure from a crutch in the axilla, the edge of a chair or, in acute circumstances, fracture of the humerus at mid-shaft (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Resisted flexion

Pain

The first question that arises is: is there a lesion of either the flexors of the wrist or the flexors of the fingers, and, if a wrist flexor is at fault, is it the radial or the ulnar tendon? Radial and ulnar deviation, tested against resistance, as well as resisted

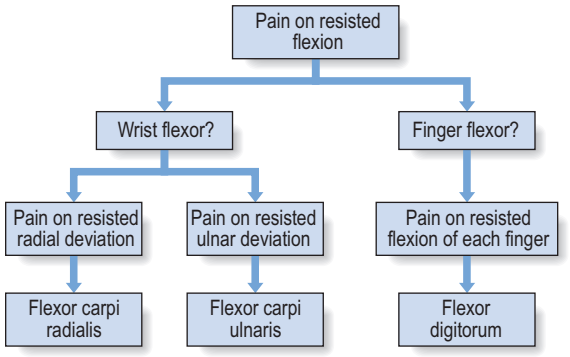

Fig 23.23 • Differentiation between the wrist and finger flexors.

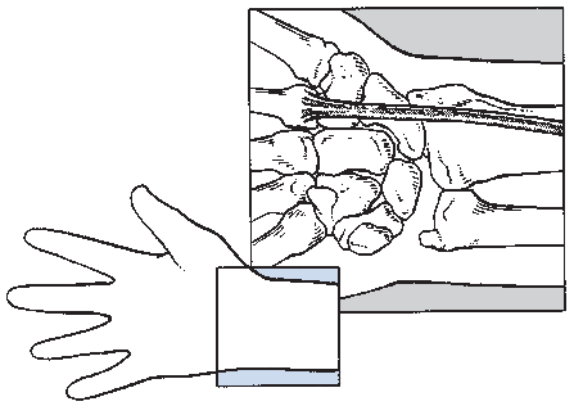

Fig 23.24 • The flexor carpi radialis.

flexion of each finger in turn, should define the affected structure (Fig. 23.23).

Flexor carpi radialis

Lesions of the flexor carpi radialis (Fig. 23.24) are not very common[117] but typically occur in women (75% of cases)[118] and are the outcome of overuse, either recreational or occupational. Pain is felt at the palmar aspect of the wrist during movements such as grasping and lifting with the fingers outstretched.

On examination, resisted flexion and resisted radial deviation of the wrist are painful. Tenderness can be palpated either over the whole distal extent of the tendon or at the insertion of the tendon at the base of the second metacarpal bone.[119]

Tenoperiosteal lesions respond well to both infiltration with triamcinolone acetonide and deep transverse friction, although friction through the thenar musculature is not easy, and is quite uncomfortable and time-consuming. Tendinous lesions are better treated with friction, as the lesion is usually too extensive.

Technique: deep transverse friction

The patient sits with the supinated arm lying on the couch and the hand over its edge. The therapist faces the patient and extends the patient's wrist with the ipsilateral hand. With the fingers of the other hand, friction is imparted to either the

Fig 23.25 • Friction to the flexor carpi radialis.

body of tendon or the insertion on the second metacarpal bone (Fig. 23.25). Friction is started at the ulnar aspect of the tendon and, during the active phase, the fingers are moved to the radial aspect.

Technique: infiltration

The patient sits and places the supinated forearm on a high couch, the wrist slightly extended. A 1 mL syringe is filled with 10 mg triamcinolone acetonide and fitted with a 2 cm needle. The tendon and its insertion at the base of the second metacarpal bone are difficult to identify through the muscles of the thumb. Therefore, the base of the second metacarpal is palpated at the dorsum by the index finger while the thumb presses on the palmar side. The needle is inserted through the thenar muscles and directed towards the palpating index finger (Fig. 23.26). Before it touches bone, the resistance of a tendinous structure is felt. Infiltration is then performed.

Flexor carpi ulnaris

Tendinitis is more common at the ulnar flexor tendon (Fig. 23.27) than at the radial flexor tendon because of the greater mobility at the ulnar side.[120] This lesion usually arises after a single excessive strain.

Usually, the patient can precisely locate the symptoms to the palmar and ulnar aspect of the wrist. Pain is elicited during resisted flexion and resisted ulnar deviations of the wrist. Palpation discloses the exact site of the lesion: distal to the pisiform bone – at the tenoperiosteal junction at the fifth metacarpal bone – or proximal to the pisiform bone in the body of the tendon.[121]

Both deep transverse friction (4–6 treatments) and infiltration with triamcinolone suspension are effective.

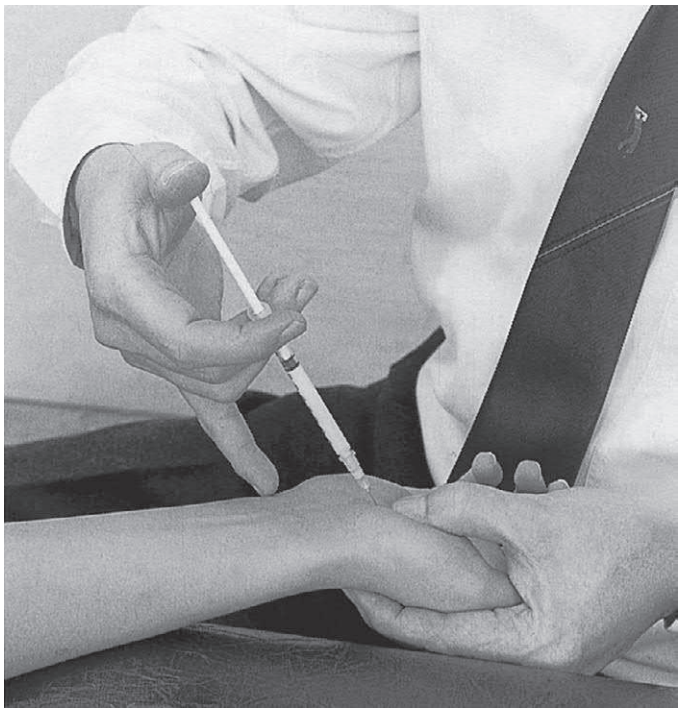

Fig 23.26 • Infiltration of the flexor carpi radialis.

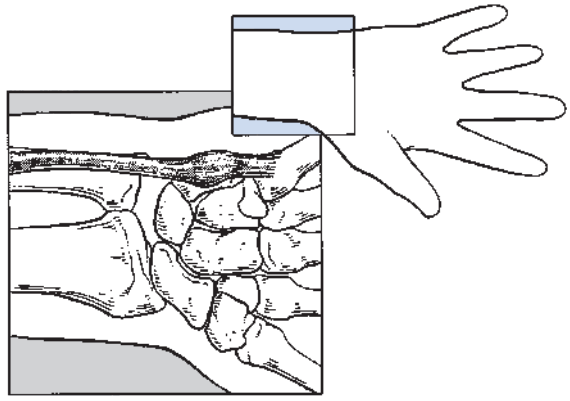

Fig 23.27 • The flexor carpi ulnaris.

Technique: deep transverse friction

The patient sits with the arm held in supination and the hand hanging over the edge of the couch. The therapist, facing the patient, extends the patient's wrist with the contralateral hand and imparts friction with the thumb of the other hand. Counterpressure is given at the dorsal aspect of the patient's wrist (Fig. 23.28). Friction starts at the radial aspect of the tendon and finishes at the ulnar aspect.

Technique: infiltration

This technique is particularly useful for a lesion at the insertion of the tendon onto the fifth metacarpal bone. The patient's hand is brought into the same position as for friction. A 1 mL syringe, filled with 10 mg of triamcinolone acetonide and fitted with a 2 cm needle, is used. The tender area is located by palpation. The operator keeps the thumb on the painful spot during the whole procedure. After the needle is inserted, tendinous resistance should be felt before a series of droplets are deposited in contact with the bone (Fig. 23.29).

Fig 23.28 • Friction to the flexor carpi ulnaris.

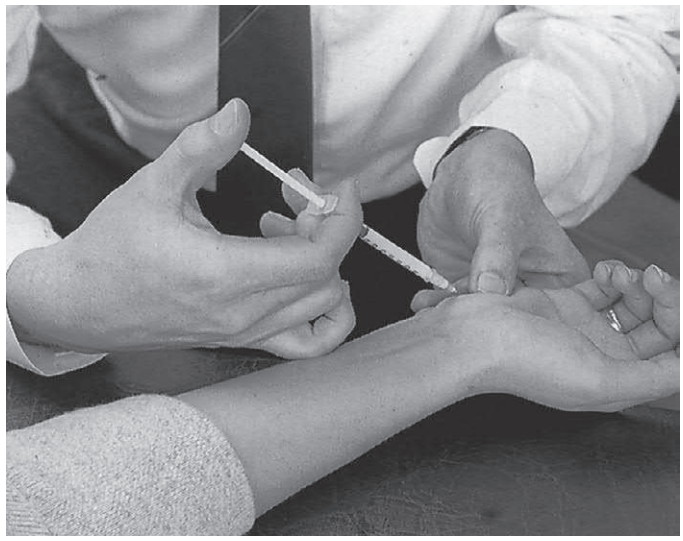

Fig 23.29 • Infiltration of the flexor carpi ulnaris.

Pisotriquetral disorders

Disorders of the joint between the pisiform and the palmar surface of the triquetrum may occur and, because of the attachment of the tendon to the pisiform bone, give rise to the same signs as in flexor carpi ulnaris tendinitis.[122] Disorders at the joint have been described as pisotriquetral arthritis[123] and pisotriquetral instability.[124] Direct pressure on the pisiform elicits pain. Side-to-side passive motion of the pisiform on the triquetrum will also lead to pain and crepitus. If pisotriquetral disorder is suggested, intra-articular steroid is required.[125] In recurrent cases, surgical removal of the pisiform may be necessary.[126,127]

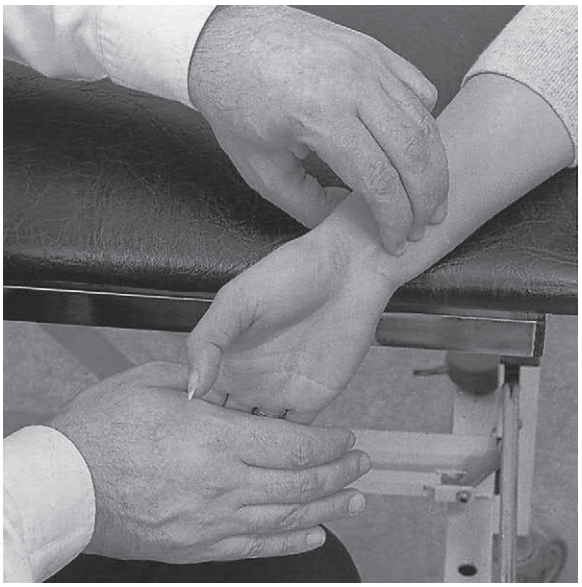

Fig 23.30 • Friction to the flexor digitorum profundus.

Flexor digitorum profundus

A lesion of the flexor digitorum profundus is either a mechanical tenosynovitis or a rheumatoid tenovaginitis. The former results from overuse. The pain is brought on by testing resisted flexion of the fingers. The lesion lies over an area 3–4 cm above the level of the carpus on the palmar aspect of the lower forearm. It is treated by deep transverse friction (see below) or by injection of a steroid suspension between the tendons.

A rheumatoid tenovaginitis is usually confined to one flexor tendon near the carpus. Early in its progress, diffuse swelling and local warmth on the palmar aspect of the forearm are the only signs.[128] Later, tenderness of the tendon may be found over a greater extent than that which occurs in overuse. After a few weeks, the swelling becomes nodular and local warmth persists.

The symptoms abate after one or two infiltrations with triamcinolone.

Swelling on a digital flexor tendon may sometimes lead to compression of the median nerve distal to the carpal tunnel, thus causing a partial syndrome (see the online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).

Technique: deep transverse friction (mechanical tenosynovitis)

The patient sits at the couch with the forearm supinated, the hand hanging over the edge of the couch. The therapist approaches the patient's arm from the radial side. With the ipsilateral hand, the wrist and fingers are brought into extension. The friction is applied with two or three fingertips of the other hand. Counterpressure is maintained with the thumb at the radial aspect of the patient's forearm (Fig. 23.30).

Friction starts at the ulnar side of the tendons and ends at the radial aspect, the therapist pulling the fingers towards him- or herself.

Box 23.2

Summary of disorders of the contractile structures

Pain

Extension

- Extensor carpi radialis longus/brevis
- Extensor carpi ulnaris
- Extensor indicis proprius
- Extensor digitorum

Flexion

- Flexor carpi radialis
- Flexor carpi ulnaris
- Flexor digitorum profundus

Weakness

Extension – bilateral

- Lead poisoning
- Bronchus carcinoma
- Other neurological conditions

Extension – unilateral

- Nerve root: C6–C8
- Radial nerve

Flexion

- Nerve root: C7, C8
- Other neurological conditions

Weakness

Weakness of wrist flexion is frequently the result of a C7 or C8 nerve root lesion, as well as more general neurological conditions:

- C7 *root palsy*: in addition, there is marked weakness of extension of the elbow; the triceps jerk is seldom affected.
- C8 *root palsy*: both the extensor carpi ulnaris and the flexor carpi ulnaris are weak. The result is that the wrist moves radially when resisted flexion is tested. Resisted extension and adduction of the thumb are also weak.

Disorders of the contractile structures are summarized in Box 23.2.

Disorders of the contractile structures. 353
Pain 353
Resisted extension. 353
Resisted flexion 357
Weakness 358
Rupture 358
Nerve lesions 358

Disorders affecting the base of the thumb may cause pain over the radial aspect of the wrist. This is why the trapezium–first metacarpal joint and its neighbouring tendinous structures are tested in examination of the wrist.

Disorders of the inert structures

The only relevant passive test for the first carpometacarpal joint is backward movement during extension. Pain and/or limitation indicate a capsular lesion. In the majority of cases, it is the anterior aspect of the capsule that is affected and the joint is found to be tender anteriorly.

The three following conditions are quite common.

Rheumatoid arthritis

Both first carpometacarpal joints are frequently affected in rheumatoid arthritis and respond well to intra-articular triamcinolone. Surgery is seldom necessary but, if so, resection arthroplasty is preferred.[1]

Traumatic arthritis

The patient describes an injury to the thumb, usually overstretching. Discomfort and pain are experienced over the thenar area and the radial side of the wrist. The backward movement during extension elicits pain and is limited. The radiograph is negative.[1]

Spontaneous recovery may take many months. The condition can be treated either by intra-articular triamcinolone or by 2 weeks' treatment with deep transverse friction. Friction is given on alternate days and directed to the anterior and anterolateral capsuloligamentous structures.

Arthrosis

Arthrosis of the trapeziometacarpal joint, or 'rhizarthrosis', is very common. It occurs most frequently in middle-aged or postmenopausal women[2,3] and affects at least 1 in 3 women over 65 and a quarter of men over 75.[4] Rhizarthrosis is often bilateral and is sometimes found in association with arthrosis at the distal interphalangeal joints of the fingers.[5] The aetiology is still very unclear. There is evidence that ligament laxity[6] and trapeziometacarpal subluxation are important early events in the development of thumb arthrosis.[7]

The main symptoms are pain in the dorsoradial and thenar area of the hand and a loss of manual ability and grip strength. In the beginning the pain is cyclic and is felt only during particular activities. As the disease progresses, pain may become constant and may even be present at night. In the final stage, when there is gross joint destruction and subluxation, pain eases but weakness of grip and inability to pinch remain.

Inspection often reveals a dorsoradial prominence of the thumb metacarpal base secondary to subluxation and osteophyte formation. Later on, adduction and Z-deformity of the thumb develop[8]: the first metacarpal is displaced radially and dorsally and the metacarpophalangeal joint is in a hyperextended position. The thenar muscles are atrophic.

© Copyright 2013 Elsevier, Ltd. All rights reserved.

On examination, the combined extension–abduction movement is limited and extremely painful. Crepitus may be felt, especially when the joint is axially compressed and then circumducted – the 'grind' test.[9,10]

The radiographic changes in trapeziometacarpal osteoarthritis are classified into four stages, ranging from mild joint narrowing and subchondral sclerosis to complete joint destruction with cystic changes and bone sclerosis.[11] The final stage shows clear signs of sclerosis of the bone, gross osteophytes and a metacarpal that is displaced radially and dorsally. However, care must be taken to base the diagnosis not only on radiographic evidence, but also on symptoms and the physical examination. Most people with radiographic evidence of degeneration of the trapeziometacarpal joint remain asymptomatic and, when questioned, only 28% will admit to pain.[12]

Treatment

The treatment that is chosen depends on the stage of the arthrosis and the functional disability of the joint (Table 24.1). Classically, conservative treatment of osteoarthritis of the trapeziometacarpal joint includes analgesics, joint protection, strengthening exercises of the intrinsic and extrinsic muscles of the thumb, and splints.[13] Surgical management is recommended to relieve intractable pain.

In early arthrosis, deep transverse friction to the anterior and lateral aspect of the capsule can cause the pain to cease but does not influence mobility.

Later in the course of the condition, intra-articular triamcinolone can be tried. It usually has a temporary result only. An open label trial found that steroids had no benefit on carpometacarpal pain at 26 weeks,[14] while a randomized controlled trial evaluating steroids against placebo injection showed that steroids had no benefit in moderate to severe trapeziometacarpal osteoarthritis at 24 weeks.[15] However, the long-term results of triamcinolone are more effective when a traumatic arthritis has supervened.

During the last few decades, intra-articular injections with hyaluronic acid have been promoted as a valuable alternative to intra-articular injections with steroids.[16] A few open label trials[17,18] found that hyaluronic acid reduced pain and improved grip strength during 6-month follow-up, and two randomized controlled trials stated 'non-inferiority' of hyaluronic acid compared with steroids for pain relief at 26 weeks.[19,20]

Indications for surgical intervention in trapeziometacarpal arthritis are similar to those for arthroplasty of most joints: persistent pain, decreased function, instability, and failure of conservative management.[21,22] Surgical options vary with the stage and nature of the disease. In the early stages, trapeziometacarpal ligament reconstruction and tendon interposition procedures[23–27] have been shown to provide good symptomatic relief. For severe or late-stage disease, some have advocated arthrodesis of the trapeziometacarpal joint, assuming that there is good mobility of the joints proximal and distal.[28–30] Arthroplasty techniques have ranged from simple partial or complete trapeziectomy to various implant and ligament interposition and reconstructions.[31,32] These techniques have been generally indicated for stage II or greater disease once conservative management has failed.

Table 24.1 Summary of treatment of capsular disorders

Deep friction	Intra-articular injection	Surgery
–	Rheumatoid arthritis	Rheumatoid arthritis
Traumatic arthritis	Traumatic arthritis	–
Early arthrosis	Moderate arthrosis	Severe arthrosis

Technique: intra-articular injection

The patient lies supine on a high couch. The physician takes the patient's outstretched hand on to his or her knee, with the thumb uppermost. With one hand the joint is palpated in the anatomical snuffbox. Caution is necessary not to mistake the edge between the metacarpal bone and an osteophyte for the joint line. With the other hand, slight traction (arrow in Fig. 24.1) and ulnar deviation are needed to open the joint. If the patient relaxes properly, the joint line can be identified by a small gap, which is marked with the nail of the palpating thumb.

A 1 mL syringe, filled with 10 mg triamcinolone acetonide, is fitted with a thin needle, 2 cm long. Traction is applied again. The needle enters at the marked line just proximal to the first metacarpal on the extensor surface. Care must be taken to avoid the radial artery and the extensor pollicis tendons. To avoid the radial artery, the needle should enter towards the dorsal (ulnar) side of the extensor pollicis brevis tendon. The needle is then directed at an angle of 60° to the horizontal. At about 1 cm, the tip is felt entering the joint capsule. If it strikes bone at less than 1 cm, the position is not intra-articular and should be adjusted until the tip is felt entering the joint. The injection is then given.[33]

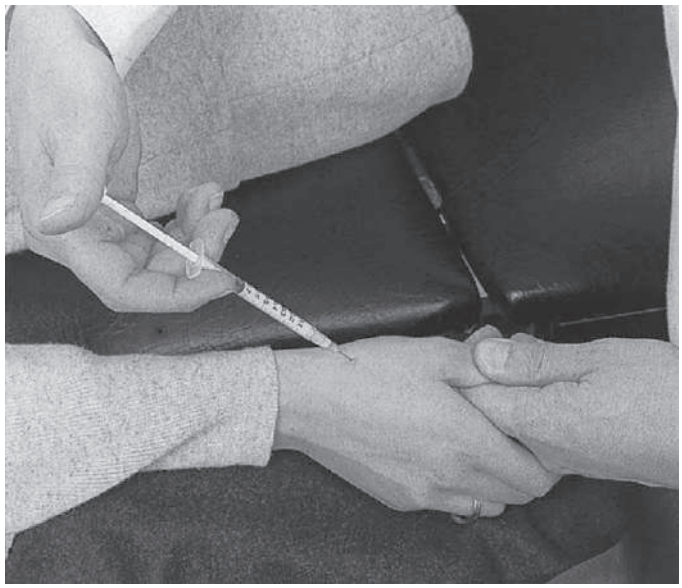
The injection is stopped when considerable resistance is encountered, which may happen after 0.5 mL has entered the joint. The patient should be warned of after-pain, which may last for up to 24 hours. Exertion should be avoided for a few days, and review carried out after 2 weeks. One to two injections should suffice.

Technique: deep transverse friction to the anterior capsule

The patient sits with the supinated arm resting on the couch, the hand hanging over its edge. The therapist extends the patient's wrist and brings the dorsum of the ipsilateral hand in contact with the dorsum of the patient's hand; with the thumb the patient's thumb is directed into extension and a slightly backward position, so as to stretch the anterior capsule. Pain should be avoided.

The joint line between the trapezium and the first metacarpal is identified. It should not be confused with the joint line between the scaphoid and the trapezium, which lies just a centimetre more proximal.

With the thumb of the other hand, friction is performed parallel to the joint line. Counterpressure is taken by the fingertips on the proximal interphalangeal joints of the supporting hand (Fig. 24.2a).



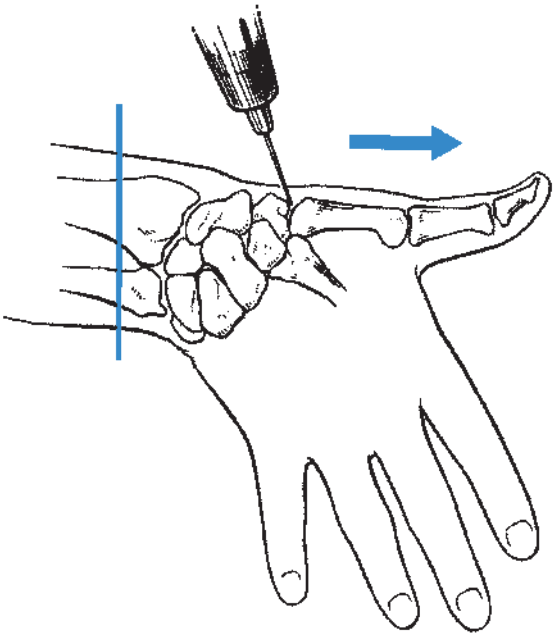


Fig 24.1 • Intra-articular injection.

Technique: deep transverse friction to the anterolateral capsule

The patient's forearm is brought into neutral position. With the contralateral hand, the therapist brings the patient's wrist into ulnar deviation and the thumb into flexion, which stretches the capsule.

Friction is imparted at the joint line and parallel to it with the thumb of the other hand. Counterpressure is given with the fingers on the ulnar aspect of the patient's hand (Fig. 24.2b). It is important to ensure that the thumb remains palmar to the extensor pollicis brevis tendon, in that the lesion lies at the anterolateral aspect of the joint.

Friction is given 2–3 times a week for about 2–3 weeks. The results are good in traumatic arthritis and early arthrosis.

Disorders of the contractile structures

Pain

Resisted extension

This movement seldom causes pain in isolation. Because the extensor brevis and abductor longus tendons lie together in one tendon sheath, in the majority cases resisted abduction is also painful.

Abductor pollicis longus, and extensor pollicis brevis (first tendon sheath)

Intersection syndrome

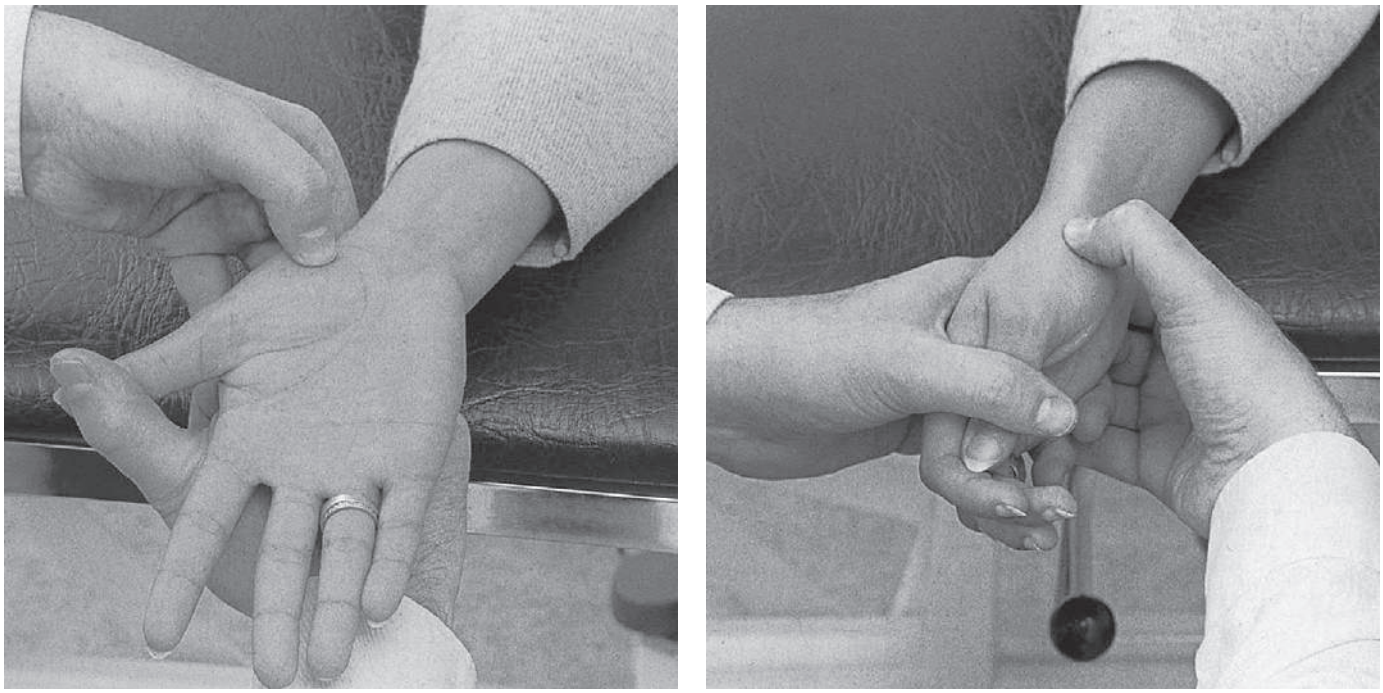
Intersection syndrome is a specific painful disorder of the forearm that is relatively common but sometimes not correctly diagnosed clinically. It has also been referred to in the literature by the terms 'peritendinitis crepitans', 'oarsmen's wrist', 'crossover syndrome', 'subcutaneous perimyositis', 'squeaker's wrist', 'bugaboo forearm' or 'abductor pollicis longus syndrome'.[34] Dobyns *et al* introduced the term 'intersection syndrome', an anatomical designation related to the area in which the musculotendinous junctions of the first extensor compartment tendons (abductor pollicis longus and extensor pollicis brevis tendons) intersect the second extensor compartment tendons (extensor carpi radialis longus and extensor carpi radialis brevis tendons), at an angle of approximately 60° (Fig. 24.3).[35]

The most plausible pathophysiology is that of a peritendinitis at the intersection of the two tendinous compartments, which spreads upwards to the musculotendinous junction. The lesion may also lie somewhat more proximally in the muscle bellies; hence the name, 'myosynovitis'.[36] This is shown by magnetic resonance imaging (MRI) findings demonstrating the presence of peritendinous oedema concentrically surrounding the second and the first extensor compartments, beginning at the point of crossover, 4–8 cm proximal to the Lister tubercle and extending proximally.[37]

The lesion always results from occupational overuse or after unusual effort. It is often associated with sports-related activities, such as rowing,[38] canoeing, playing raquet sports, horse riding and skiing.[39,40]

The patient mentions crepitus during wrist movements. On examination, resisted extension and resisted abduction of the thumb are painful. Some passive wrist movements can also be painful. This puzzling phenomenon can be explained by the fact that discomfort is increased not only by movements that stretch the tendons (e.g. passive flexion of the thumb and ulnar deviation of the wrist), but also by every movement that pushes the tendon into the tendon sheath (e.g. thumb extension, radial deviation and flexion or extension of the wrist).

On palpation, tenderness and swelling are found in a region about 4–8 cm proximal to the Lister tubercle, where the first and second extensor compartment tendons cross. In cases of



(a) (b)

Fig 24.2 • Friction to the anterior (a) and anterolateral capsule (b).

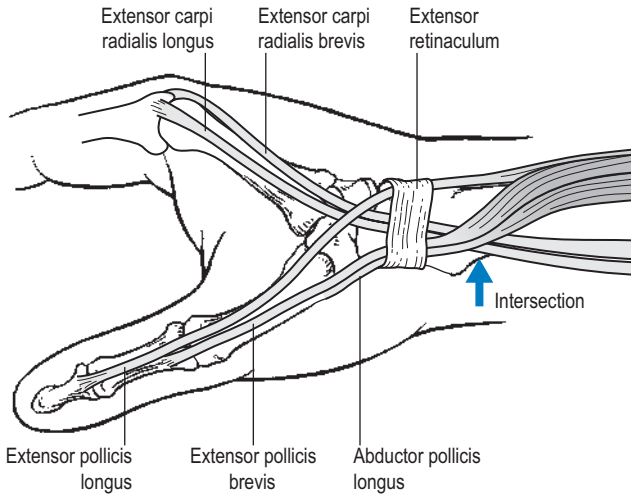


Fig 24.3 • Intersection syndrome: the lesions lies at the intersection of compartments one and two, between 4 and 8 cm proximal of Lister's tubercle.

recent onset, a silky crepitus during active wrist movements can be palpated.

The differential diagnosis is made from suppurative inflammation of the tendon sheaths, de Quervain's tenosynovitis (see below), early chronic evolutive polyarthritis, arthrosis of the trapezium–first metacarpal joint of the thumb, lesions of the radial collateral ligament, and tendinosis of the extensor carpi radialis longus and/or brevis.

After an initial stage involving a great deal of pain and disability, the condition may evolve towards a more chronic state. Spontaneous cure may take many months and only occurs when the patient gives the wrist complete rest. Treatment with non-steroidal anti-inflammatory drugs, immobilization and infiltration of steroid or local anaesthetic does not always lead to swift, full and permanent recovery. Deep transverse friction, however (three times a week, over 2 weeks), is extremely successful in this condition, to such a degree that all other treatments must be considered obsolete. This view was confirmed by Paton in 1978,[41] who had used deep transverse friction since 1947 without failure. Bisschop describes 62 cases – 48 men and 14 women – that he treated between 1975 and 1982. The onset was recent (less than 6 weeks) in 55 cases and chronic (2.6 months on average) in 7. Forty-eight of the patients received other treatments, with poor results: steroid infiltration in 16 cases; local anaesthetic infiltration in 4; plaster immobilization in 13 (average 1.8 weeks); partial immobilization with tape in 2; ice friction in 4; physiotherapy in 9. Deep transverse friction – performed three times a week for 15 minutes – led to complete recovery in all but one case, with an average of 6.7 treatments, and 39 patients improved from the first treatment onwards.[42]

Technique: deep transverse friction

The patient's forearm rests in pronation on the couch, the hand over its edge. With the contralateral hand the therapist brings the patient's wrist and thumb into flexion (Fig. 24.4). This stretches the tendons. The other hand takes hold of the patient's wrist; the thumb then lies flat on the site of the lesion.

Movement starts with the thumb at the ulnar side of the tendons. By supination of the arm, the thumb passes over the tendons to the radial aspect. Repeated movement results in a to-and-fro movement.

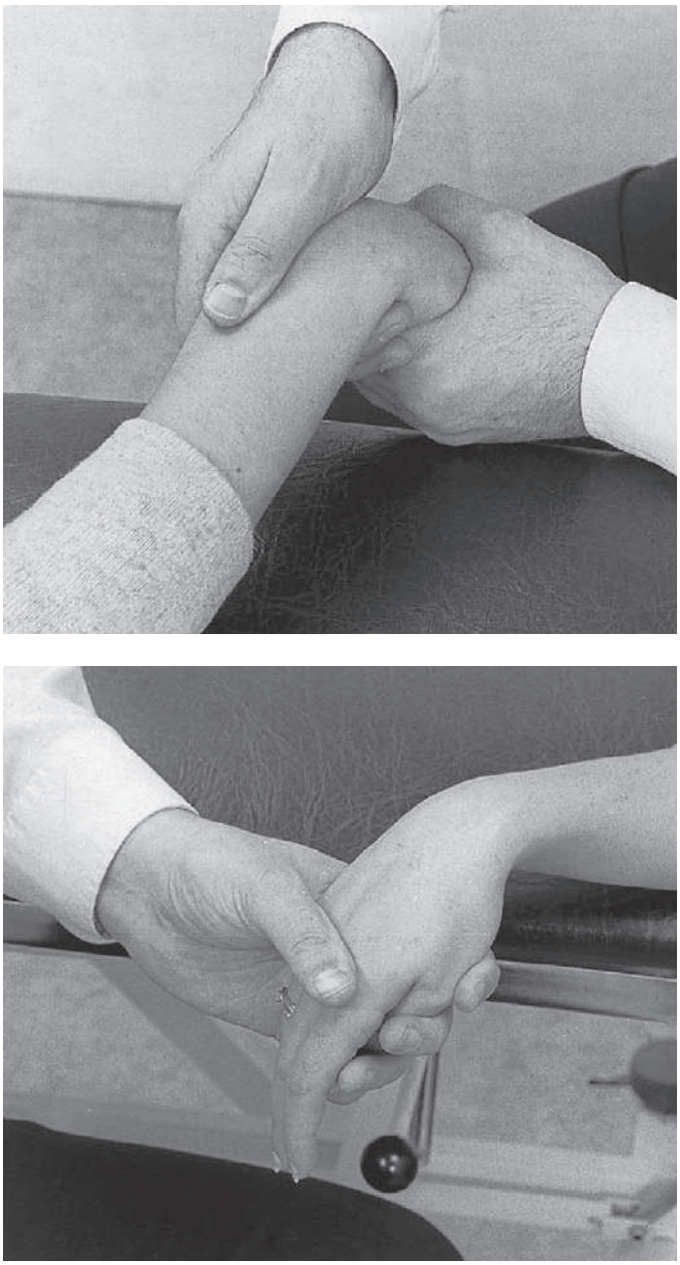

Fig 24.4 • (a) Friction to the abductor pollicis longus, and extensor pollicis longus and brevis; (b) detail of hand fixation.

Tenovaginitis of the first compartment

This is a lesion of the common tendon sheath of the abductor pollicis longus and extensor pollicis brevis tendons at the wrist. Two conditions can be distinguished – mechanical and rheumatoid – that require the same treatment.

Mechanical tenovaginitis

Fritz de Quervain, a Swiss physician, is given credit for first describing this condition in a report of five cases in 1895.[43] The disorder has since been known as de Quervain's disease, tenovaginitis stenosans or styloiditis radii.[44] Although the term 'stenosing tenosynovitis' is frequently used, the pathophysiology of de Quervain's disease does not involve inflammation. On histopathological examination, de Quervain's disease is not characterized by inflammation, but by thickening of the tendon sheath and most notably by the accumulation of mucopolysaccharide, an indicator of myxoid degeneration.[45] Therefore de Quervain's disease should be seen as a result of intrinsic, degenerative mechanisms rather than extrinsic, inflammatory ones. The term 'styloiditis radii' is also a misnomer as the lesion is not bony or periosteal.

Incidence of de Quervain's disease has risen considerably in recent decades.[46] It occurs mostly in women, with an average age of 47, and almost never appears before the age of 30.[47] A significant association was noted in patients with de Quervain's disease after pregnancy.[48] The cause is presumed to be endocrine in origin and similar to the carpal tunnel syndrome described during pregnancy and the lactating postpartum period.[49]

Very often de Quervain's disease comes on spontaneously, but it can also result from overuse. Swift repeated movement with exertion of considerable strength is a possible cause.[50]

Symptoms consist of pain and/or tenderness at the radial styloid, sometimes radiating down to the thumb and up the lower forearm. Often there is localized swelling over the distal part of the radius. The patient finds the symptoms very disabling, preventing the hand from being used properly. Triggering may complicate the more severe forms[51] and demonstrates a more recalcitrant course when treated non-operatively.[52]

On examination, resisted extension and abduction of the thumb are painful. Passive movements of wrist and thumb also cause pain, as they slide the tendon up and down within its irritated sheath, so setting up painful friction. Very occasionally, resisted radial deviation of the wrist also hurts because the thumb tendons assist this movement. Finkelstein's test (deviating the wrist to the ulnar side, while the patient makes a fist with the thumb inside the fingers) reproduces the symptoms.[53] Some consider this pathognomonic.[54,55] Because the lesion is a tenovaginitis, crepitus is always absent but localized swelling can often be palpated.

Palpation must be performed over a wide area, as there are three possible localizations for the lesion[56]: at the tenoperiosteal insertion of the abductor pollicis longus into the base of the first metacarpal bone; at the level of the carpus; and at the groove on the lower extremity of the radius (Fig. 24.5).

It is important not to be misled by the localization of tenderness. Very often, the styloid process of the radius is more tender than the tendon itself, which has led to the lesion being described as styloiditis radii. This is a misnomer, since it gives the impression that the lesion is bony and lies at the styloid process. That this is not so can be shown during clinical examination and the progress of treatment: pain increases when resisted movements of the thumb are tested and disappears as the result of treatment directed to the tendons. Styloiditis radii does not exist and is another example of the phenomenon that Cyriax called 'associated tenderness'.

Spontaneous recovery may take 3–4 years. However, treatment is quite simple. The lesion responds remarkably well to one or only occasionally two injections with triamcinolone suspension,[57] provided that the injection is correctly placed between tendon and tendon sheath. The effectiveness of injection therapy is often attributed to the anti-inflammatory effects of corticosteroids but the exact mechanism of action remains unclear. Reviews of the effectiveness of corticosteroid injection

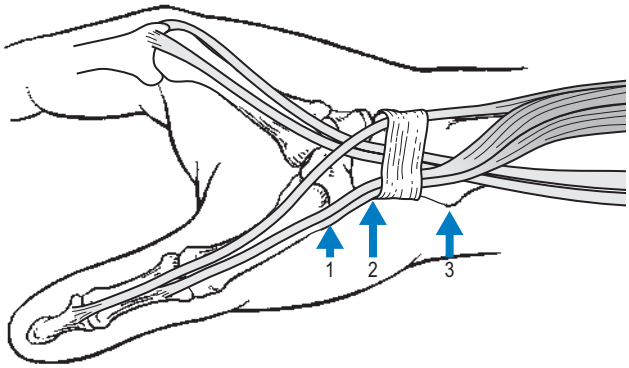

Fig 24.5 • Three possible localizations for mechanical tenovaginitis in the first compartment: 1, insertion of abductor pollicis longus; 2, carpus; 3, distal radius.

for de Quervain's disease showed success rates between 78 and 89%.[58–61] In a controlled, prospective, double-blind study by Zingas *et al*, the accuracy of infiltration in the first extensor compartment was defined and correlated with clinical relief of the disorder. The authors concluded that only those patients in whom the steroid solution really entered the tendon sheath were cured.[62] Failure to inject may therefore be caused by misplacement of the needle or by anatomical variations of the tendon sheaths. Anatomical[63] and ultrasonographic[64] studies confirm the observations during surgery[65] that the first extensor compartment may contain a septum separating the extensor pollicis brevis tendon from the abductor pollicis longus. During a study of variants of the tendon of the abductor pollicis longus in 110 upper extremities, Melling *et al* found an intertendinous septum in 30%.[66] This was recently confirmed by Gousheh.[67] Leslie *et al* found that most wrists for which injection fails have a separate extensor pollicis brevis compartment at surgical release. They recommend a second, more dorsal injection in patients when the first has failed.[68]

Other treatments, such as deep transverse friction, ointments and immobilization, should be regarded as obsolete. Decompressive surgery is only used in those rare cases that do not respond to conservative treatment.[69] Simple decompression of both tendons and partial resection of the extensor ligament give excellent long-term results.[70] For those patients who have a septum in the first extensor compartment, Yuasa and Kiyoshige suggest decompressing only the extensor pollicis brevis subcompartment.[71]

Rheumatoid tenosynovitis

In this condition, there is a striking discrepancy between symptoms and signs. Contrary to a mechanical disorder, which shows little swelling and gross disability, rheumatoid tenosynovitis presents with marked thickening of the tendon sheath but not a great deal of pain.

The condition responds well to one or two injections with triamcinolone suspension. There is no tendency to recurrence.

Technique: injection

The patient lies supine on a high couch, the forearm halfway between pronation and supination and supported on the operator's thigh. The wrist is held in ulnar deviation and the thumb slightly flexed. The tendons are easily identified when the patient is asked to extend and abduct the thumb actively. The border between the two tendons is identified and marked. The common sheath containing the extensor pollicis brevis and the abductor pollicis longus tendons is pinched between thumb and index finger.

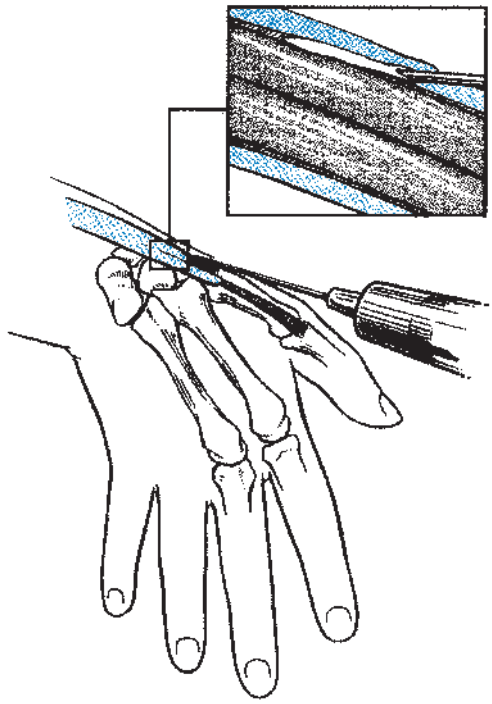

Fig 24.6 • Infiltration of the abductor pollicis longus and extensor pollicis brevis.

A 1 mL syringe is filled with 10 mg triamcinolone acetonide and fitted with the thinnest possible needle. A point is chosen just proximal to the base of the first metacarpal bone and the needle is thrust in almost horizontally between the two tendons so that the tip comes to lie in the common tendon sheath. When the fluid is forced in, the palpating fingers feel a small, sausage-shaped swelling along the course of the tendons (Fig. 24.6); 0.5–1 mL of fluid can be injected before counterpressure is experienced on the barrel of the syringe.

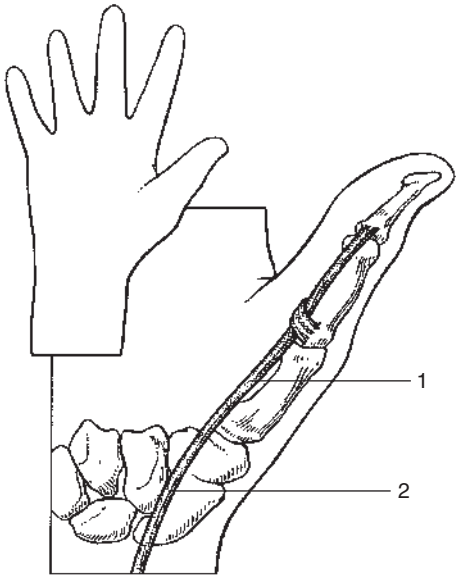

Fig 24.7 • The flexor pollicis longus: 1, level of the first metacarpal; 2, level of the carpus.

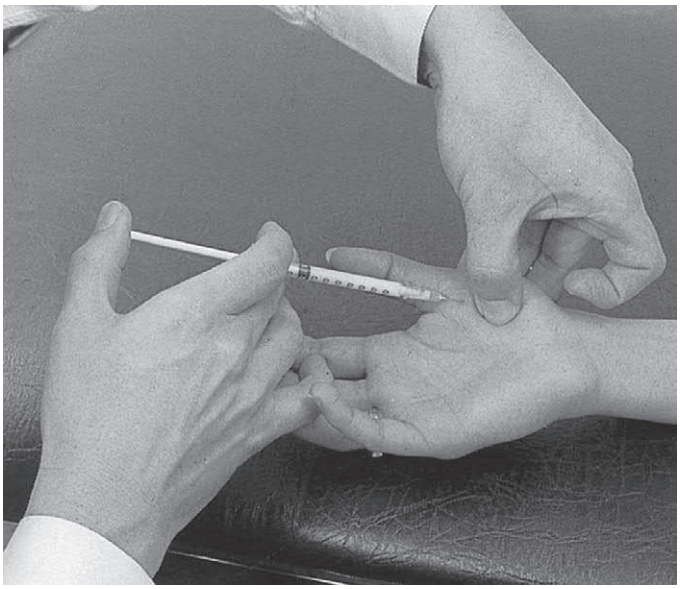

Fig 24.8 • Infiltration of the flexor pollicis longus.

Because of the risk of lipodystrophy from subcutaneous injection, care must be taken that fluid does not flow back into the subcutaneous tissue when the needle is withdrawn.

Extensor pollicis longus

Pain on resisted extension of the thumb is rare and is the consequence of a lesion of the tendon of the extensor pollicis at its carpal extent. Overuse ('drummer boy palsy'), forced wrist extension, direct trauma or distal fractures of the radius may all precipitate an extensor pollicis longus tendinitis.[72] Pain is felt over the dorsal aspect of the wrist and can be reproduced by testing resisted extension of the thumb.

Treatment consists of deep transverse friction and the condition takes about 2 weeks to cure.

Resisted flexion

Flexor pollicis longus

Tenosynovitis of the flexor pollicis longus may present at two different sites which can be differentiated by palpation: at the level of the first metacarpal (Fig. 24.7), where it responds well to an infiltration of triamcinolone but not to deep transverse friction; and at the level of the carpus, where crepitus may be present. Deep transverse friction is then effective.

Technique: infiltration

The patient sits with the hand resting on the couch. When the patient is asked to flex the thumb against resistance, the tendon can be palpated and the lesion thus precisely located. The tender spot along the first metacarpal shaft is identified. A syringe filled with 10 mg of triamcinolone suspension fitted with the thinnest possible 2 cm needle is used. The needle is inserted at the level of the tenderness and drug is infiltrated using several withdrawals and reinsertions along the inflamed tendon (Fig. 24.8).

Fig 24.9 • Friction to the flexor pollicis longus.

Technique: friction

The patient sits with the hand on the couch. The therapist sits in front of the patient's hand. With the contralateral hand, the wrist and thumb are brought into extension. With the thumb of the other hand, the tender spot is identified, which is deep in between the tendons of flexor carpi radialis and palmaris longus, level with the carpus. The tendon can be felt when the patient is asked to perform flexion and extension of the thumb. Counterpressure is applied with the fingers at the dorsum of the patient's wrist (Fig. 24.9). Friction is started at the radial side of the tendon and ended at the ulnar side. The movement

is performed by a pronation–supination movement of the forearm.

Trigger thumb

A tendinous node frequently forms on the flexor pollicis longus and becomes engaged in the tendon sheath. The mechanism is as follows: the nodule catches the proximal end of the fibrous sheath at the carpometacarpal pulley with flexion of the thumb, causing the symptoms of trigger thumb with extension. Initially, patients experience intermittent pain, swelling and triggering of the involved digit. In the most severe state, the digit becomes locked in the flexed position, after which the patient has to extend the joint passively with the help of the other hand. A snap and pain may accompany this.[73] This typical history suggests the diagnosis, because resisted movements of the thumb do not elicit pain. The tender node can be palpated, just proximal to the head of the first metacarpal bone, and is felt to move when the thumb is flexed and extended.

Spontaneous cure may occur but takes several months.[74] One infiltration with triamcinolone is usually curative.[75] When the condition recurs, simple surgery to split the tendon sheath longitudinally will give lasting relief from symptoms.[76]

Technique: infiltration

The patient lies supine on the couch and the operator sits adjacent. The patient's hand is placed on the operator's thigh, palm upwards. A tuberculin syringe is filled with 1 mL of a 10 mg/mL triamcinolone solution and attached to a thin needle, 2 cm long. With one finger the tender node, which lies just proximal to the metacarpophalangeal joint, is identified. The needle is inserted about 1 cm distally and directed toward the palpating finger (Fig. 24.10). Half of the solution is infiltrated around, the rest into the nodule.

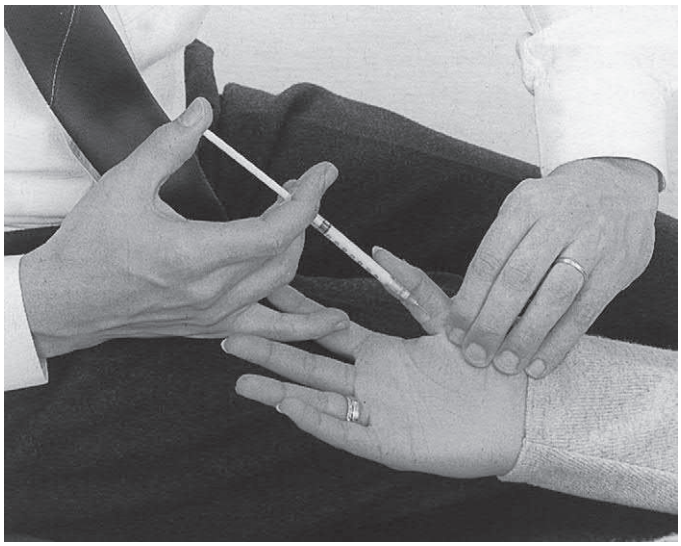

Fig 24.10 • Infiltration of the flexor pollicis longus in trigger thumb.

The patient should be warned that there may be considerable after-pain. The result is evaluated after 2 weeks; a second infiltration is needed only rarely.

Weakness

Weakness of one or several muscles of the thumb may follow either rupture of a tendon or a nerve lesion.

Rupture

A tendinous rupture is easily detected by clinical examination.

Rupture of the extensor pollicis longus tendon occurs rarely after a fracture at the distal extremity of the radius (Colles' fracture); it usually happens some weeks later as the result of the tendon being frayed by a bony callus.[77,78] It is also seen in patients with advanced rheumatoid arthritis.

Surgical repair is the appropriate treatment and, in acute cases, this should be done with some urgency to prevent a second rupture, which often follows.[79,80]

Nerve lesions

Nerve lesions causing weakness of the thumb may lie at different levels (Table 24.2).

- *C8 nerve root*: compression of the C8 nerve root, usually caused by a C7 disc protrusion, leads to weakness of adduction and extension of the thumb. This is accompanied by weakened ulnar deviation of the wrist.
- *Brachial plexus*: when the lower trunk of the brachial plexus becomes affected at the thoracic outlet – for example, as the result of compression by a cervical rib – there may be marked wasting of the abductor pollicis brevis, which does not necessarily cause weakness of abduction of the thumb. In advanced cases, weakness of the muscles innervated by the median and ulnar nerves may be detected.

Table 24.2 Nerve lesions and weakness of the thumb

Weakness	Muscle	Nerve
Extension	Extensor pollicis longus Extensor pollicis brevis	Radial Radial
Flexion	Flexor pollicis longus Flexor pollicis brevis	Anterior interosseous Ulnar/(median)
Abduction	Abductor pollicis longus Abductor pollicis brevis	Posterior interosseous Median

Box 24.1

Summary of disorders of the thumb

Disorders of the joint capsule

- Rheumatoid arthritis
- Traumatic arthritis
- Arthrosis

Disorders of the contractile structures

Pain

Resisted extension

- Abductor pollicis longus
- Extensor pollicis longus/brevis
- Abductor pollicis longus
- Extensor pollicis brevis
- Extensor pollicis longus

Resisted flexion

- Flexor pollicis longus
- Trigger thumb

Weakness

- Rupture
- Nerve lesions

- *Median nerve*: long-standing compression of the median nerve in the carpal tunnel may lead to slight weakness and wasting of the thenar muscles.
- *Posterior interosseous nerve*: a lesion of the posterior interosseous nerve at the elbow results in weakness of thumb abduction and finger extension (see online chapter *Nerve lesions and entrapment neuropathies of the upper limb*).
- *Ulnar nerve*: entrapment of the ulnar nerve in the hand gives rise to weakness of thumb adduction.

Disorders of the thumb are summarized in Box 24.1.

Introduction

Thoracic or abdominal wall pain is a common complaint and poses a major diagnostic challenge to physician and therapist.

The pain is often referred from visceral disorders, although the frequency of musculoskeletal lesions of the thorax and the abdomen should not be underestimated. A physician not familiar with the musculoskeletal disorders of the region could be tempted to ascribe unexplained pain to vague lesions such as intercostal neuralgia, neuritis, cardiac neurosis, pleurodynia or rib syndromes. Again, lack of an exact diagnosis leads to inadequate and unsuccessful treatment. The absence of a precise (orthopaedic) diagnosis can, to a certain extent, be a consequence of the complexity of the region itself. However, another important reason is the lack of an appropriate clinical approach to this part of the body. Thorough examination should not be restricted to the routine visceral examination (e.g. auscultation, percussion and palpation) but also must include proper orthopaedic and neurological tests. Although a large number of reliable technical investigations for detecting all types of visceral disorders are available, the same cannot be said when it comes to musculoskeletal disorders, for which technical investigations are often of limited diagnostic value.

Clinically, the thoracic region is approached in a different way from the cervical or the lumbar spine because it behaves differently in many aspects.

Principal differences between the thoracic and the lumbar and cervical spines

Visceral versus musculoskeletal pain

Because referred pain from visceral problems can mimic pain of musculoskeletal origin and vice versa, the first step towards diagnosis must always be to differentiate these two categories. The character of the pain is usually of little help in the differential diagnosis because it has the same features in both. Pain referred from heart, lungs and intestines is usually poorly localized and vaguely delineated, and is referred to a segmental or multisegmental distribution. The behaviour of the pain may also mislead the examiner. One of the main characteristics of pain in lesions of moving parts is that it is brought on by posture and movement. This is also the case in thoracic lesions: if the patient's symptoms depend on activity rather than on visceral function, a cause originating from moving parts should be considered. However, it is important to keep in mind the

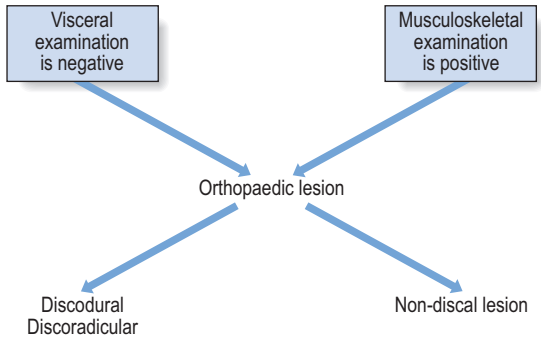

Fig 25.1 • Routine for differentiation between thoracic and abdominal wall pain.

fact that posture, physical activity, a deep breath or a cough may also influence visceral pain in the thorax or abdomen.

The best method of differentiating is to work in two complementary ways: exclusion of any visceral disorder through a thorough internal check-up, together with positive confirmation of a provisional orthopaedic diagnosis (Fig. 25.1). This routine will also safeguard against unnecessary technical investigations and delays in diagnosis and treatment.[1–3]

Discal lesions

Discodural and discoradicular interactions are well-known causes of cervical and lumbar pain.

In a discodural lesion, a shifted component of the disc impinges on the dura and causes pain that has multisegmental characteristics (crossing the midline and occupying several dermatomes). Discodural conflicts are characterized by two sets of symptoms and signs: articular and dural (see Ch. 33).

In a discoradicular lesion, the subluxated disc component impinges on the nerve root and its dural sleeve. The pain and paraesthesia that result are strictly segmental. Discoradicular conflicts are characterized by three sets of symptoms and signs: articular, root and cord.

Disc lesions also commonly occur in the thoracic spine but often show characteristics that are quite different from those found at the lumbar and cervical spines.

- *The articular signs are subtle*: a discodural interaction at the cervical or lumbar level usually presents with a clear partial articular pattern: some movements hurt or are limited and others do not, always in an asymmetrical way. This is not so in the thoracic spine. Because of the rigidity of the thorax, such an obvious pattern is seldom found. Very often, only one of the six passive movements, usually a rotation, is positive and then only slightly so. Therefore diagnosis in the thoracic spine is more tentative and may have to be based on smaller, subtler abnormalities.
- *Neurological deficit is seldom encountered in a thoracic disc lesion*: whereas some degree of neurological deficit is a common finding in cervical or lumbar posterolateral disc lesions, muscular weakness is rarely detectable in thoracic discoradicular lesions. Also, disturbance of sensation is very rare. This absence of neurological signs is probably the outcome of the location of the nerve root in the intervertebral foramen, where it lies mainly behind the lower aspect of the vertebral body and less behind the disc (see online chapter *Applied anatomy of the thorax and abdomen*).
- *There is no tendency to spontaneous recovery*: in the lumbar and cervical spines there is usually a spontaneous cure for root pain, which seldom lasts longer than 4 months at the cervical level and 12 months at the lumbar level. At the thoracic level, no such tendency exists and constant root pain can persist for many years.
- *Protrusions can usually be reduced*: although thoracic disc lesions are more difficult to diagnose, they are easily and effectively cured. Protrusions – no matter how long they have been present, or whether they are posterocentral or posterolateral, or soft or hard – can usually be reduced by 1–3 sessions of manipulations. Unlike at the lumbar or cervical levels, time is not a criterion for reducibility. Hence a disc displacement may well prove reducible after constant root pain, even of several years' standing. Traction is seldom required because the protrusions are usually of the annular type.

Non-discal lesions

In the thorax, non-discal musculoskeletal lesions are also encountered frequently. To name but a few: ribs, rib joints, cartilage, intercostal and abdominal muscles. This is in contrast to the cervical and lumbar spines, where lesions of the disc are the principal cause of dysfunction and pain.

Referred pain

Both musculoskeletal and visceral lesions can be the source of pain referred to the thoracic and/or abdominal wall.

Pain referred from musculoskeletal structures

Dura mater and nerve roots

Pain originating from the dura mater is referred in a multisegmental way: it crosses the midline and may cover several consecutive dermatomes (see p. 18). A possible explanation for this phenomenon may lie in its multisegmental origin, which is reflected in the considerable overlap between the fibres of the consecutive sinuvertebral nerves innervating its anterior aspect.[4] Recent research has demonstrated that dural pain may spread over eight segments with considerable overlap between adjacent and contralateral dura mater.[5] This may be an explanation for the fact that lower cervical discodural conflicts may produce pain that spreads into the upper thoracic level (Fig. 25.2a) or that lumbar dural pain causes pain in the lower thoracic region (Fig. 25.2b).

Pain originating from a nerve root sleeve has a strict segmental reference and is restricted to the borders of the dermatome.

Thoracic disc lesions may thus cause referred pain in the thorax, not only as the result of extrasegmental reference in

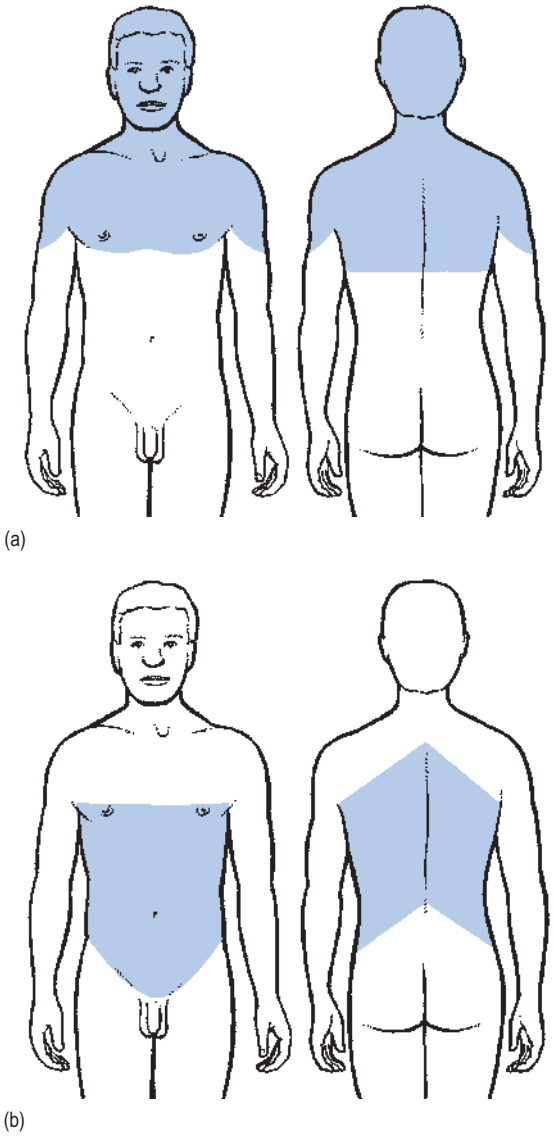

Fig 25.2 • Extrasegmental pain: (a) cervical origin; (b) thoracic origin.

the case of discodural contact, but also when a discoradicular interaction has been created. However, cervical and lumbar discal lesions may also be the origin of thoracic referred pain.

Cervical disc lesions

Some cervical disc lesions may cause pain in the thoracic region.

Cervical discodural interactions

Low cervical discodural interactions very often result in unilateral interscapular pain, usually felt above T6 and spread over several dermatomes. The pain is also often referred to the sternum and the precordial region. Exceptionally, the pain may be felt only in the anterior chest, so misleading almost all clinicians. It is important to remember that extrasegmentally referred pain of cervical origin never spreads into the upper limb (see p. 18).

Cervical discoradicular interactions

A posterolateral disc protrusion compressing the C5, C6, C7 or C8 nerve root gives rise to unilateral root pain characterized mainly by a sharp pain down the upper limb. There may also be some degree of scapular pain, especially in C7 lesions, but this is usually not very severe (see p. 156).

The C4 nerve root gives rise to pain in the trapezius area, the infraclavicular chest and the scapular region above the scapular spine.

Thoracic disc lesions

Thoracic discodural and discoradicular interactions are common causes of referred pain in the thoracic and abdominal region.

Thoracic discodural interactions

It is important to note that extrasegmental pain from a postero-central thoracic disc protrusion usually remains in the trunk itself, where it can spread anteriorly and/or posteriorly over several segments (see Fig. 25.2b). It seldom spreads into the neck or into the buttocks. The pain is usually unilateral and spreads over several segments. Exceptionally it is felt centrally at the spine, radiating bilaterally towards the sides.

Thoracic discoradicular interactions

A posterolateral impingement on the two upper thoracic roots produces pain felt in the arm (Fig. 25.3). If the T1 nerve root is involved, pain may be referred to the ulnar side of the forearm, whereas a T2 nerve root compression gives rise to pain felt over the inner aspect of the arm from the elbow to the axilla, at the anterior aspect of the upper thorax around the clavicle and at the posterior upper thorax around the scapular spine. Clinically the upper two thoracic segments belong to the cervical spine and are thus most easily examined with the cervical segments.

If the 3rd–12th root is compressed, pain spreads unilaterally as a band around the thorax, sometimes reaching anteriorly as far as the sternum (see Fig. 25.3).

The following landmarks may be helpful in determining which root is involved:

- If pain is felt around the nipple, the T5 nerve root is at fault.
- Because the epigastrium belongs to the T7 and T8 segments, pain present here arises from structures of the same origin.
- Pain at the umbilicus and in the iliac fossa may point to a lesion of the T9, T10 and T11 nerve roots.
- If the T11 or T12 thoracic root is compressed, pain may be referred to the groin or even further down to the testicle.

Lumbar disc lesions

Lumbar discodural interactions

Extrasegmentally referred pain from a lumbar discodural interaction is usually felt in the lumbar area and the abdomen, sometimes radiating into the lower limbs. The pain seldom spreads into the lower thorax.

Lumbar discoradicular interactions

Segmentally referred pain from L1, L2 and L3 nerve roots may be felt in the side and in the groin.

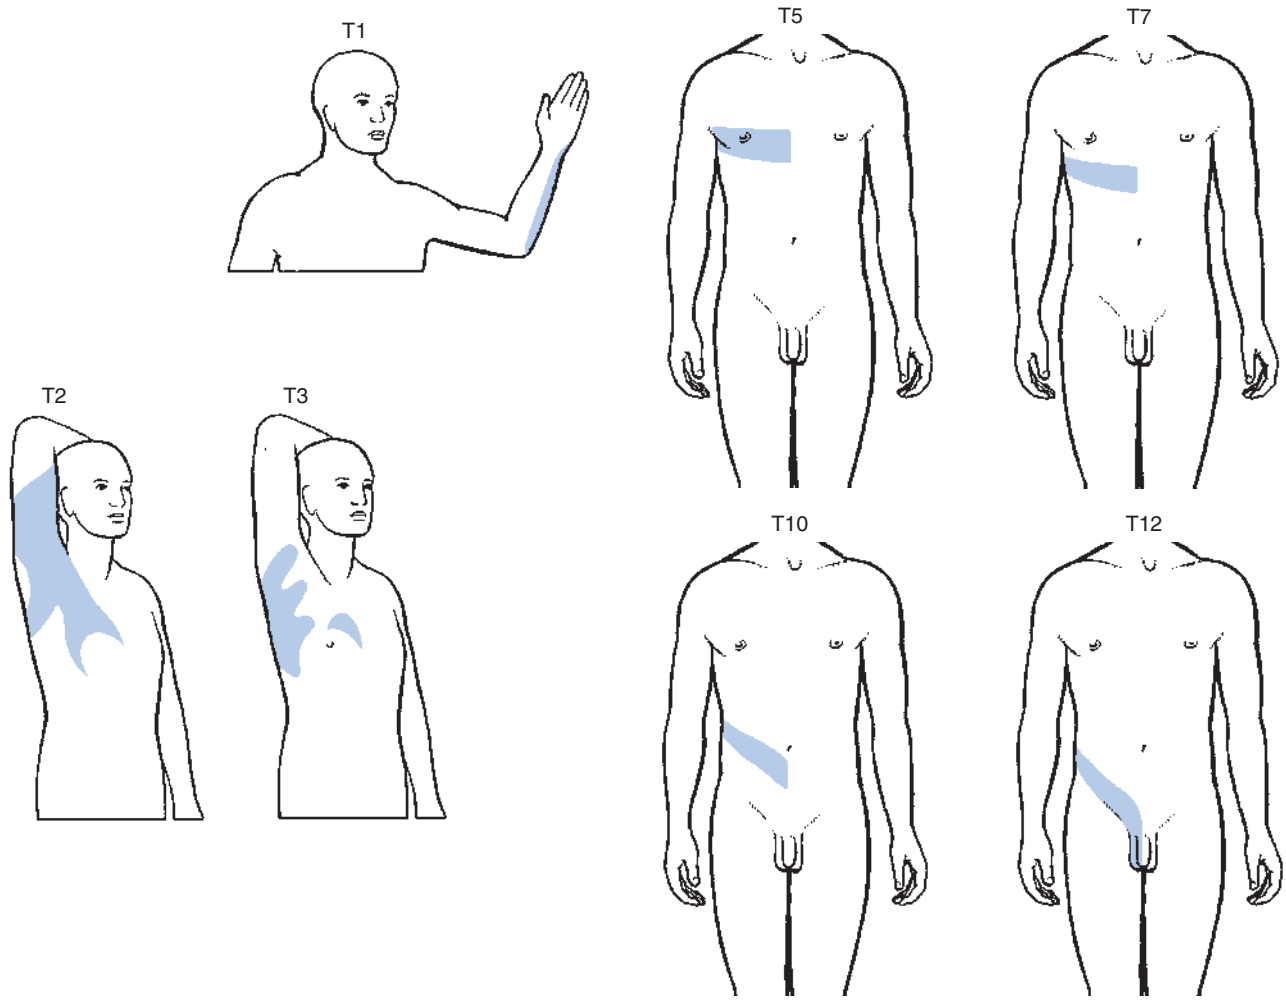

Fig 25.3 • Segmental referred pain of thoracic origin.

Nerves

Neuritis

Neuritis of the spinal accessory nerve, the long thoracic nerve and the suprascapular nerve can provoke unilateral pain at the base of the neck and over the scapula.

Herpes zoster

In that the thorax is often the seat of a herpes zoster infection, unilateral spontaneous pain of recent onset always calls for a careful inspection of the skin for erythema and grouped vesicles.

Bones

Osseous structures usually do not give rise to much in the way of referred pain; the pain remains typically local. Intense though localized pain is a warning sign and the following conditions should be considered:

- *Traumatic fracture of a vertebral body*: severe central pain is to be expected for about 2–6 weeks. For the first week there is often girdle pain. Thereafter it gradually disappears. If uncomplicated, spontaneous cure is to be expected within 12 weeks.
- *Vertebral tumours*: all types of bony tumour of the vertebrae, primary or metastatic, as well as infections, initially provoke local pain in the centre of the back.
- *Contusion or fracture of a rib*: the patient can point exactly to the tender spot. The same is the case in malignant invasion.
- *Disorders of the sternum*: traumatic disorders and tumours of the sternum may also give rise to local sternal pain.

Joints and ligaments

Ligaments and joints consistently obey the rules of referred pain, which means that the deeper the location of the affected structure and the closer its position to the midline, the more referred pain is to be expected. On the other hand, the further the lesion lies from the spinal axis and the more superficial it is, the more accurate will be its localization by the pain it provokes.

- *Manubriosternal and sternoclavicular joints*: as these are superficially located, the pain is felt locally.
- *Costochondral and chondrosternal joints* (Tietze's syndrome and costochondritis): the patient is able to indicate the site of the lesion accurately.

- *Intervertebral facet joints*: these give rise to unilateral paravertebral pain, felt deeply and locally, but not going further lateral than the medial edge of the scapula. If several joints are affected at the same time, as may be the case in ankylosing spondylitis, the pain spreads more in a craniocaudal direction than mediolaterally; the opposite is true for a disc protrusion.
- *Costovertebral and costotransverse joints*: the pain is felt unilaterally between the vertebral column and the scapula.
- *Anterior longitudinal ligament*: when this ligament is affected, pain is usually located anteriorly behind the sternum.
- *Posterior longitudinal ligament*: involvement of this ligament causes pain in the back, felt centrally between the scapulae.
- *Disorders of the costocoracoid fascia or the trapezoid and conoid ligaments* (see online chapter *Disorders of the inert structures*): the pain is usually felt in the infraclavicular fossa.

Muscular lesions

Muscular sprains of the intercostal muscles, the abdominals and the muscles of the shoulder girdle usually provoke well-localized pain at the site of the lesion.

Pain referred from visceral structures

The heart

Pain arising from disorders of the heart can be referred to dermatomes C8–T4 because the heart is derived largely from these segments. Therefore pain can radiate towards the tip of the shoulder, to the anterior chest and to the corresponding region of the back. It may also be referred towards the ulnar side of both upper limbs, though referral to the left side is more common (Fig. 25.4a). Pain from the pericardium always arises from the parietal surface because this is the only part which has a sensory innervation.

The aorta

Pain from the aorta, as in dissecting aneurysm, may be felt behind the sternum or in the abdomen, depending on the exact level of the disorder. It often radiates into the back and may expand as the lesion progresses.

The lungs

The lungs are insensitive. Therefore pain is caused either by the parietal pleura, as in pleurisy, or by invasion of the chest wall by a tumour.

The parietal pleura

Pleuritic pain is caused by an inflammation of the parietal pleura (pleurisy). Though the visceral pleura does not contain any nociceptors, the parietal pleura is innervated by somatic nerves that sense pain when the parietal pleura is inflamed. Parietal pleurae of the outer rib cage and lateral aspect of each hemidiaphragm are innervated by intercostal nerves. Pain is localized to the cutaneous distribution of those nerves. The phrenic nerve supplies innervations to the central part of each hemidiaphragm which is a C4 structure, with pain reference to the trapezius area.[6]

The oesophagus

Disorders of the oesophagus (T4–T6) usually give rise to pain felt at any part of the sternum, often radiating between the scapulae into the back (Fig. 25.4b).

The diaphragm

The central part of the diaphragm is mainly derived from the third, fourth and sometimes, although rarely, the fifth cervical segments. Pain from irritation of the central part of the diaphragm is felt at the tip of the shoulders and the base of the neck. Pain from the peripheral part is felt more locally in the lower thorax and in the upper abdomen at the costal margin (Fig. 25.4c).

The stomach and duodenum

Pain from stomach and duodenum (T6–T10) is most commonly felt in the epigastrium and upper abdomen, sometimes substernally and exceptionally in the lower thoracic part of the back (Fig. 25.4d).

The liver, gallbladder and bile ducts

The liver is derived from the right side of T7–T9. The gallbladder and bile ducts are of right T6–T10 origin. Pain is felt in the right hypochondrium and may radiate towards the inferior angle of the right scapula (T7–T9) (Fig. 25.4e).

The pancreas

Patients suffering from a pancreatic disorder complain of upper abdominal pain often referred to the back at T8 (Fig. 25.4f).

The spleen

Pain arising from disorders of the spleen is usually felt in the left hypochondrium, sometimes in the left side at low thoracic level (T7–T10).

The small intestine, appendix and colon

Problems in the small intestine (T9–T10) give rise to pain felt around the umbilicus. In disorders of the colon (T10–S5), pain is usually felt in the neighbourhood of the lesion. The appendix is a T10–L1 structure.

The kidneys and ureters

Disorders of kidney and ureters (T10–L1) give rise to pain felt posteriorly in the side, at and just below the lower ribs, and at the anterolateral aspect of the abdomen. The pain often radiates towards the testicles or the labia (Fig. 25.4g).[7]

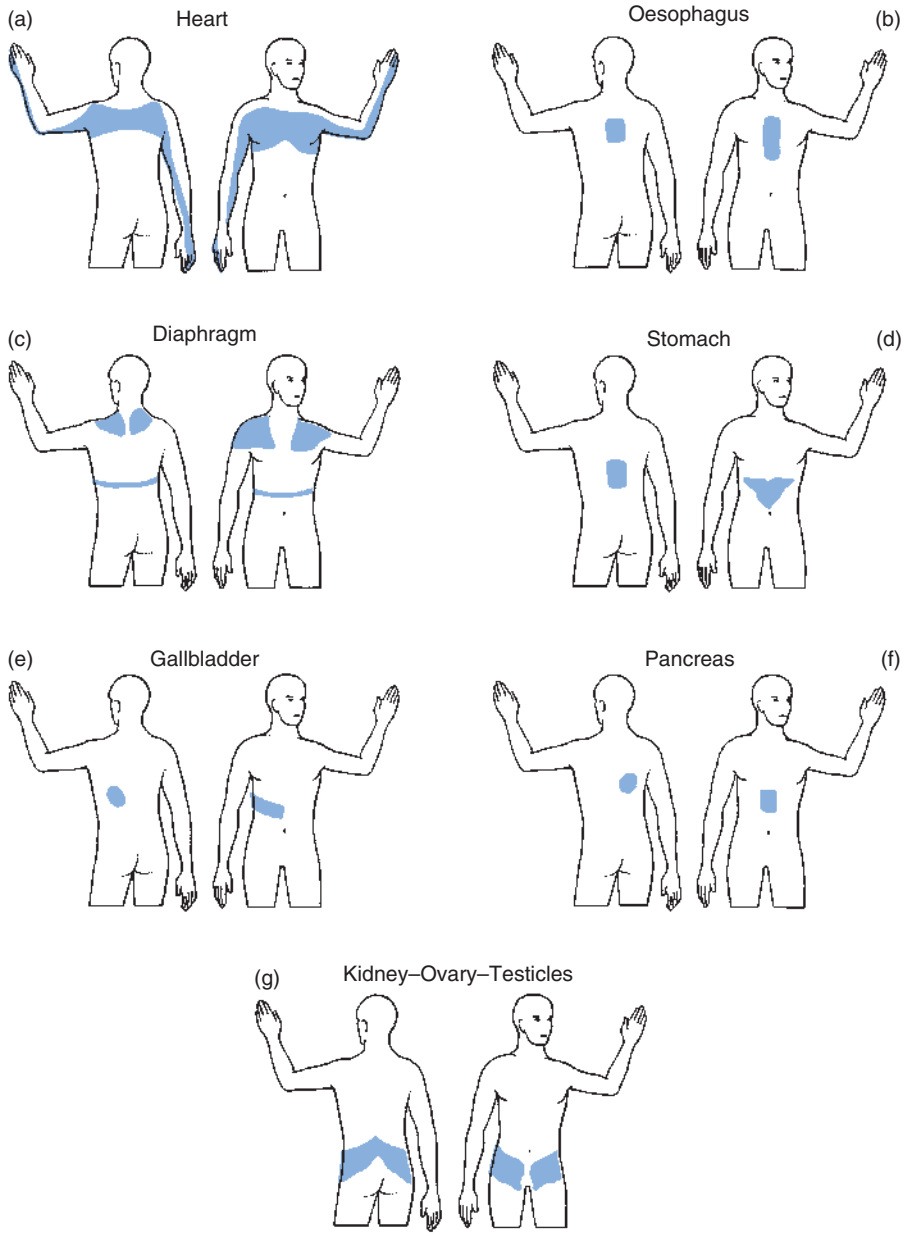

Fig 25.4 • Pain referred from visceral structures: (a) heart; (b) oesophagus; (c) diaphragm; (d) stomach; (e) gallbladder; (f) pancreas; (g) kidney/ovary/testicles.

Reproductive system

Disorders of the ovaries (T11–L1) may result in unilateral low abdominal pain, sometimes felt in the periumbilical area. Testicular problems (T11–L1) give rise to scrotal pain, sometimes radiating into the groin and to the side.

See Box 25.1 for a summary of referred pain in the thorax and abdomen.

History

In dealing with pain in the thorax or abdomen, the main goal of history taking is to differentiate between musculoskeletal and visceral problems. As already pointed out, a relationship between the patient's symptoms and positions or activities does not necessarily exclude a visceral disorder, because in several visceral disorders the same relationship exists.

The history is kept simple and clear. Detailed information is elicited about pain, paraesthesia and the intake of anticoagulants or the presence of bleeding disorders.

Pain

What made the pain come on?

If the patient mentions an injury to the chest, a bony problem of the ribs, sternum or vertebra is likely. In a pathological fracture sudden pain may follow a very trivial movement.

Box 25.1

Summary of referred pain in the thorax and abdomen

Pain of musculoskeletal origin

Dura mater and nerve roots

- Cervical disc lesions
- Thoracic disc lesions
- Lumbar disc lesions

Nerves

- Neuritis
  - Spinal accessory nerve
  - Long thoracic nerve
  - Suprascapular nerve
- Herpes zoster

Bones

- Vertebrae
  - Fracture
  - Bony tumours
  - Infections
- Ribs
  - Contusion and fracture
  - Malignant invasion of a rib
- Sternum
  - Fracture
  - Tumours

Joints and ligaments

- Manubriosternal and sternoclavicular joints
- Costochondral and chondrosternal joints
- Intervertebral facet joints
- Costovertebral and costotransverse joints
- Anterior and posterior longitudinal ligaments
- Costocoracoid and coracoclavicular ligaments

Muscular lesions

- Intercostals
- Pectoralis major
- Pectoralis minor
- Subclavius
- Latissimus dorsi
- Serratus posterior inferior
- Abdominals

Pain of a visceral nature

- Heart
- Aorta
- Pleura and lungs
- Oesophagus
- Diaphragm
- Stomach and duodenum
- Gallbladder and bile ducts
- Pancreas
- Spleen
- Small intestine and colon
- Kidney and ureters
- Genitals

When the pain has come on without trauma, it is of interest to know what the patient was doing at the time and in which position the body was held. Thoracic disc lesions are, just like lumbar ones, most often the result of a combined flexion–rotation movement. However, in disc lesions a history of such provocation cannot always be obtained, the patient stating that the pain started without any specific activity or posture.

Pain that came on after a forceful movement of trunk or arms – such as during sporting activities – may be from a muscular lesion.

Arthritis of the costovertebral, costotransverse or facet joints begins spontaneously. When it is the result of ankylosing spondylitis, pain and stiffness often occur in phases and are usually worst in the early morning.

Warning

Pain of spontaneous onset, increasing in intensity and constantly expanding, should be suspected of being caused by a tumour.

Where was the pain at the beginning, where did it spread or shift to, and where is it now?

When the pain is felt between the scapulae above T6, a cervical disc problem is most likely. In such cases, clinical examination of the cervical spine should be done initially. If this is negative, clinical examination of the thorax follows.

A thoracic disc lesion usually gives rise to discomfort felt centrally or unilaterally in the posterior thorax. Here, as in the cervical spine, the pain may be felt centrally at first and then shift more to the side. A shifting pain suggests a shifting (disc) lesion.

A posterocentral protrusion interfering with the dura normally results in unilateral extrasegmental referred pain, usually felt in the anterior chest. However, it can also give rise to abdominal pain, discomfort in the groin and even lumbar pain. Sometimes bilateral extrasegmental pain is felt posteriorly and over several segments on both sides.

An acute 'thoracic' lumbago may exceptionally cause pain felt only at the sternum. This is a most misleading phenomenon, as it is not very logical to think of a disc problem in a patient with an acute sternal ache not preceded by any posterior thoracic pain. The possibility of such reference should always be borne in mind.

In posterolateral disc protrusions, pain is felt unilaterally and is referred to one segment only. It is mainly felt posteriorly and at the side but sometimes also anteriorly. This type of protrusion usually follows a posterocentral displacement that has subsequently shifted more laterally. In this case, root pain is preceded by a period of extrasegmental referred dural pain. In the rare event of a primary posterolateral protrusion, the disc fragment moves directly in a posterolateral direction. From the onset, pain is felt to the side, radiating segmentally anteriorly and not preceded by extrasegmental pain.

Pain which increases and expands all the time is from a 'growing' disorder, usually a tumour. Older patients who are symptom-free on first waking in the morning but complain of

central posterior thoracic pain that starts after some hours and increases throughout the day, are likely to be suffering from posterior bulging of the whole content of an intervertebral disc as a consequence of excessive thoracic kyphosis.

Pain felt at the base of the neck is sometimes the result of a problem at the first costovertebral joint, the sternoclavicular joint or a fracture of the first rib.

Pain at the sternum is seldom the result of a musculoskeletal disorder. Most often it has a visceral origin. The same is true for pain felt in the abdomen: muscular lesions do exist but are rare. They usually give rise to well-localized pain.

Is the pain influenced by coughing, sneezing or deep inspiration?

When a Valsalva manœuvre or a deep breath provokes or increases the cervical or lumbar pain, it is generally interpreted as a dural symptom, from interference with the dura mater by a protruded disc or a tumour. In the thoracic area, it is not so simple. Many disorders other than problems of the dura may give rise to the same symptom. Deep inspiration may increase pain because of one of a number of visceral disorders or other musculoskeletal problems. Tumours of the respiratory tract, pleurisy, lung embolism, pneumothorax and even pericarditis can all give rise to pain increased by coughing or respiration. The same may be found in non-discal musculoskeletal problems of the ribs and sternum. Fractures and contusions of the ribs, a sprained intercostal muscle and a fracture of the sternum are all in the same class. Consequently, the influence of respiration on symptoms at the thoracic level is only regarded as a dural symptom once there is clinical certainty of disc protrusion. In thoracic disc protrusions it is more usual for deep inspiration, rather than a cough, to exacerbate the symptoms.

Paraesthesia

Protrusion of a disc in the thoracic region can produce pins and needles in two ways. First, it may be the result of compression of the spinal cord, which is characterized by extrasegmental pins and needles felt in both feet and typically increased or provoked by flexion of the neck. Cord compression and paraesthesia can also be caused by intra- and extraspinal tumours, intraspinal haemorrhage or a vertebral fracture. Second, paraesthesia can be stem from posterolateral protrusion compressing a nerve root. For example, pins and needles may be felt in the groin from compression of the T12 nerve root. In this event, the features are always localized and limited to the corresponding dermatome.

Both causes are rare, and when paraesthesia is present, other conditions, such as neuropathy due to generalized disorders (diabetes, pernicious anaemia and multiple sclerosis), must always been considered first.

Anticoagulant treatment and bleeding disorders

The use of anticoagulants is always an absolute contraindication to manipulation of the spine, because it can lead to uncontrollable intraspinal bleeding. The same applies in congenital or acquired disorders of blood coagulation.

Inspection and palpation

On inspection, the curvature of the thoracic spine is noted. Scoliosis and hyperkyphosis may be detected.

Scoliosis

A deformity in the frontal plane is named scoliosis. If present, it is important to determine whether it is located at the lumbar or thoracic level. Thoracic scoliosis can often be voluntarily corrected by the patient. In this event, it is postural and has no specific pathological implications. In structural scoliosis, the deformity cannot be corrected by muscular activity. There is often associated shoulder asymmetry too. In this event, the scapula at the convex side is usually more prominent and the arm of this side touches the hip, but the other arm hangs further away from the body.

Kyphosis

A hyperkyphotic thoracic spine with a flattened lumbar spine may suggest ankylosing spondylitis. An excessive low thoracic and high lumbar kyphosis can be the result of Scheuermann's disease or osteoporosis.

Sometimes a localized angular kyphosis is found as the result of a collapsed vertebral body, usually due to pathological or traumatic fracture or resulting from adolescent osteochondrosis. It is best felt by gliding the fingers over the spinous processes in a craniocaudal direction. It is more difficult to detect at the thorax than elsewhere because of the general kyphotic shape of the thoracic spine.

Functional examination

Clinical routine differs significantly according to the level of the pain (Fig. 25.5). For a number of reasons, pain felt above the T6 level (mid-scapular) demands a preceding clinical examination of the cervical spine and the shoulder girdle. First, the upper two thoracic vertebrae, anatomically belonging to the thoracic spine but clinically part of the cervical spine, are tested in the clinical examination of the cervical spine. Second, it was demonstrated previously that cervical discodural interactions often provoke extrasegmentally referred pain in the upper half of the thorax. Third, numerous lesions of the thoracic apex and the shoulder girdle, although causing pain in the cranial aspect of the thorax, are only detected by proper examination of the cervical spine and/or the shoulder girdle: a tumour of the apex of the lung involving the T1 nerve root is only detected by cervical tests; neuritis of the suprascapular nerve causes pain in the supraspinatus fossa and is detected by a combined weakness of supra- and infraspinatus muscles. A fracture of the first rib provokes upper thoracic pain but the diagnosis can be missed if the examiner proceeds immediately

with examination of the thoracic spine. For all these reasons, in patients with upper thoracic pain, a full cervical examination followed by examination of the shoulder girdle must be done first. Only when these are negative should a thorough examination of the thoracic spine follow.

If the patient has pain below T6, a cervical or shoulder girdle problem is unlikely and attention is immediately directed to the thoracic spine.

Functional examination of the thoracic spine consists of a large set of basic tests. The examination is performed with the patient standing, sitting and lying prone. During the procedure, dural, articular, muscular and cord signs are sought. Sometimes, when particular symptoms or signs from the basic examination warrant, the procedure is completed by specific accessory tests.

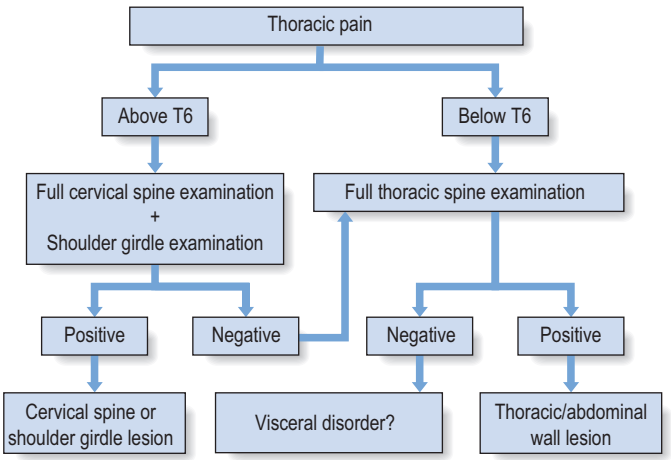

Fig 25.5 • Examination strategy in thoracic pain.

Standing

Dural tests

It is believed that deep inspiration, neck flexion and some scapular movements may indirectly stretch the dura mater.

Taking a deep breath (Fig. 25.6a)

The patient is asked to take a deep breath and to state if the pain increases. A positive test is regarded as a dural sign only when, after the rest of the examination is performed, a disc lesion seems to be present. In such a case, stretching of the dura mater via the intercostal nerve roots is interfered with.

Flexion of the neck (Fig. 25.6b)

The patient is asked to bend the head actively forward. This may increase the pain or provoke paraesthesia.

In thoracic spine problems, pain during active neck flexion is basically regarded as a dural sign because flexion stretches the dura mater from above. However, pain on neck flexion as the result of impaired dural mobility does not necessarily mean a disc lesion is present. Indeed, any kind of intraspinal space-occupying lesion that interferes with the dura, such as a tumour, may provoke pain on neck flexion. A problem with one of the posterior ligaments or posterior paravertebral muscles may also cause pain on neck flexion.

Sometimes a patient feels a sudden sensation on neck flexion, resembling an electrical discharge going down his back and occasionally even spreading towards both arms and legs. Sometimes it also occurs on extension of the neck. This is known as Lhermitte's sign and was previously regarded as pathognomonic for disorders of the cord at the cervical level. In later reports it has been suggested that problems of the thoracic cord may cause the same sign. This can be caused by

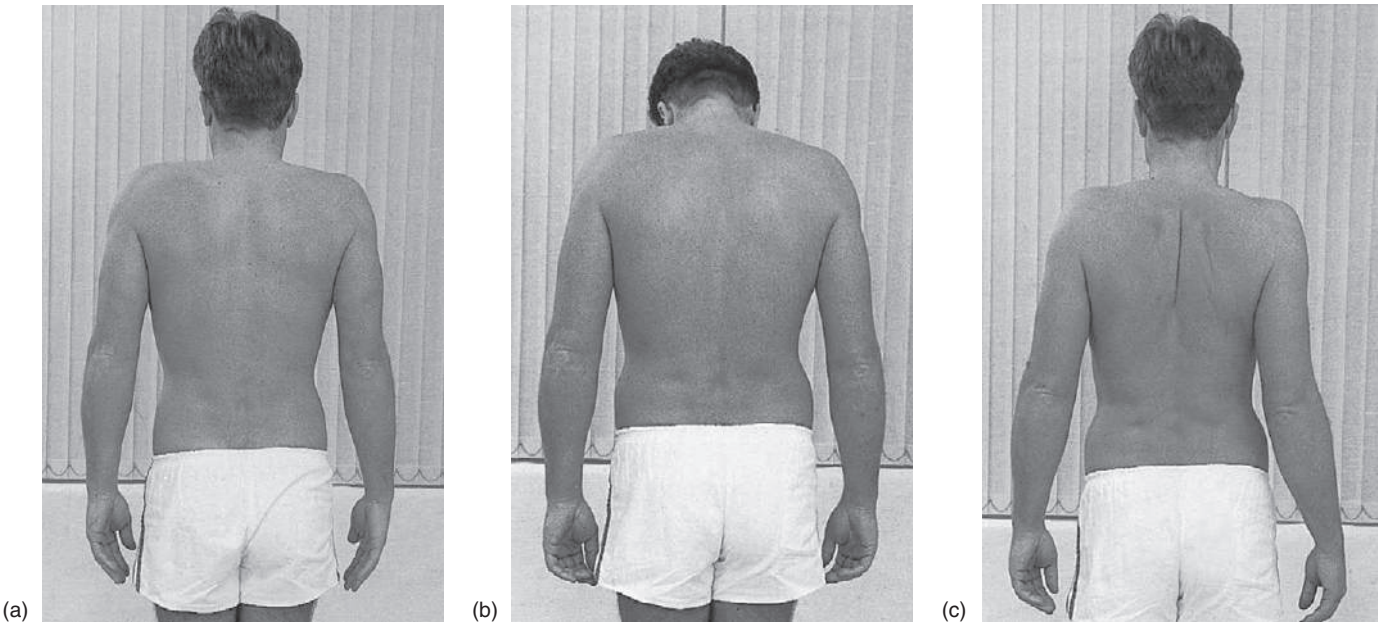

Fig 25.6 • Dural tests at the thoracic level: (a) taking a deep breath; (b) flexion of the neck; (c) backward movement of the scapulae.

multiple sclerosis, a tumour of the cord, disc lesions, tuberculosis, spondylosis, arachnoiditis or radiation myelopathy.[8]

Neck flexion may also provoke or increase pins and needles. If these are felt in one or both lower limbs, this draws attention to compression of the spinal cord at the thoracic level, which is most commonly the result of a disc lesion or a tumour.

Shoulder movements: upwards, forwards and backwards

The patient is now asked to shrug both shoulders and to bring them forwards and backwards.

These tests are basically active movements of the structures of the shoulder girdle. Therefore some will be positive when a disorder of one of those structures is present (see online chapter *Applied anatomy of the shoulder girdle*).

However, if one or all of these movements elicits pain, it is most frequently the result of a thoracic disc lesion, because they all (to a greater or lesser degree) stretch the dura mater at the thoracic level, which is elongated in a cranial direction via the T1 and T2 nerve roots (Cyriax[9]: p. 202). The most sensitive test is scapular approximation (shoulders backwards, Fig. 25.6c).

Active trunk movements

The patient is now asked to perform six active movements of the trunk. These involve both the thoracic and the lumbar spine. Differentiation is made by the level of the pain, as indicated by the patient, and on extension pressure at the end of the examination.

On flexion, extension and side flexion to both sides the range of movement is greatest in the lumbar spine, rather than the thorax. Rotation movements, in contrast, occur only slightly at the lumbar level and involve mostly the thoracic spine.

The movements performed are:

- Anteflexion (Fig. 25.7a)
- Extension (Fig. 25.7b)
- Left side flexion (Fig. 25.7c)
- Right side flexion (Fig. 25.7d)
- Left rotation (Fig. 25.7e)
- Right rotation (Fig. 25.7f).

The patient performs these movements actively. Pain and limitation are noted. In structural scoliosis the associated hump persists and is accentuated on forward bending.

While performing rotations, the patient keeps the head in neutral position in relation to the shoulders, to avoid cervical rotation.

Conclusions from active trunk movements

In principle, the six movements described so far are articular. However, because they are performed actively, they involve some contractile structures as well. Passive and resisted movements (see below) provide the key in differential diagnosis between inert and contractile structures. After these tests, the examiner should know whether an articular pattern is present or not.

The articular pattern of the thoracic spine is an equal degree of pain and limitation of both side flexions and of both rotations, together with a larger limitation of extension and little or no limitation of anteflexion (Fig. 25.8). It resembles the pattern for the cervical spine. If this is found, a disorder of the entire segment of motion, such as in ankylosing spondylitis or osteoarthrosis, is present.

Any other combination of abnormal tests is regarded as a partial articular pattern (Fig. 25.9). Such a combination could be, for instance, pain on one rotation or one side flexion together with one rotation, or one side flexion and extension, or three, four or five of the six movements being positive in producing pain or limitation. As long as abnormal tests are present in a non-symmetrical way, the pattern is regarded as being partial articular.

In all types of disc lesion a partial articular pattern is expected. In the thoracic spine, a common finding is that only one out of the six articular movements is positive – usually one of the rotations. Differentiation must always be made from a facet joint lesion or a muscular lesion, in which a partial articular pattern is also found. In the latter, some of the resisted movements are more painful.

Warning

When side flexion away from the painful side (Fig. 25.10) is the only painful and limited movement, this always indicates a severe extra-articular lesion such as a pulmonary or abdominal tumour or a spinal neurofibroma.

Sitting

The examination is now continued by looking at passive and resisted rotations to both sides, with the patient sitting. In the seated position Babinski's reflex is also elicited.

Passive tests

- Passive left rotation (Fig. 25.11a)
- Passive right rotation (Fig. 25.11b).

The patient crosses both arms in front of the chest. The knees are held between the examiner's legs to immobilize the pelvis. The patient's trunk is now twisted towards the left and the right by the examiner. Pain, range of movement and end-feel are noted.

The normal end-feel is elastic. A hard end-feel is typical of ankylosing spondylitis or advanced arthrosis. Both an empty end-feel and muscle spasm suggest a severe disorder: neoplasm, fracture and infectious disorders.

Rarely, pain is present at half range, disappearing when rotation continues. This is known as a painful arc and was regarded by Cyriax[9] as pathognomonic for a disc lesion when combined with a partial articular pattern.

At the end of both passive rotations the patient is asked to bend the head actively forwards. If this movement further increases the pain, it is regarded as a dural sign if the rest of the examination suggests that a disc lesion is present.

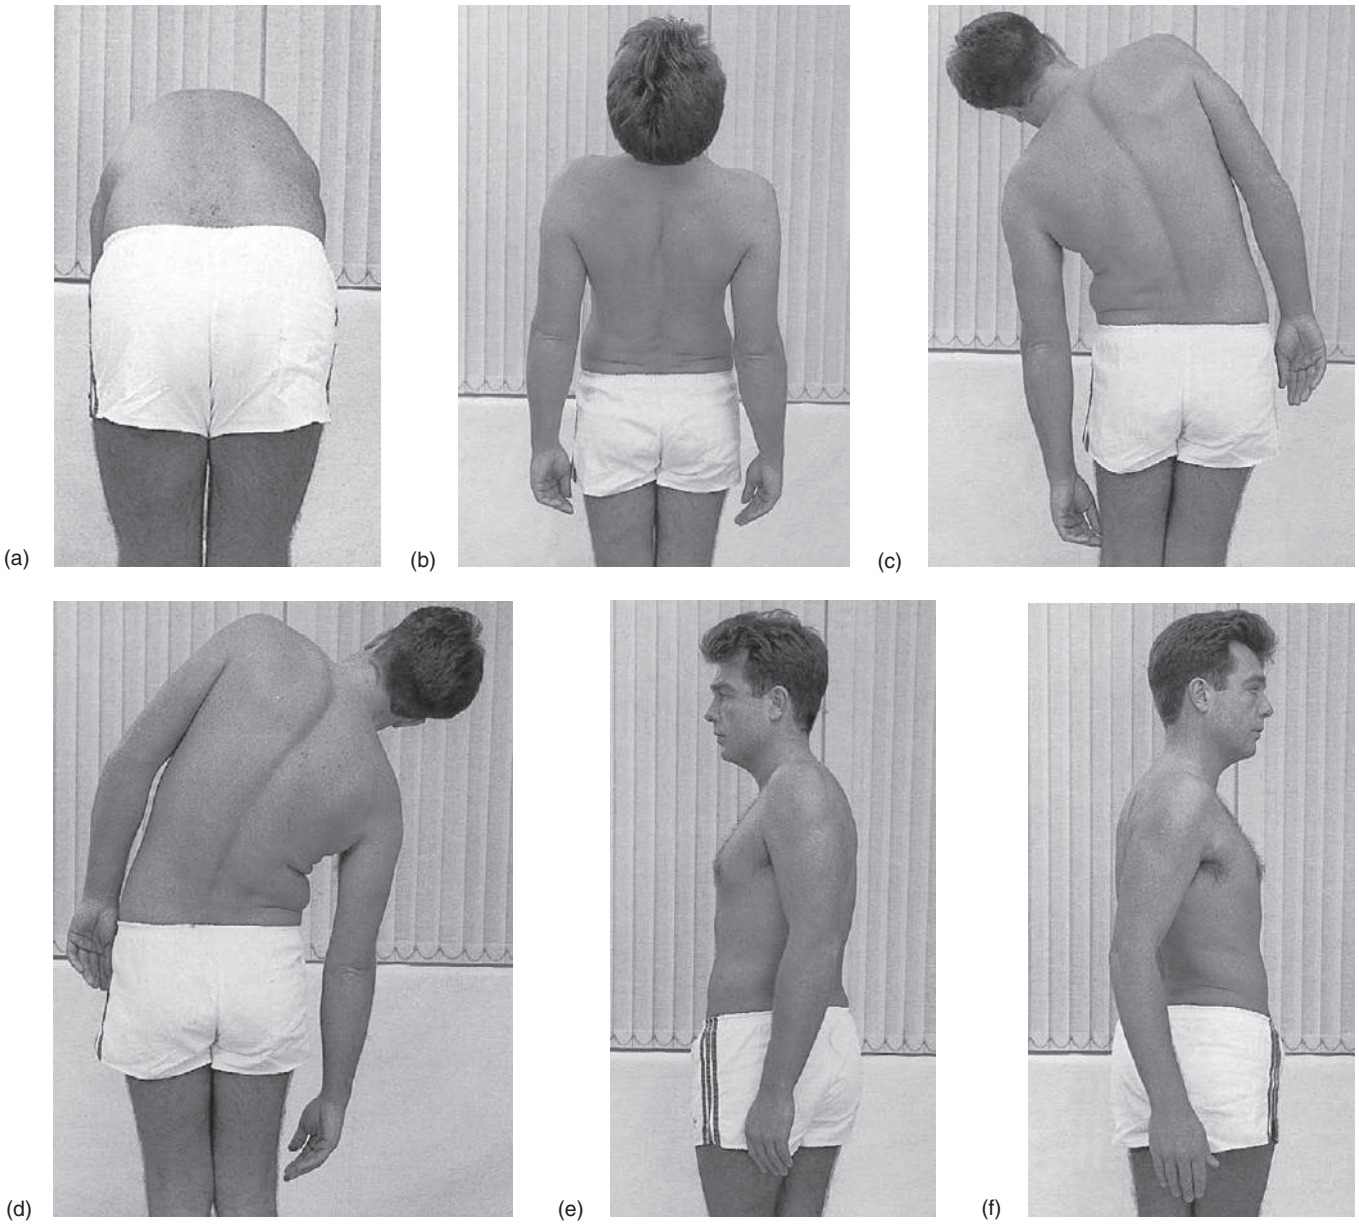

Fig 25.7 • Active trunk movements: (a) anteflexion; (b) extension; (c) left side flexion; (d) right side flexion; (e) left rotation; (f) right rotation.

Resisted tests

In the same position as used for the passive tests, isometric contractions are done. The patient is asked to twist the trunk to the left (Fig. 25.12a) and to the right (Fig. 25.12b) while the examiner applies counterpressure at both shoulders, so that the patient is kept immobile. Pain and weakness are noted. Because muscular lesions do occasionally occur at this level, these tests must always be performed.

The results of both resisted and passive rotations are carefully compared. In a disc lesion, passive rotations are more painful than resisted ones. Given that resisted movements are more painful, a muscular problem is most likely, unless a psychogenic problem or a rib fracture is present. In both events, accessory tests should follow (see below).

Cord sign: plantar reflex

The examiner glides a relatively sharp instrument along the lateral aspect of the sole, starting at the heel and moving forwards and medially towards the big toe (Fig. 25.13). Normally the toes either do not move at all or they all uniformly go into flexion. This test is pathological if the patient spreads the toes apart and the big toe moves into extension. A positive test indicates interruption of the descending motor fibres. If there is the slightest doubt about interference with the spinal cord, a full neurological examination of the lower limbs must be carried out. This includes all reflexes in the lower limbs and abdomen, resisted movements of the thigh and leg musculature, control of coordination, testing for numbness and temperature sensitivity, and the straight leg raising test.

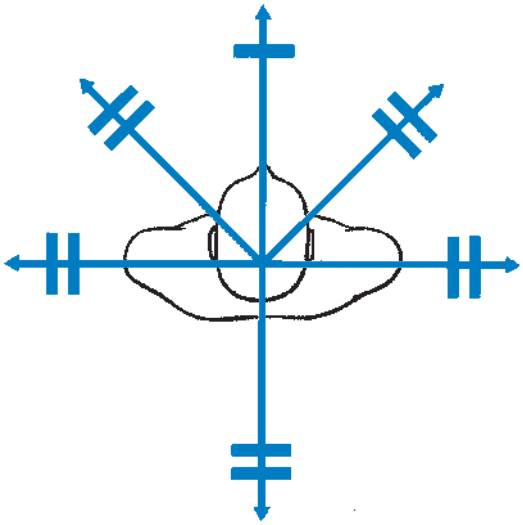

Fig 25.8 • The full articular pattern.

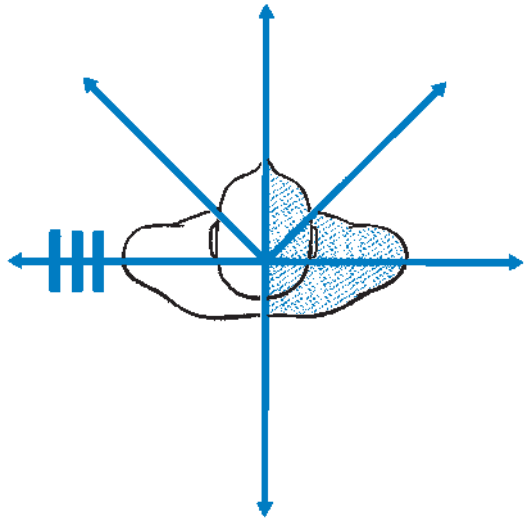

Fig 25.10 • Pain and limitation on side flexion away from the painful (coloured) side is a warning sign for serious disorders.

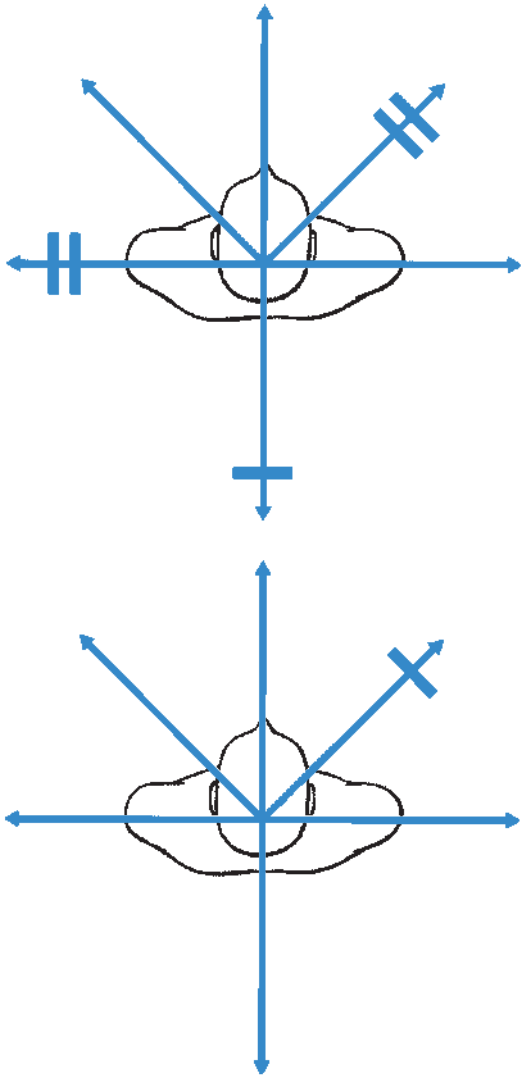

Fig 25.9 • Examples of partial articular patterns.

Lying prone

Location of affected level by passive extension thrust

The patient lies prone and a hyperextension thrust is given over every thoracic spinous process to locate the painful level. To do this, the hand is placed obliquely, with the fifth metacarpal bone on the spinous process (Fig. 25.14). Identification of the exact level is important, because some manipulations for thoracic disc protrusions are performed specifically at the level at fault.

During extension pressure, attention is also paid to the type of end-feel. Normally it is elastic. Muscle spasm is a warning of more severe disorders.

Accessory tests

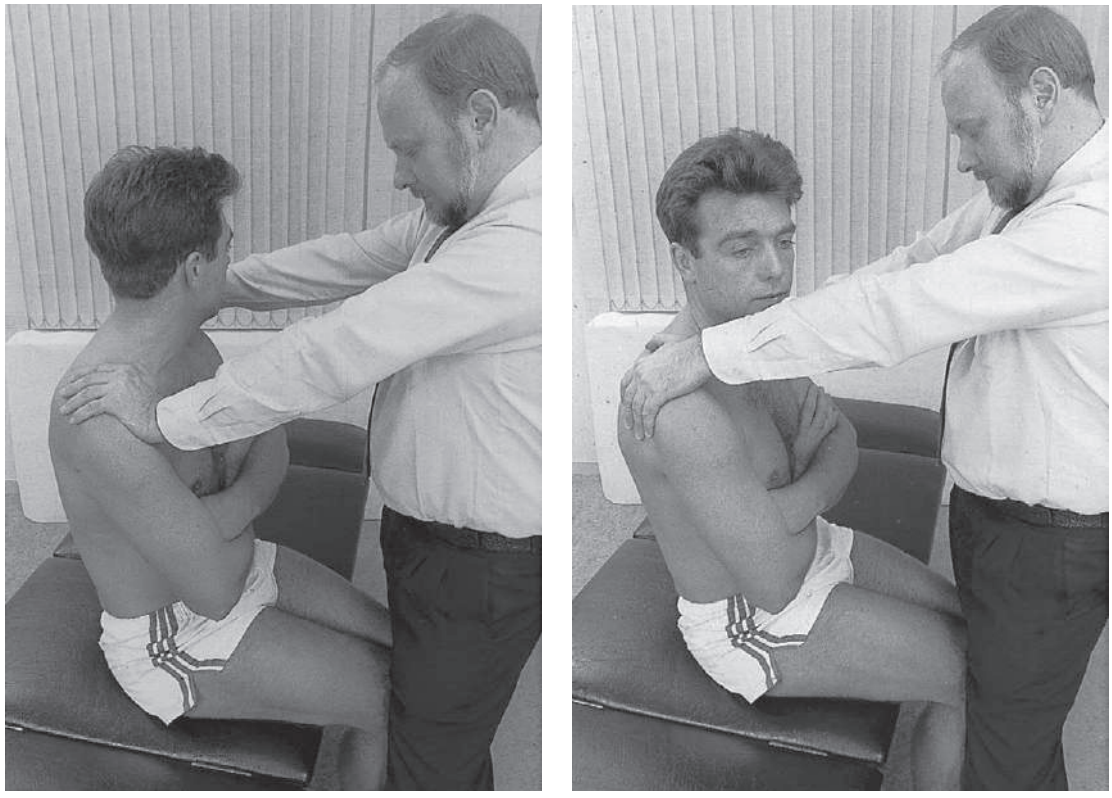
To reach a diagnosis, the basic clinical examination normally suffices. In circumstances that remain unclear or when a muscular problem is suspected, accessory movements must be carried out.

Stretching the T1 nerve root

The patient is asked to lift the arm sideways from the horizontal. The hand is now put in the neck by flexing the elbow (Fig. 25.15). This movement stretches the T1 nerve root via the ulnar nerve, which may provoke pain between the scapulae or down the arm when the mobility of the T1 nerve root is impaired. The test is useful for differentiating between a problem of the cervical spine and one of the upper thorax which interferes with the dura or the T1 nerve root: if it is painful, a thoracic problem is more likely.

(a) (b)

Fig 25.11 • Passive rotation: (a) left; (b) right. At the end of each movement the patient is asked to bend the head forwards.



(a) (b)

Fig 25.12 • Resisted rotation: (a) left; (b) right.

Fig 25.13 • Testing the plantar reflex.

Resisted movements and extension of the trunk

To gain more information on a muscular lesion, the following resisted movements should be performed.

Resisted side flexion (Fig. 25.16)
The patient stands, with the feet slightly apart. The examiner places himself at the patient's painless side, hips against each other, and puts the arm around the patient's farther shoulder. The patient is now asked to bend sideways away from the examiner. By holding the patient's shoulder, side flexion of the trunk is resisted.

Resisted flexion (Fig. 25.17)
With the patient sitting down, the examiner places one hand on the proximal part of the sternum and the other on the patient's knees. The patient tries to bend forwards against resistance exerted by the examiner. This is a test for all the flexors of the abdomen and of the hip.

Extension of the trunk

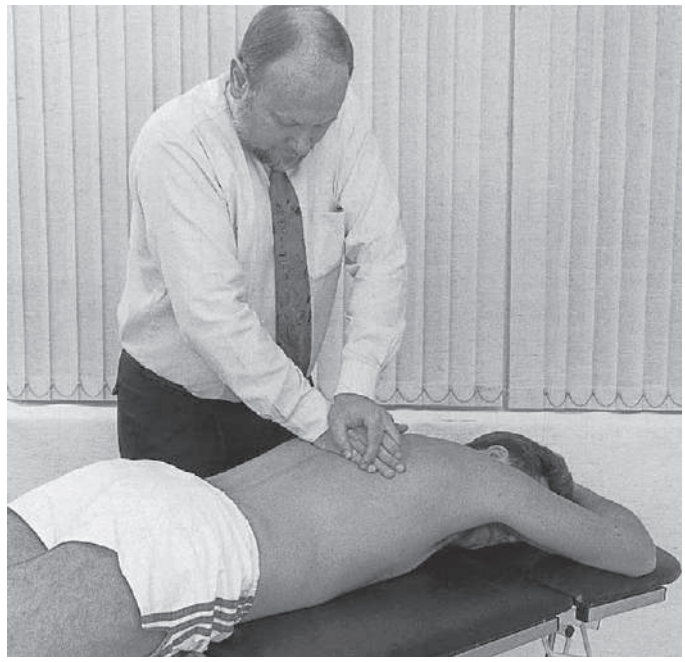
This movement is performed in three different ways.

Resisted extension (Fig. 25.18a)
Resisted extension is best done with the patient prone. Counterpressure is applied at the proximal part of the thorax and at the posterior aspect of the knees.

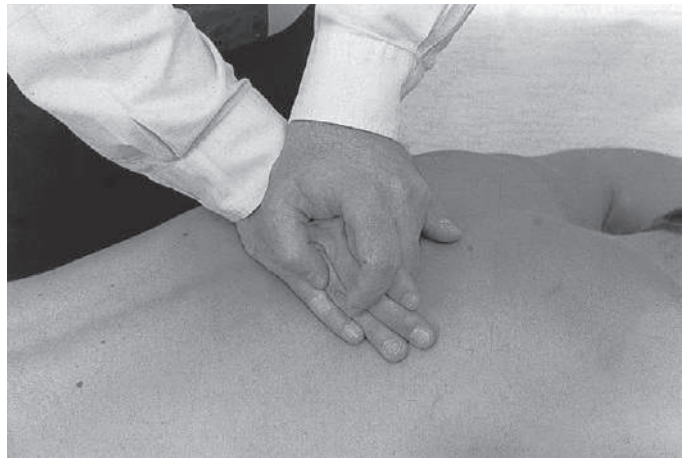
Active extension (Fig. 25.18b)
For active extension the patient remains prone and is asked to lay both hands on the sacrum and lift the trunk off the couch actively by use of the paravertebral muscles.

Passive extension (Fig. 25.18c)
For passive extension the patient pushes the body up off the couch by means of the arms. The pelvis must stay down on the couch.

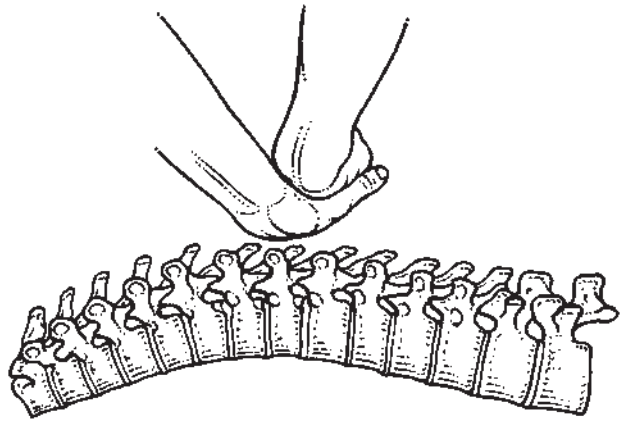
The results of extension movements are carefully compared with each other. In a muscular lesion, active and resisted extension is painful but resisted extension is the most distressing. In a lesion of an inert structure, active and passive extension is painful but the latter provokes the most pain.



(a)



(b)



(c)

Fig 25.14 • Passive extension thrust.

Testing the long thoracic nerve

The patient pushes against a wall with the arms stretched out horizontally in front (Fig. 25.19). If the medial edge of the scapula moves away from the thorax to produce a winged appearance, a disorder of the long thoracic nerve is present.

Oscillation of a rib

The examiner stands on the pain-free side and places one hand distally on the thorax, with the fifth metacarpal bone exactly on the suspected rib. The other hand rests with the pisiform bone on the contralateral transverse process of the corresponding vertebra (Fig. 25.20). Oscillations are now given by the hand resting on the rib. At the same time, the other hand is used to prevent rotation of the vertebra by pressing simultaneously on the transverse process. These oscillations influence mainly the costovertebral and costotransverse joints. When there is inflammation, pain will be provoked; when ankylosing spondylitis is present, the movement will be less elastic.

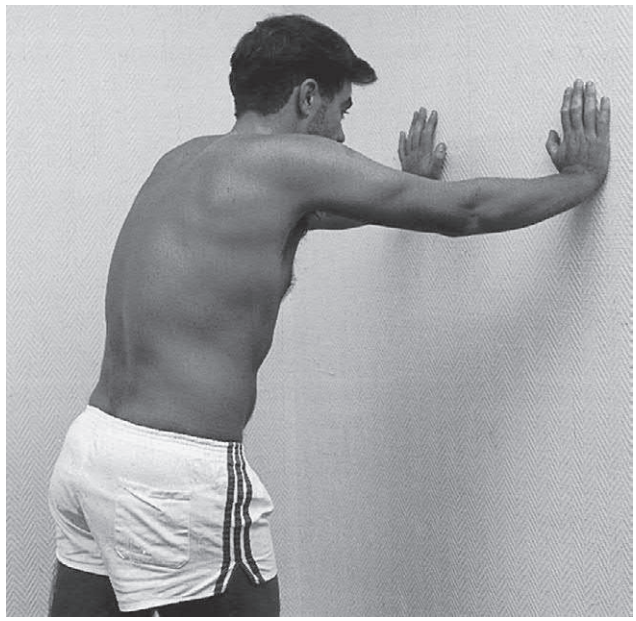

Fig 25.19 • Testing the long thoracic nerve.

Neurological examination

A full neurological examination must be carried out when compression of the spinal cord or a neurological disorder is suspected.

The following accessory tests should be performed.

Beevor's sign

The patient lies supine, crosses the arms in front of the chest and is asked to raise the trunk slightly off the couch. The examiner pays attention to the umbilicus, which should not move during this test. Any movement in a cranial or caudal direction or to the side may point towards a denervation of the contralateral muscles.

Cremasteric reflex (in men)

When the pointed end of a reflex hammer is glided over the medial aspect of the thigh, the ipsilateral half of the scrotum moves upwards via contraction of the cremaster muscle. Absence of this reflex may point towards a lesion of the spinal cord.

Full neurological examination of the lower limbs

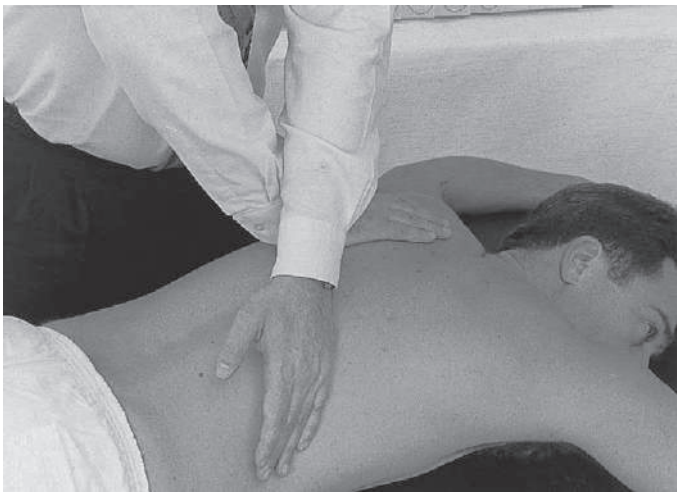
This is described in Table 25.1.

Oppenheim's sign

This may confirm a positive Babinski's sign. When the fingers are slid downwards along the tibia, no movement of the toes should occur. In cord compression, the big toe extends while the others spread. However, this test is less reliable than a Babinski's sign.

Palpation

If a muscular lesion is suspected, the affected structure should be palpated.



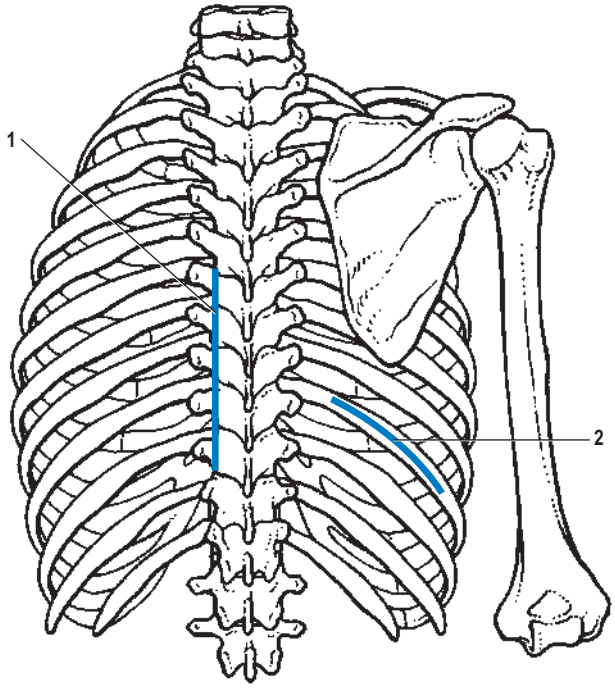


Fig 25.20 • Oscillation of a rib: 1, position of fifth metacarpal right hand; 2, position of fifth metacarpal left hand.

Palpation is also necessary to differentiate between a lesion of an intercostal muscle and a true rib problem.

In a disc lesion, cutaneous anaesthesia must always be checked. If present in the territory of one nerve root, a posterolateral protrusion is likely; bilateral numbness suggests compression of the spinal cord instead.

The clinical examination of the thoracic spine is summarized in Box 25.2.

Technical investigations

Plain radiographs are useful in confirming osseous lesions and in the evaluation of degree and development of scoliosis.

Table 25.1 Full neurological examination of the lower limbs

Tests	Nerve root
Inspection of gait

Numbness	

During the last decades the use of computed tomography (CT) in combination with myelography and magnetic resonance imaging (MRI) has greatly increased the ability to visualize thoracic spine disorders accurately. MRI is the best way to define the specific abnormality, as well as the effect on the adjacent spinal cord. CT after myelography may be useful as well, especially in those patients in whom there is involvement of the posterior ligamentous and osseous structures of the thoracic spinal canal.[10]

However, the superior resolution of the available imaging methods has also made the incidental detection of asymptomatic thoracic disc abnormalities more common.[11] As with the lumbar and the cervical spine, it has become evident that the correlation between gross anatomical findings on MRI and clinical signs and symptoms detected by the clinician may be lacking. A significant proportion of the population has disc disease as depicted on imaging studies, yet many have no clinical findings at all.[12,13] The relative frequency of asymptomatic thoracic herniated nucleus pulposus has been documented in several studies.[14,15] Wood *et al* reviewed MRI studies of the thoracic spines of 90 asymptomatic individuals to determine the prevalence of abnormal anatomical findings: 66 (73%) had positive anatomical findings at one level or more, including herniation of a disc in 33 (37%), bulging of a disc in 48 (53%), an annular tear in 52 (58%), deformation of the spinal cord in 26 (29%) and Scheuermann endplate irregularities or kyphosis in 34 (38%).[16]

Awwad *et al* retrospectively reviewed postmyelography CT scans of 433 patients and identified 68 asymptomatic thoracic

Box 25.2

Summary of the clinical examination of the thoracic spine

History

Pain

What made the pain come on?

- Injury?
  - Bony problem
- Spontaneous onset?
  - Disc lesion
  - Arthritis
  - Tumour
- Forceful activity?
  - Muscular lesion

Where was the pain at the beginning/where did it spread or shift to/where is it now?

- Interscapular above T6?
  - Cervical problem

herniated discs. After comparing the imaging characteristics with a series of five symptomatic thoracic herniated discs, the authors were unable to identify any features that could reliably classify a herniated disc as asymptomatic or symptomatic.[17]

All these studies clearly demonstrate that thoracic disc herniations shown by MRI may not be related to patients' symptoms. The diagnosis 'symptomatic thoracic disc lesion' is therefore primarily a clinical one.

Although the spine is anatomically part of the thoracic cage, we prefer to discuss the thoracic disorders in two main categories – spinal lesions (this chapter and Ch. 28) and lesions of the thoracic cage and abdomen (see online chapter *Disorders of the thoracic cage and abdomen*). Thoracic ankylosing spondylitis is discussed separately (Ch. 29). This is done to standardize the discussion of the spine throughout, in the hope that a better clinical understanding may result.

Introduction

Cervical and lumbar disc lesions are widely accepted as common causes of pain. For the thoracic spine, the situation is different. Although thoracic disc lesions giving rise to compression of the spinal cord are well recognized,[1–5] disc protrusion resulting in pain without causing neurological signs is poorly documented.[6] The incidence of thoracic disc lesions affecting the spinal cord is about one case per million people per year,[3,7] usually affecting adults, although cases have been reported in children as young as 12.[8] The existence of minor thoracic disc lesions provoking pain in the absence of cord compression was first established by Hochman, who removed a disc protrusion at T8–T9 in a 67-year-old lady with continuous unilateral pain in the thorax.[9] Neurological signs were not present. The diagnosis was established by computed tomography (CT).

The incidence of minor thoracic disc lesions is much higher. Degenerative changes of the thoracic spine are observed in approximately half of asymptomatic subjects and 30% have a posterior disc protrusion.[10] A recent magnetic resonance imaging (MRI) study found a prevalence of thoracic disc herniations of 37% in asymptomatic subjects, disc bulging in 53% and annular tears in 58%.[11] Another study of asymptomatic patients identified impressive disc protrusions in no less than 16%.[12] An unexpectedly high prevalence of thoracic disc herniation (14.5%) was also demonstrated in the thoracic spines of a group of 48 oncology patients examined by MRI.[13] Although these relatively high figures do not correspond to the real clinical situation, we believe that symptomatic thoracic disc protrusions are far more common than is generally accepted and agree with Krämer,[14] who estimated the frequency of thoracic disc lesions to be about 2% of all symptomatic disc lesions. Recent studies also confirmed the incidence of symptomatic thoracic disc prolapses as being between 0.15% and 4% of all intervertebral disc prolapses.[15,16]

However, the clinical diagnosis is often not made and the patients are frequently classified as suffering from intercostal neuralgia, neuritis, cardiac neurosis or pleurodynia. If left untreated, the pain can persist for many years, causing continuing morbidity. Nevertheless, the majority of such lesions can easily be reduced in a few manipulative sessions, fully relieving the patient's pain.

© Copyright 2013 Elsevier, Ltd. All rights reserved.

Although more frequently present than commonly believed, thoracic disc protrusions are clinically far less common than those in the lumbar spine because of the greater rigidity of the thoracic spine. This is partly a result of the stabilizing effect of the rib cage on the thoracic spine and partly due to the thoracic intervertebral discs, which are thinner on account of a less voluminous nucleus pulposus.[17] Therefore extension and flexion movements are of a smaller range in the thoracic spine.

Minor thoracic disc lesions occur most often between T4 and T8. Those with cord compression are usually found in the lower half of the thorax.[6,18] About 70% lie between T9 and T12, the commonest level (29%) being T11. A logical explanation for this could be that the lower segments have an increased mobility due to free ribs at these levels.[19] Another reason could be that the cord has a critical vascular supply at this level.[20]

Clinical presentation

It is hypothesized that disc degenerations and disc displacements are of themselves painless events because the disc is almost completely without nociceptive structures. Clinical syndromes originate only when a subluxated fragment of disc tissue impinges on the sensitive dura mater or on the dural nerve root sleeve. This clinical hypothesis is extensively discussed in the lumbar section of this book (see Chs 31 and 33).

Disc displacements (protrusions and prolapses) are either soft (nuclear) or hard (annular), and may have a posterocentral or posterolateral localization.

Posterocentral protrusions compressing the dura mater may provoke multisegmental pain, which is mainly referred into the posterior thorax but may also spread into the anterior chest, the abdomen or the lumbar area.[21] The pain is never referred down the arm. When a posterocentral displacement increases, cord compression can result.

Posterolateral protrusions interfering with the dural sleeve around the nerve root result in pain that is segmentally referred into the corresponding dermatome. A more massive posterolateral protrusion may compress the ganglion or the nerve root fibres, resulting in motor and/or sensory disturbances in the innervation area of the root.

When the T1 nerve root is compressed by a disc lesion, pain is referred to the inner side of the arm between elbow and wrist. A T2 nerve root impingement creates pain referred towards the clavicle and to the scapular spine and down the inner side of the upper arm. The corresponding dermatomes of the T3–T8 nerve roots follow the intercostal spaces, ending at the lower margin of the thoracic cage. The dermatomes of T9–T11 include a part of the abdomen, and T11 also includes part of the groin (see Fig. 25.3).[22,23]

Thoracic disc protrusions may give rise to four different clinical presentations: chronic thoracic backache, acute thoracic lumbago, thoracic root pain and spinal cord compression (Cyriax:[24] pp. 202–205).

Each clinical pattern corresponds to a specific type of disc lesion. Besides dural and articular signs and symptoms, elements which may indicate compression of the spinal cord must always be sought.

Symptoms and signs

The clinical findings in symptomatic thoracic disc displacements are analogous to the lumbar and cervical disc syndromes. Again, both dural and articular signs and symptoms can be identified (see Ch. 52).

Dural symptoms

Increasing the intra-abdominal pressure by deep inspiration, coughing or sneezing may aggravate the pain in all types of symptomatic disc displacements. A deep breath usually has more effect than does a cough – the opposite is true for the lumbar spine – and is the consequence of traction exerted on the dura mater via the intercostal nerves. This dural symptom is of major importance in the lumbar spine but is less helpful in the thorax. Indeed, pain from other disorders of a musculoskeletal or visceral nature may also be under the influence of respiratory movements. Therefore these symptoms are nonspecific at the thoracic level and can be interpreted only as suggesting that the dura is involved when the rest of the history and examination indicates a disc lesion.

Articular symptoms

Pain in disc lesions is caused by certain positions and movements, and disappears with others. Often activities in prolonged flexion or rotation movements provoke or increase the pain.

Dural signs

In disc lesions interfering with the normal mobility of the dura mater or of the dural nerve sleeve, movements that stretch the dura pull in harder against the protrusion and increase compression and pain. The movements regarded as dural signs are:

- Pain on neck flexion
- Pain on movements of the scapulae, most commonly on scapular approximation, which stretches the dura via the T1 and T2 nerve roots.

Articular signs

A disc lesion usually affects only a part of the intervertebral joint. Therefore, certain movements cause biomechanical changes that result in forcing the protrusion against the dura. Consequently, it is to be expected that on clinical examination only some of the active movements will increase the discodural interactions while other movements will be without effect and therefore painless. This results in a partial articular pattern, which is an absolute condition for the diagnosis of a disc protrusion, although it is not pathognomonic.

Examples of non-articular patterns are illustrated in Figure 27.1.

Depending on the degree of the compression, the partial articular pattern is more or less pronounced: more tests are painful and more severe pain is present. However, frequently, only one movement is painful, most commonly one of the rotations.

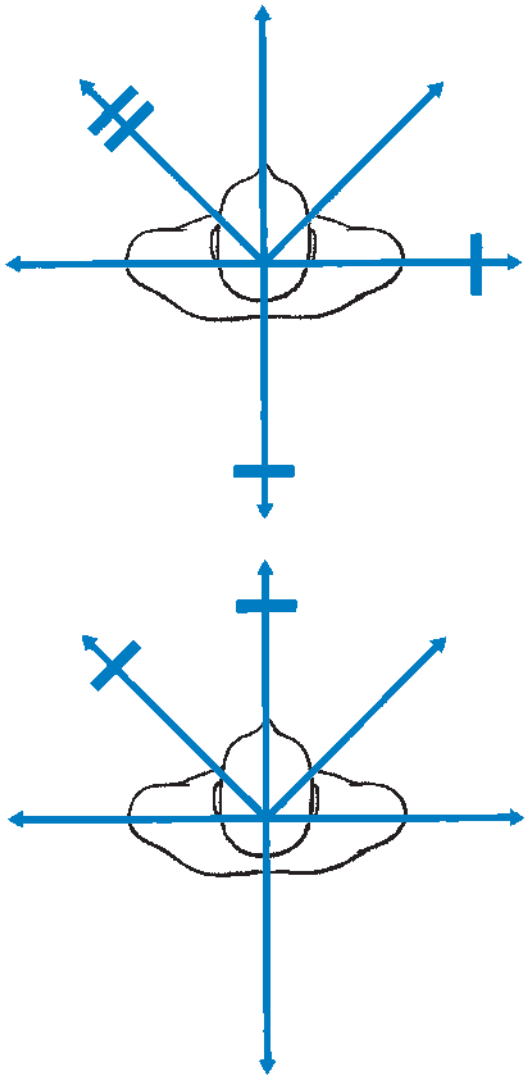

Fig 27.1 • Examples of partial articular patterns.

Often both articular and dural signs are present, although the latter are sometimes absent.

Exceptionally, a combination of a partial articular pattern with pain on one or more resisted movements is found. In this event, the question that arises is whether there is a muscular problem or a lesion of an inert structure. In the latter, pain on passive movements is more severe whereas, in the former, resisted movements are more painful.

Pain and limitation on side flexion towards the painless side as the only positive movement does not match the pattern of a disc lesion. Other disorders, such as a pulmonary or abdominal tumour with invasion of the thoracoabdominal wall, must be considered. An intraspinal tumour – for example, a neurofibroma – is also possible (see online chapter *Disorders of the thoracic spine and their treatment*).

Warning

If pain and limitation on side flexion away from the painful side is the only abnormal movement (Fig. 27.2), a tumour should be suspected.

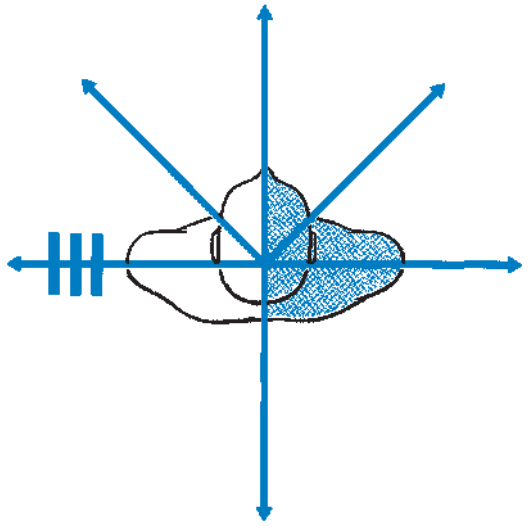

Fig 27.2 • Pain and limitation only on side flexion away from the painful (coloured) side is a warning sign for serious disorders.

Table 27.1 Articular and dural symptoms and signs in thoracic disc lesions

	Symptoms	Signs
Articular	Particular movements or postures increase the pain; others ease	Existence of a partial articular pattern
Dural	Pain on deep breath	Pain on neck flexion Pain on scapular movements

Symptoms and signs of cord compression

In thoracic disc lesions, careful attention must always be paid to abnormal neurological elements that may indicate compression of the spinal cord: pins and needles in both feet, disturbed coordination of lower limbs and positive Babinski's sign (see Table 27.1 and pp. 165–168).

Clinical types of thoracic disc protrusion

Symptomatic disc displacements in the thoracic spine may give rise to four different clinical syndromes: acute thoracic 'lumbago', chronic thoracic backache or 'dorsalgia', thoracic root pain and spinal cord compression (Figs 27.3–27.5).[24] Each syndrome corresponds to a specific type of disc lesion.

It is obvious that, besides dural and articular signs and symptoms, elements that may indicate compression of the spinal cord must always be sought.

Thoracic backache

A small annular posterocentral disc displacement causes a unilateral discodural interaction. The subsequent unilateral

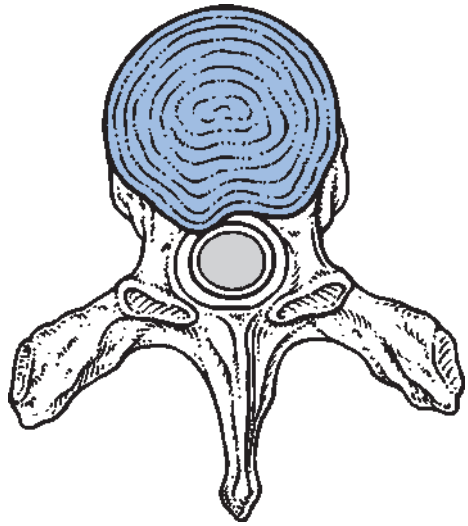

Fig 27.3 • Thoracic disc displacement: small posterior displacement with dural contact – nuclear 'lumbago' or dorsalgia.

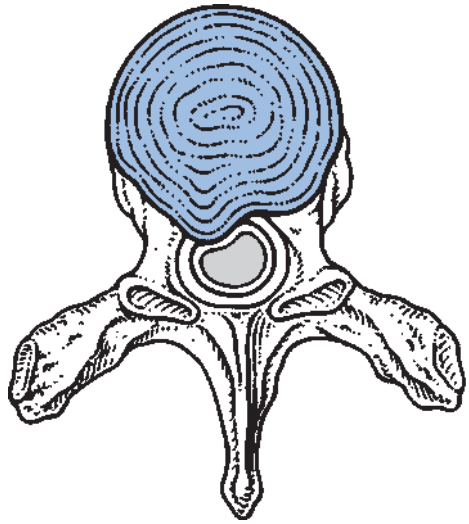

Fig 27.4 • Thoracic disc displacement: massive posterior displacement – cord compression.

interscapular pain is of moderate severity and is usually brought on by prolonged activities or postures in anteflexion. The pain gets worse during or after particular movements or positions and wears off on rest, but seldom disappears completely. In chronic thoracic backache there is no spontaneous recovery and untreated pain can persist for many years.

Because the pain is usually not severe, the articular signs are not always very impressive. However, no matter how subtle the outcome of the tests, some 'asymmetry' in the clinical picture will always be present. It is, for instance, not unexceptional to find only one articular movement that is slightly positive, very often one of the rotations.

This non-articular pattern, in the absence of pain on resisted movements, can usually be interpreted as the outcome of a disc lesion. A further argument in favour of this diagnosis is

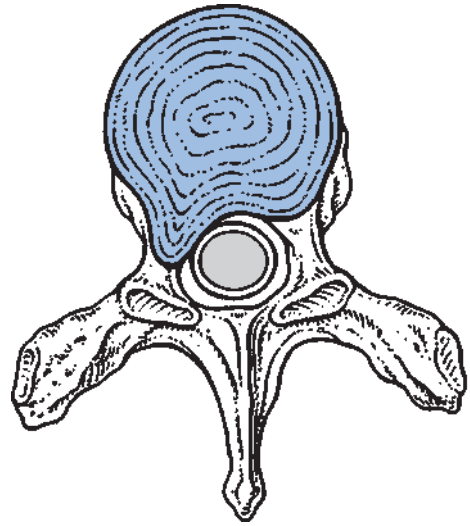

Fig 27.5 • Thoracic disc displacement: posterolateral displacement with radicular compression.

when neck flexion increases the pain on full passive rotation of the trunk (dural sign).

If both posterior pain and anterior thoracic pain are present, the posterior pain is often influenced by articular movements and the anterior pain is increased by neck flexion.

Disc lesions at level T1 and T2 may give rise to diagnostic difficulties in that very little spinal mobility exists at this level and articular movements may have no influence at all on the pain, so none is positive. The pain is often provoked only by flexion of the neck, which then suggests a cervical disc lesion. When this pattern is found, a differential diagnosis between both types of disc protrusion must be made. Stretching the T1 root and performing all three scapular movements provides the key: they may provoke or increase the pain in a high thoracic disc lesion but usually have no influence on a cervical disc protrusion.

In chronic thoracic backache there is no spontaneous recovery and untreated pain can persist for many years.

All cases of thoracic backache from a disc protrusion, in the absence of any contraindication, should be treated by manipulations, which are usually quickly successful. If this fails, traction must be tried. If there is frequent recurrence, sclerosant infiltrations into the different ligaments and facet capsules must be given to increase spinal stability.

Special case: self-reducing disc lesion

As the term implies, the disc undergoes spontaneous reduction. Patients who suffer from this condition usually sit for most of the day. On waking up in the morning they are symptom-free but, after they sit for some hours, pain starts in the mid-thorax and gets progressively worse. On lying down, the pain gradually eases off. The time needed for the pain to disappear fully depends on the degree of displacement and is initially from 10 to 15 minutes. Later, or if the patient sits for a longer period, it may take an hour or more. Pain may be absent when prolonged sitting is not part of the daily routine – for example, at weekends.

In this condition the disc gradually dehydrates as the result of the prolonged sitting position.[25] Simultaneously, the imposed kyphosis pushes the whole intra-articular content of the disc posteriorly, compressing the dura mater and resulting in thoracic backache. On lying down, the effects of hyperkyphosis and gravity are largely diminished and the disc shifts spontaneously back into its original position. These patients should avoid prolonged anteflexion. Manipulative reduction is useless but sclerosant infiltrations may be helpful.

Acute thoracic lumbago

Due to a combined flexion–rotation movement of the trunk, the patient becomes suddenly immobilized by a sharp posterior pain in the thorax, with the trunk fixed in flexion. The condition is similar to acute lumbago at the lumbar spine. In both, the underlying cause is a posterocentral disc protrusion. Pain is usually felt posteriorly in the centre of the back, radiating unilaterally or bilaterally around the chest. In high thoracic lesions, the pain may even reach the sternum; in low thoracic lesions, the pain is sometimes referred to the abdomen.

A deep breath is very painful and normally hurts more than a cough. Sudden onset in the absence of injury in a middle-aged person, together with pain on deep inspiration and on neck flexion, is very suggestive of such a disc lesion.

A partial articular pattern is present in which three, four or five movements are painful, and in severe instances all movements cause pain, but still in an asymmetrical way. The symptoms and signs are thus much more pronounced than in thoracic backache.

If the patient stays in bed for some days, spontaneous resolution occurs over about 2 weeks. Cure can be obtained much more quickly by manipulative reduction. Exceptionally the pain can be so severe that the patient can hardly stand up or needs a great deal of time to turn around on the couch. Such patients should remain in bed until they have improved to such a point that normal manipulations become possible. A manipulative attempt should not be made during the initial period because it is unbearable. Sometimes special oscillatory techniques can be tried.

Recurrence may occur but the pain is not necessarily always felt at the same side.

Special case: sternal lumbago

This is a rare disorder that often causes diagnostic difficulties. A high or mid-thoracic posterocentral protrusion coming on suddenly can give rise to agonizing pain felt only anteriorly over the sternum or in the epigastrium, without back pain. Differential diagnosis with an acute myocardial infarction has to be made but is not always simple. The effect of deep inspiration can be helpful: it increases the pain of a disc lesion but usually does not affect that originating from the myocardium.

Thoracic root pain

As in the cervical and lumbar spines, two types of root pain can be encountered: a primary and a secondary posterolateral protrusion. The latter is more common. In the first type, the protrusion is deviated in a posterolateral direction from the onset; in the second, there is first a posterocentral protrusion that later shifts laterally, analogous to a lumbar disc lesion.

- *In a primary posterolateral protrusion*, segmental pain is felt from the start at the lateral aspect of the thorax and often radiates unilaterally to the front of the chest or the abdomen. The absence of pain in the back may lead to the discogenic origin being overlooked.
- *In a secondary posterolateral protrusion*, an extrasegmental posterocentral or posterior unilateral pain is initially present, which then moves more to the side and sometimes towards the anterior thorax or abdomen – meanwhile becoming segmentally referred – a sequence of symptoms that strongly suggests a secondary posterolateral disc lesion.

Both types of root compression give rise to segmental referred pain. This has a unilateral band-shaped distribution that follows the intercostal nerves. At the thoracic level a posterolateral protrusion seldom gives rise to pins and needles. If present, they follow the same segmental distribution as the pain. As the T12 dermatome spreads into the lower abdomen, interference with this nerve root can result in pain and occasionally pins and needles in the groin and/or the testicles.[26]

On functional examination, a partial articular pattern is usually found. Occasionally, the patient feels nothing on articular movements but flexion of the neck provokes a sharp unilateral sternal pain, sometimes accompanied by pins and needles in the same place. As flexion of the neck also stretches the nerve roots via the dura, one of these can be pulled further against a protrusion, resulting in a sudden pain.

Neurological signs are seldom encountered and, if present, are always difficult to diagnose. As the majority of the thoracic nerve roots cannot be stretched by movements of arms or trunk, an analogue of straight leg raising does not exist. Moreover, motor deficit, except for a T1 lesion, cannot be tested. The only feature that is occasionally found is numbness. When present, it is of little help in determining the exact level of the protrusion because the dermatomes overlap. Only numbness in the groin draws attention to a nerve root palsy – T12. In rare instances, an area of hyperaesthesia is felt in the front of the chest.

A T1 root palsy is detected during the clinical examination of the cervical spine. It is seldom the result of a disc protrusion but usually the outcome of a serious disorder such as a superior sulcus tumour of the lung, a neurofibroma or vertebral metastases. Although T1–T2 discoradicular compressions with neurological deficit have been reported,[27–29] it should be kept in mind that if a neurological deficit of T1 is present, more severe disorders should always be excluded first (see see online chapter *Disorders of the thoracic spine and their treatment*).

Thoracic disc lesions compressing a nerve root do not usually resolve spontaneously, although there are a few reports of spontaneous regression at a lower thoracic level.[30,31] However, posterolateral thoracic disc protrusions which cause root pain remain reducible by manipulation, no matter how long they have existed. Where manipulation has failed or where neurological deficit is present, a sinuvertebral block should be given.

Compression of the spinal cord

The spinal cord is most vulnerable at the lower thoracic levels, between T9 and T12,[29,32] because the spinal canal is at its narrowest there and the vascularization is at its most critical.[33] It has been suggested that signs of cord compression do not always stem from pressure on the cord itself, but rather are the result of interference with the blood supply.[3–5]

Osteophytes narrowing the spinal canal are an extra contributing factor.[34] Previous injury to the thoracic spine can also play a role in the later development of cord compression, although this circumstance is rare.

History

The most commonly observed chronological sequence in cord compression is pain, followed by sensory disturbance, motor weakness and finally visceral dysfunction. All of these features may be present in any combination.

Pain

Initially almost all patients complain of pain. It is never particularly severe, often has a vague band-shaped distribution, and may sometimes disappear completely.[35–38] It is usually localized in the back, although it may radiate into the pelvis or groin and down the legs. Occasionally, patients complain of subumbilical pain.[1] The quality varies from a constant, dull and burning pain to – exceptionally – a lancinating, cramping and spasmodic pain.

Pins and needles

These are the most common symptom. They are usually felt in one or both feet, sometimes radiating into the legs, and are often provoked or increased by flexion of the neck.

Numbness

Later in the course, unilateral or bilateral numbness may set in and may be accompanied by a motor palsy. The numbness is more a diminution of normal sensation than a complete loss of sensitivity. It often starts at the big toe and is accompanied by a subjective sensation of coldness.[3]

Weakness

Because of interference with motor function, patients often complain of difficulty on walking, which sometimes presents as subjective weakness of the legs with unsteadiness or stiffness; it may, however, truly interfere with gait, making the patient stagger or even making walking impossible. It is important to note that the patient's subjective complaint of motor weakness is not always confirmable clinically.

Visceral symptoms

Very often visceral symptoms involving the urinary tract or bowel are also mentioned. Urinary symptoms may vary from difficulty in starting, to urgency, change in frequency, incontinence, incomplete emptying and even complete urinary retention. Occasionally, patients complain of impotence or of decreased sensation during intercourse.

Bowel problems are of the same nature as those related to the urinary tract, with constipation quite frequently present.

Functional examination

The functional examination normally confirms what is already expected from the history. The most characteristic signs are found on neurological examination; the articular signs are of secondary importance.

Some or all of the following neurological signs may be present:

- Disturbed coordination with spastic gait.
- Increased muscle tone, with the affected muscles not limited to one myotome.[39] Occasionally, weakness of the lower abdominal muscles can be demonstrated, when the umbilicus is seen to move as the patient attempts to sit up.[1] This is known as Beevor's sign.
- Weakness and/or atrophy of some lower limb muscles.
- Hyperreactive patellar or Achilles tendon reflexes with ankle clonus.
- Occasionally, absent tendon reflexes, particularly and inevitably when a flaccid type of paraplegia is present. The abdominal reflexes are often absent or diminished, most commonly in both lower quadrants. All these signs may be unilateral or bilateral.
- Positive Babinski's and Oppenheim's signs.
- Absence of the cremasteric reflex.
- Numbness.
- Limitation of straight leg raising, sometimes bilateral.[2]
- Occasionally, a Brown–Séquard syndrome in cord compression.[6] It is characterized by an ipsilateral flaccid segmental palsy, together with an ipsilateral spastic palsy below the lesion, with ipsilateral anaesthesia and loss of proprioception and loss of appreciation of the vibration of a tuning fork. Contralateral discrimination of pain sensation (analgesia) and thermoanaesthesia may be present and are both sited below the lesion.[40,41]

Although many of these tests are not included in the basic examination, they should be undertaken when the slightest suspicion of compression of the spinal cord exists.

Sometimes the neurological disturbances are found to extend proximal to the territory of the level of compression. This may be the outcome of interference with the blood supply of the anterior spinal artery rather than compression on the cord as such.[3–5]

Differential diagnosis

Differentiation from other compressive disorders of the spinal cord, such as neoplasm, infection, vertebral fracture and epidural haematoma, dissecting aneurysm and diseases of the cord (multiple sclerosis, Guillain–Barré syndrome and amyotrophic lateral sclerosis), is not always easy and requires further clinical reasoning and more technical investigations.

Technical investigations

The clinical description given above necessitates further imaging investigations. A plain radiograph sometimes shows

calcification in the disc that is at fault.[1,6,29,42] However, other authors, including Cyriax, consider calcification, together with the accompanying narrowing of the intervertebral joint space, to be non-specific.[43]

A myelogram usually indicates the level of the lesion with certainty, although special projections may be needed.[44]

Today, MRI is the imaging method of choice in the investigation of the thoracic spinal canal.[45] It provides a good-quality image over the entire length of the spine and can assess the morphology of the discs and cord. It is non-invasive, has comparable sensitivity to conventional myelography in visualizing lumbar nerve roots, and allows overall assessment of the spinal canal even in the presence of cerebrospinal fluid block.[46,47]

Treatment

The only treatment in cord compression is surgery.

Warning

Summary of warning signs: these are two-fold.

1. Presence of neurological signs.
   First exclude: neoplastic process
   infectious process
   fracture
   If negative: consider disc protrusion
2. Side flexion away from the painful side is the only painful and limited movement:
   No disc lesion is present but a tumour is most likely

Treatment

Almost all thoracic disc protrusions can be reduced by manipulation in 3–5 sessions. If manipulation does not succeed after, say, three sessions, the diagnosis should be reconsidered and, if a disc lesion is confirmed, traction can be tried. Traction can also be used for thoracic postural pain syndrome and for lateral recess stenosis in the thorax (see later). Other treatments, discussed later, include sinuvertebral blocks for persistent root pain or for root pain with neurological deficit, surgery, bed rest and prevention of recurrence.

Manipulation

Indications

All actual and symptomatic thoracic disc protrusions should be manipulated, in the absence of contraindications.

Unlike in the cervical and the lumbar spine, the type of onset is of less importance for treatment of the thoracic spine, since the great majority of thoracic disc protrusions are annular. Consequently, manipulations should be tried first. If these fail, and if the diagnosis of a disc lesion is confirmed, a nuclear protrusion should be considered. The time that has elapsed from the onset of pain can also be disregarded, because thoracic disc protrusions remain reducible regardless of their duration. Although T1 and T2 disc lesions will come to light in the cervical examination (rather than the thoracic examination), when a disc protrusion is present it should be treated using manipulative techniques designed for the thoracic spine.

Indications for and contraindications to manipulation are summarized in Box 27.1.

Box 27.1

Indications for and contraindications to manipulation

Indications

- All symptomatic disc displacements in the absence of contraindications

Contraindications

Relative

- Absence of actual symptomatic disc displacement
- Self-reducing disc lesion
- Monoradicular neurological deficit

Absolute

- Signs and/or symptoms of cord compression
- Patients with bleeding disorders
- Patients on anticoagulant treatment

Contraindications

Relative contraindications

Disc protrusion is not present

It is obvious that, in the absence of a disc protrusion, manipulation is inappropriate and could even do harm by displacing a disc fragment.

Self-reducing disc lesions

In self-reducing disc displacements, no manipulative attempt must be undertaken because reduction occurs on lying down. However, measures for prevention of recurrences must be taken. A series of infiltrations with sclerosant solution is then the treatment of choice.

Segmental neurological deficit

Neurological deficit indicates that the protrusion is too large to be reduced. Therefore no manipulative attempt is made if monoradicular numbness and/or motor palsy is found. Should this be present, the patient can be treated by an infiltration around the nerve root.

Central protrusion

This occurs mainly in young patients with a large thoracic kyphosis, is nuclear in origin and posterocentrally localized, and causes bilateral radiation of pain. The treatment of choice is sustained traction.

Absolute contraindications

Cord compression

Signs and symptoms of compression on the spinal cord, such as a positive Babinski's sign, weakness of the lower limbs or spastic paresis, are absolute contraindications to manipulation. Such patients should be operated on at once.

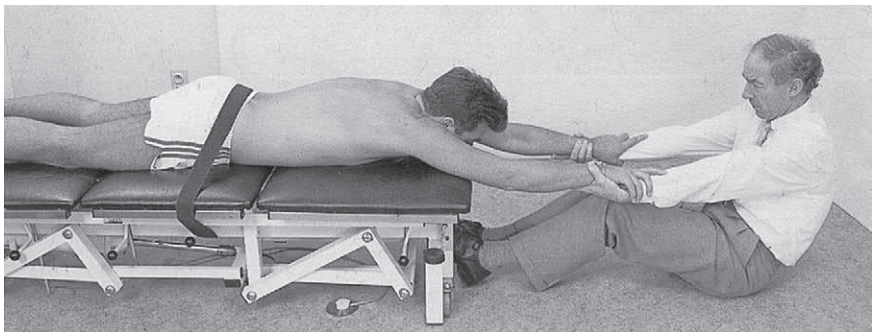

Fig 27.6 • Traction given by one assistant, using a belt.

Fig 27.7 • Traction is applied via the head if the lesion is situated above T6.

Sometimes patients with cord compression are encountered who complain of pins and needles only in the legs and feet, increased or provoked by flexion of the neck. On clinical examination, further evidence of cord compression is not found. The implication is that the protrusion interferes minimally with the cord; nevertheless, manipulations could easily increase the problem and are absolutely contraindicated. This does not apply to sustained traction, which can be tried in cases in which the clinical features have not been present for too long.

Bleeding disorders

Patients who suffer from bleeding disorders, either inherited or acquired, or who are on anticoagulants should never be subject to manipulation because this could provoke an intraspinal haematoma. If a patient on anticoagulants suffers from a disc lesion, the anticoagulants must be stopped over a period of days (should the condition for which treatment is prescribed permit) until blood coagulation has returned to normal. Manipulation can then be performed safely.

Techniques

Thoracic manipulations are always performed under strong traction. Three main types of procedure are considered: extension techniques in which extension is always present, sometimes together with a rotation; rotation techniques, in which rotation is the only element and extension is not incorporated; a third type, the 'high thoracic technique', used only in upper thoracic disc lesions.

All extension manipulations of the thoracic spine are specific, i.e. they are performed only at the two vertebrae on either side of the disc protrusion.

Principle of strong traction

No one can foresee with absolute certainty the direction in which the protruded fragment will move during a manipulation. Theoretically, it could be displaced further towards the spinal cord. To avoid this and for a number of other beneficial effects (see p. 256), traction is always incorporated in thoracic manipulation.

Traction is normally provided by one assistant who sits beyond the patient's head and takes hold of either the head or the hands. Stabilization of the pelvis is provided either by a second assistant sitting at the patient's legs and holding the ankles or by a fixation belt around the pelvis (Fig. 27.6). Whether traction is given via the head or the arms depends on the level of the lesion and the patient's comfort. As traction on the arms opens the intervertebral joints only from T6 downwards, traction must be given via the head in disc protrusions above T6 (Fig. 27.7).

If traction via the arms provokes pain anywhere in the upper limb, it is replaced by traction on the head.

> Disc protrusion above T6: traction via the head.
> Disc protrusion below T6: traction via the hands.

Traction via the head is provided by putting one hand under the patient's chin and the other below the occiput, with the head and neck always kept in the neutral position (see Fig. 27.7). Both hands pull equally hard.

Traction via the arms is achieved by the patient and assistant taking each other's wrists in their hands.

Before any manipulation is done the assistant must first create traction because very often slack in a belt must be taken up and adjustment may be needed.

The traction provided should always be given with maximum force in order to open the joint space as far as possible. Because maximum traction can only be maintained for a few seconds, it is only given after the manipulator has taken up all the slack of the manœuvre to be performed. The different steps of the manipulation, including traction, are coordinated by the manipulator.

Although exerted with as much strength as possible, traction is not a manipulation in itself. In other words, the assistant does not add a jerk to the pull during the manipulation but only maintains the pull maximally until the manipulation is complete.

Amount of force

Each manipulation must be performed with a reasonable amount of force. This depends on both the manipulator's and patient's physical size and the level of the protrusion. If a large examiner is dealing with a lightly built patient, the whole of the former's strength will not be used, but if a lightly built manipulator has to manipulate a heavier person, the maximum effort may be needed to achieve good results.

Because the upper half of the thorax is the most rigid, disc protrusions at this level require more forceful manipulation than for the lower half. Therefore a lesion below T6 can be treated with a less vigorous impulse.

All manipulation must be performed using the body. The most common mistake occurs when the manipulator uses his arms rather than his body. This leads to a loss of the slack already taken up and results in increased amplitude of manipulation, which may be dangerous because the manipulator has no control over the force used.

Extension techniques in prone position

Unless the patient is 60 years old or more, extension techniques are used initially. All extension manipulations are specific in that they are performed directly on the vertebrae between which the lesion lies.

Identifying the level of the lesion

The two most painful consecutive spinous processes are identified by extension pressure. The protrusion normally lies between their corresponding vertebrae. If only one spinous process is found to be tender, the disc at fault is usually the one lying just below. This being so, the extension manipulations are undertaken between the vertebra with the tender spinous process and the one immediately below.

Sometimes all spinous processes are equally tender on extension pressure. It can then be useful to take two consecutive spinous processes between the fingertips one by one and to try to rotate them in the opposite direction towards each other. This is done at all levels and the two that prove most painful are indicative of the level of the lesion.

From this point on, in describing the different extension techniques, the phrase 'two most tender spinous processes' is used. It is important to understand that this always means the two most tender on extension pressure and not just on palpation for local tenderness.

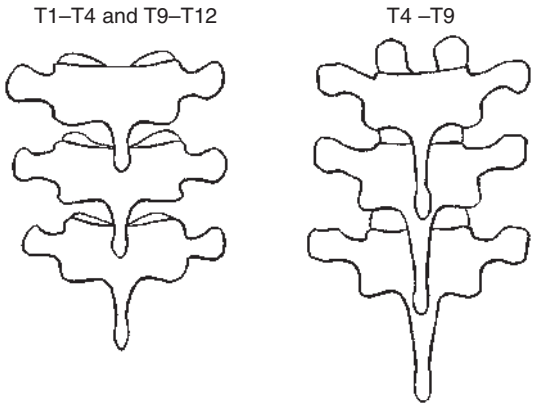

Fig 27.8 • Relationship between the level of the spinous processes and their corresponding transverse processes.

Some extension techniques are executed on the transverse processes. To be able to perform these manipulations at the right level, it is essential to have a good knowledge of the relationship between the spinous processes and their corresponding transverse processes, because this varies with the level (Fig. 27.8).

- *T1–T4 and T9–T12:* there is a difference of one level between the consecutive vertebrae, i.e. the transverse process of one vertebra lies level with the spinous process of the vertebra above. For example, the transverse process of T3 lies level with the spinous process of T2.
- *T4–T9:* there is a difference of 1½ levels. The transverse process lies level with the interspinal line between the spinous processes of the first and the second vertebrae above (Fig. 27.9). The transverse process of T8, for example, lies between the spinous processes of T6–T7, that of T9 between T7–T8.

Direction of rotation

This is important in manipulations that include an element of rotation. Manipulation is first undertaken in the direction of the less painful rotation. If this is only partly or completely unhelpful or makes the patient worse, rotation in the other direction follows.

The direction of the rotation is always defined by the direction in which the anterior part of the upper vertebra rotates. So when the upper vertebra rotates to the left, the movement is defined as a left rotation (Fig. 27.10).

Technique I: central pressure (Fig. 27.11)

The patient lies prone on a low couch. The two most tender spinous processes are marked. The examiner stands to the side, facing the patient, and places one hand, reinforced by the other, on the lower of the two processes. Because the thoracic spinous processes cover each other like tiles on a roof, it is logical to place the hands on the lower one in order to achieve as much movement as possible between the vertebrae. If the hand is placed on the upper vertebra, the movement is assured by the bony contact between the spinous processes; when the hand is placed on the lower vertebra, it is pushed away from the upper vertebra, resulting in increased range of motion.

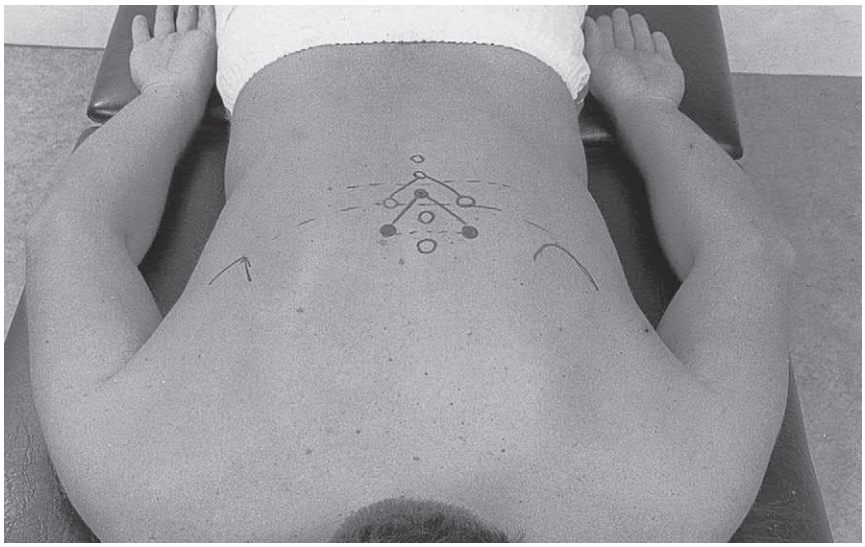

Fig 27.9 • The 1½-level difference between the spinous and transverse processes, which is present in T4–T9.

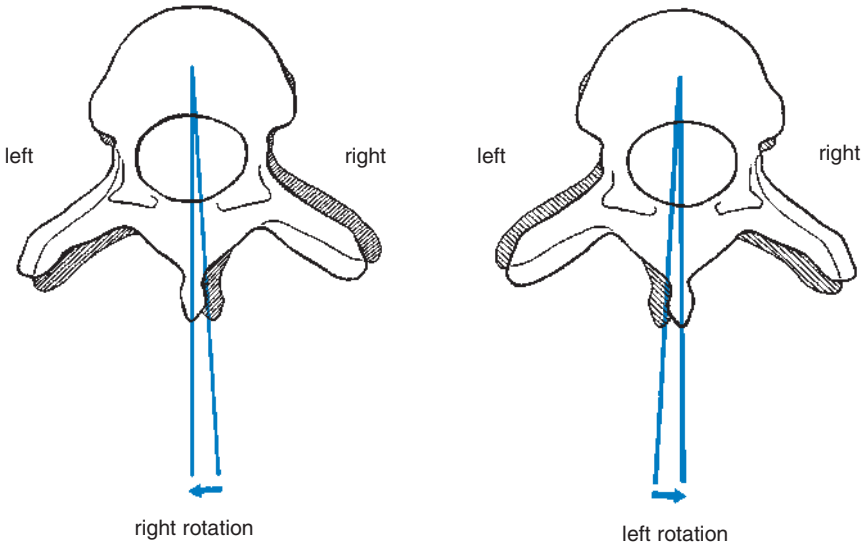

Fig 27.10 • Direction of rotation.

The hand makes contact with the spinous process via the fifth metacarpal bone and, to make the manœuvre less painful, the hand is placed slightly oblique so that the hypothenar muscles lie between the bones of the hand and the patient's spine.

The assistants adopt the positions already described.

The manipulator leans over the patient, the shoulders vertically above the hands, elbows straight, and feet a distance away from or close to the couch, depending on the effort to be used. All the slack is taken up by use of the body weight and is maintained until the final manipulative thrust is given. The patient is now asked to relax fully by taking a deep breath, followed by a maximal expiration. The moment the patient starts to breathe out, the manipulator tells the assistants to pull. Waiting until the end of expiration and under maximal traction, the final extension thrust is given by the manipulator's body, transmitted to the patient via the arm and hands.

Technique II: unilateral pressure (Fig. 27.12)

This manipulation is performed unilaterally on the transverse process.

The patient lies prone and the two most painful spinous processes and their corresponding transverse processes are marked. Vertical pressure is exerted on the transverse process of the lower of the two vertebrae.

The manipulator stands on the contralateral side of the patient: on the left for a right rotation. One hand, reinforced by the other, is placed with the pisiform bone on the transverse process. To make good bony contact, the paravertebral muscles are first moved to the side. This is achieved by pushing the muscles away from the vertebra with the base of the lower hand. One assistant holds the patient's ankles, while the other grasps the head or hands. With the elbows straight, the manipulator leans over the patient and brings the body weight perpendicular over the spine, taking up all the slack. The patient

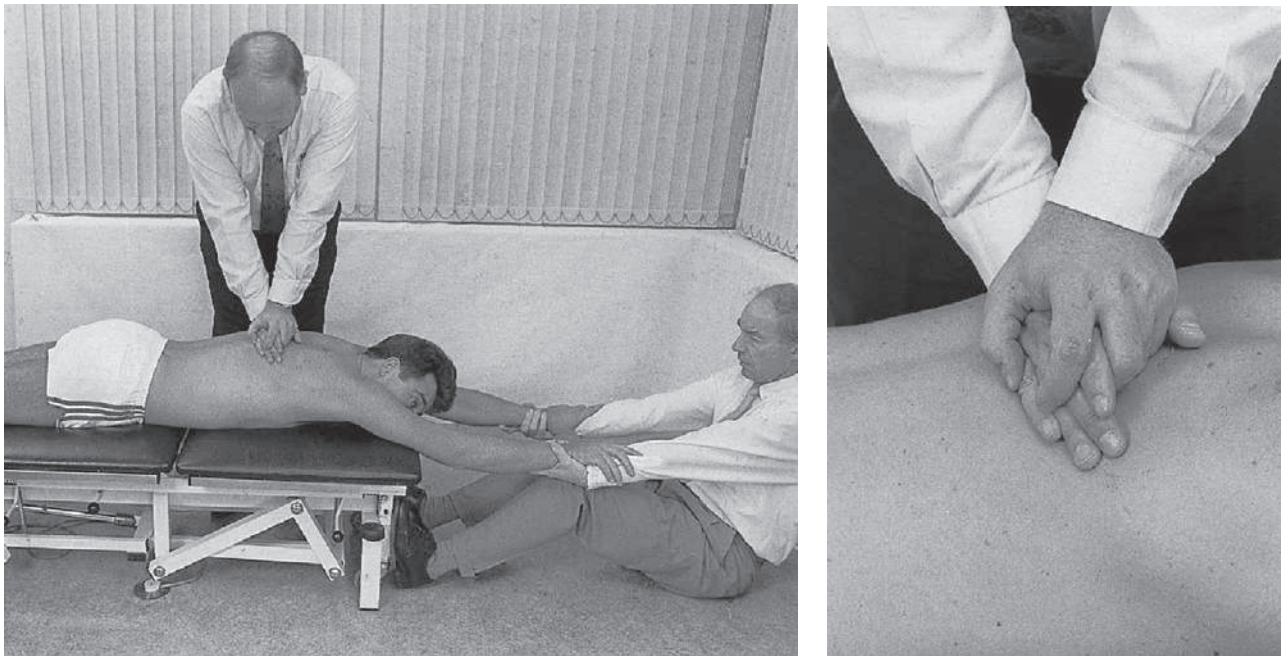

Fig 27.11 • Central pressure.

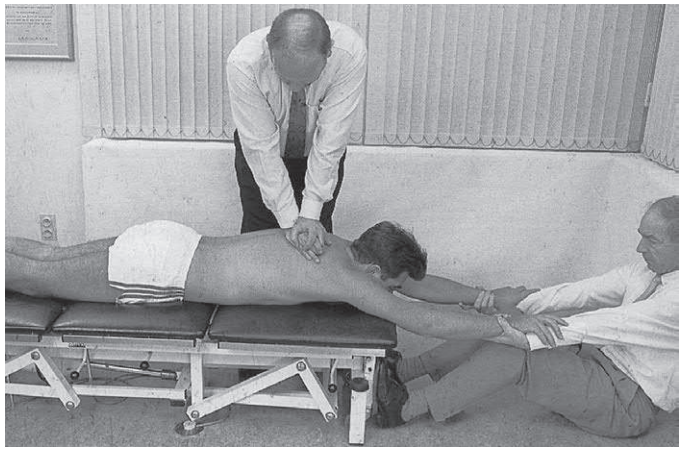

Fig 27.12 • Unilateral pressure.

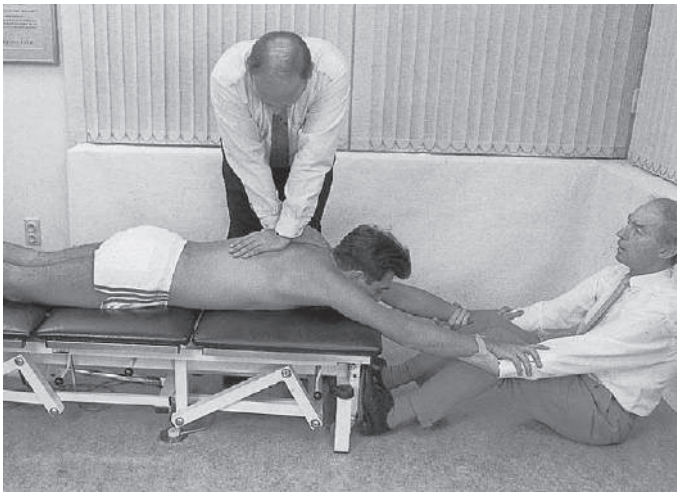
is now asked to relax, take a deep breath in and then expire fully. The assistants are told to pull. After a couple of seconds of traction, the manipulator gives the final jerk vertically downwards. This causes a rotation and an extension movement.

Technique III: using crossed hands (Fig. 27.13)
Although a strong rotation element is present in this manipulation, it is still regarded as an extension technique.

The patient lies prone on a low couch. The manipulator can choose to stand on either side of the patient. The two most tender spinous processes and their corresponding transverse processes are marked. The rotation found during the clinical examination to be the less painful is performed first. If this is without benefit, the opposite rotation is performed. One hand is put on the transverse process of one vertebra, the other hand on the transverse process of the second vertebra on the opposite side. Care should be taken to cross the hands fully. The



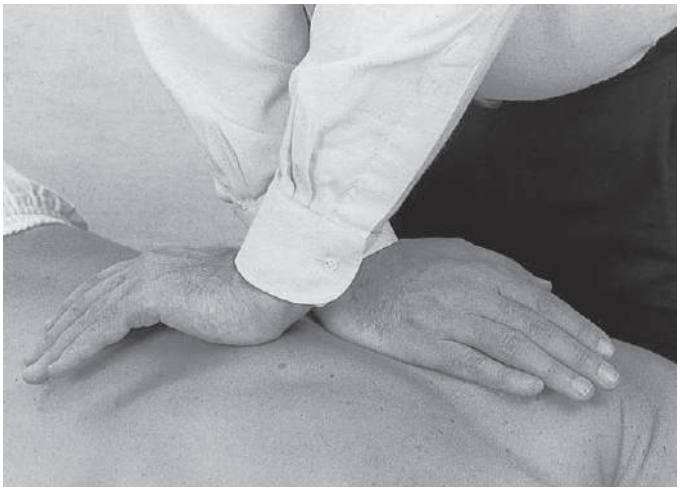


Fig 27.13 • Using crossed hands.

hand closer to the manipulator is placed on the transverse process via the pisiform bone. The other hand is in contact via the base of the trapezium–first metacarpal joint. Good bony contact is essential and is achieved by first pushing the paravertebral muscles away from the spine. The trapezium–first metacarpal joint of the one hand and the pisiform of the other are first placed just to the side of the spinous process. Both hands are now twisted into ulnar deviation, so pushing the muscles further to the side, and are then brought back closer to the midline but still remain on the transverse processes.

With the elbows straight, the manipulator leans over the patient and brings both shoulders vertically above the hands. As a result, all the slack is taken up. The assistants provide traction and the final jerk from the manipulator's body follows.

Extension technique in supine position

The patient lies supine just near the edge of the couch and places both hands behind the neck, the fingers covering the upper thoracic spinal processes. The elbows are placed well forwards and close together. The manipulator stands on the right-hand side facing the patient. By grasping the patient's left shoulder in the right hand and both elbows on the left hand (Fig. 27.14a), the manipulator flexes the patient's neck and trunk and rolls the upper body inwards (Fig. 27.14b).

Then a fist is made with the middle, ring and little fingers of the right hand – thumb and index finger are left out. This fist is now brought into firm contact with the lower vertebra of the segment being manipulated – the thenar eminence against the left and the middle phalanx of the flexed middle finger against the right transverse process. In this way the spinous process of the lower vertebra lies in the groove between these two eminences (Fig. 27.14c).

Now the patient is lowered back again until the manipulator's hand is wedged between the patient and the couch. In order to achieve full control over the movement, the patient's elbows are firmly held against the manipulator's sternum (Fig. 27.14d). Leaning well over the patient and using the weight of the trunk, the manipulator obtains considerable separation at the intervertebral joint. At the moment when the limit of tissue tension is felt (and the patient relaxes as fully as possible), the manipulator pushes the body forwards to apply a certain amount of overpressure. At that moment a 'click' or 'snap' is nearly always heard and felt, and the result of the manipulation is then assessed.

Variations

- If the patient is not able to reach the upper thoracic spine with the hands because of stiffness or a painful shoulder, the technique may be varied by crossing the arms fully over the chest. The right hand clasps the left shoulder, the left hand the right shoulder.
- Some degree of rotation can be added if the thenar eminence and the middle phalanx of the middle finger are positioned on two consecutive transverse processes and not on those of the same vertebra.

Techniques for upper thoracic disc lesions

Rotation techniques for upper thoracic disc lesions (Fig. 27.15)

This manœuvre is suitable only for upper thoracic disc lesions. It is best performed on a couch of medium height. The less painful rotation is done first.

The patient lies prone. For a right rotation, the manipulator stands facing the patient on the left-hand side. The right arm of the patient lies fully medially rotated on his back, the elbow flexed. One assistant exerts traction via the patient's head and also rotates it slightly to the right. In this way, the cervical spine is kept in neutral position during the whole manœuvre. The other assistant holds both of the patient's feet.

The manipulator hooks his left arm underneath the patient's furthest shoulder so that the proximal part of the lower arm can lift the patient's shoulder off the couch. The right hand is placed on the dorsal aspect of the ribs as high and as close to the thoracic spine as possible. The fingers of both hands are now clasped together. Both hands rest on the ribs, just lateral to the spine and no further down than mid-thorax. The manipulator now bends the trunk to the right, meanwhile pulling the patient's right shoulder off the couch via the left lower arm. The rest of the spine is held down on the couch by both hands pressing on the ribs. The assistants are asked to apply traction and the manipulator suddenly increases the side flexion. With this final movement, extension and rotation at the upper thoracic spine are increased. The rigidity of the upper thorax allows movement over only a small range.

Longitudinal traction for upper thoracic disc lesions (Fig. 27.16)

The patient stands or sits with the back to the manipulator. A sitting position is preferred if the patient is taller or heavier in weight than the manipulator. The patient is then asked to grasp the hands behind the neck, allowing the elbows to drop forwards.

The manipulator threads the arms in front of the patient's axillae and grasps both wrists. The patient is then asked to bend the head, so allowing the elbows to drop further forwards and to lean backwards against the chest of the manipulator. The latter performs a preliminary lift and at the moment the patient allows the trunk to sag, suddenly extends the knees. This results in a longitudinal traction and separation particular to the upper thoracic joints. A 'click' or 'snap' is felt and the result then assessed.

Some degree of extension may be added to this technique. The manipulator achieves this by adopting a slightly modified starting position: turning the trunk slightly to one side allows positioning of the lower ribs against the spine at the level at which manipulation is required.

Warning

Beware of forcefully flexing the neck of the patient during the upward thrust.

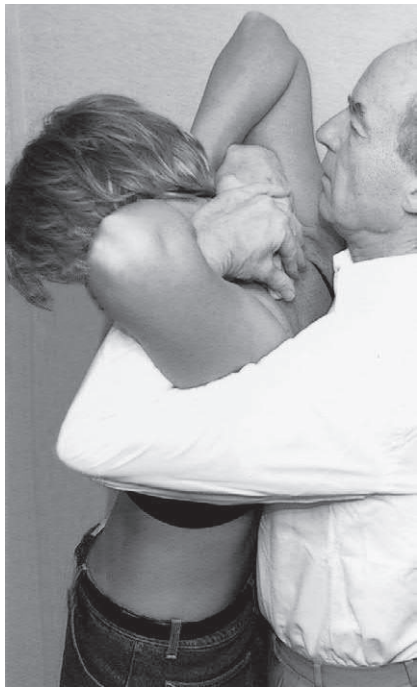

Fig 27.16 • Longitudinal traction for upper thoracic disc lesions.

Choice of manœuvre

The different techniques are used in a specific sequence, depending on the patient's age, the level of the protrusion and the immediate result of the preceding manipulation.

After each manœuvre the patient is re-examined and, if improved, the same manœuvre is repeated several times with increasing strength until the patient has completely recovered or until no further improvement is obtained. In the latter event, another type of manipulation follows. If the patient does not improve or even becomes worse, the same manipulation is not carried out a second time but is immediately replaced by another. In such cases, the same type of technique is performed, but in the opposite direction. If this manipulation also aggravates the lesion, manipulation must be stopped and the diagnosis reconsidered.

Improvement is indicated by pain, which is perceived over a small area and/or which becomes less severe. Another important sign is centralization of the pain: pain that first spreads far distally or laterally, but becomes more centrally localized, is regarded as an improvement.[48,49] Manipulations are stopped as soon as the pain has disappeared and the clinical examination becomes negative. A total number of 5 (elderly) to 10 (younger patients) manipulations are executed during one session. These can be repeated daily, although for the elderly it is advisable to allow 3 or 4 days in between. It may take 3–5 sessions before the patient has fully recovered. A certain amount of after-pain is sometimes present. If there is a recurrence, the patient should return as soon as possible to be manipulated again.

Usually the extension techniques are used first. In patients over 60 years of age, however, extension techniques may fracture a rib and are therefore never used. The same applies if the extension pressure on the spinous processes performed at the end of the clinical examination is very painful. In such a case, oscillatory techniques should then be used (see below).

Warning

Extension techniques should never be used in patients over 60 years of age or when there is excessive pain on extension pressure.

Failure of manipulative reduction

Ninety-five percent of thoracic disc lesions are reduced in 3–5 sessions. If, after 3–5 manipulative sessions, relief of symptoms is not obtained, it should be accepted that either the diagnosis is wrong or the disc lesion is not suitable for manipulation. The latter may be the result of too large a protrusion, as shown by the presence of neurological deficit, or may occur when a nuclear disc lesion is present (Box 27.2).

Oscillatory techniques

Some cases respond better to oscillations. These consist of gentle high-frequency mobilizations at 2–3 vibrations per second. Oscillations should be given for 10–15 minutes daily and are performed as either central or unilateral pressure to the thoracic spine.[50]

Indications

There are three groups of indications:

- Patients who present with a great deal of discomfort but with very minor articular signs on clinical examination.
- Patients with acute thoracic lumbago who are in such pain that they cannot tolerate normal manipulations. Oscillatory techniques can be used until the pain is

Box 27.2

Unsuccessful manipulations

Wrong diagnosis: no disc protrusion?

- Facet joint?
- Tumour?
- Muscular lesion?
- Osseous lesion?
- Ligamentous lesion?
- Visceral disorder?

Disc protrusion confirmed

- Check for neurological deficit
  1. If neurological deficit is present:
     - Stop manipulation
     - Give sinuvertebral block
  2. If no neurological deficit is present, consider nuclear protrusion:
     - Stop manipulation
     - Try traction

reduced to a level at which normal manipulations can be started.

- Patients who cannot tolerate the extension or rotation techniques.

Sustained traction

In some patients with thoracic disc protrusion, reduction by means of traction may be needed. However, traction may be technically impossible in patients suffering from orthopnoea, asthma or hiatus hernia or who have recently undergone thoracic or abdominal surgery (see Ch. 40).[51]

Indications

- *Central protrusions*: it can be dangerous to manipulate very central protrusions, as there is a possibility of causing compression of the spinal cord. Central protrusions are present mainly in those with a marked thoracic kyphosis, either postural or after a wedge fracture. These patients complain of central pain radiating to both sides.
- *Failure of manipulation*: patients suffering from a disc lesion in whom manipulative attempts have failed or who have been made worse, should receive traction unless nerve root compression with neurological deficit is present. There is usually a history of gradual onset, although this is not pathognomonic in the thoracic spine for a nuclear protrusion.
- *Symptoms of cord compression in the absence of signs*: patients suffering from a thoracic disc protrusion with pins and needles in both feet can undergo cautious traction if no other symptoms or signs of cord compression are present.
- *Thoracic postural pain syndrome*: these patients can be helped by daily sustained traction with increasing traction-free intervals (see online chapter *Disorders of the thoracic spine and their treatment*).
- *Disc lesions at a very kyphotic thoracic joint.*
- *Disc lesions adjacent to a wedge fracture of a vertebral body.*
- *Anterior and lateral erosion* (see online chapter *Disorders of the thoracic spine and their treatment*).
- *Lateral recess stenosis* (see online chapter *Disorders of the thoracic spine and their treatment*).

Technique

Traction is given daily over 30–45 minutes. Thoracic discs above T9 are treated with cervical traction. For these, the rules of cervical traction should be observed (see Ch. 11).

For thoracic protrusions below T9, traction is given using the lumbar technique (see Ch. 40). An intensity of 35 kg (small person) to 70 kg (heavy, well-built person) is used. Obviously, the thoracic belt should be placed cranial to the level of the lesion. The initial traction sessions are used as the manipulator's guide for positioning the patient and for the strength to be used.

Results

Improvement normally begins after 6–10 sessions, whereas full cure may require up to 20 sessions.

Sinuvertebral nerve block

In persistant root pain or in pain associated with neurological deficit, a sinuvertebral nerve block is the treatment of choice. This should only be performed under radiological control.

Bed rest

If both manipulation and traction have failed and no indication for surgical intervention is present, the only remaining alternative is prolonged rest in bed in the hope that removing the influence of gravity on the spine may allow the protrusion to reduce spontaneously.

Surgery: removal of protruded discs

The main indication is early cord compression by a progressive disc lesion.

Laminectomies done before 1960 were dangerous interventions with disappointing results.[52,53] It was found that almost all serious complications occurred among those having midline protrusions at levels T10–T11.[53] This is probably the outcome of the shape of the spinal canal, which is quite narrow at this level. The posterior approach used required some displacement of the cord in a very confined space, with consequent considerable risk to the blood supply.

Since 1960 a transthoracic lateral approach has been used and in recent years more progress has been made with new thoracoscopic microsurgical techniques.[54,55] They seem to give better results and fewer complications.[56] Recently,

percutaneous laser disc decompression – intervertebral discs are treated by reduction of intradiscal pressure through laser energy – has also been promoted as a valuable method in treating recalcitrant thoracic disc lesions.[57]

Prevention of recurrence

Postural prophylaxis

Reduction of a thoracic disc protrusion normally does not cause much in the way of difficulties but recurrence is not uncommon and stability is often difficult to achieve. This is obviously because of the normal thoracic kyphosis which results in a posteriorly directed force acting on the disc.

All the rules on prophylaxis for the lumbar spine are also applicable here (see Ch. 40). However, it is much more difficult and sometimes even impossible to put them into practice. For example, it is impossible to obtain the equivalent of lumbar lordosis because even the most flexible person cannot get beyond a straight line in full extension. The most hazardous movements are those that include combined flexion and rotation elements. Lifting a weight at the same time makes them even more dangerous. Therefore patients should avoid rotating their trunk but must turn their body around using their legs and should bend their knees to lift.

Sitting for a prolonged period in a kyphotic posture must also be avoided.

Ligamentous sclerosis

In those patients in whom the risk of recurrence is high (thoracic hyperkyphosis), or when recurrence is frequent, local reinforcement is needed for the supraspinal and interspinal ligaments and for the capsules of the facet joints of the vertebrae between which the protrusion lies. This can be achieved by infiltrating a sclerosant solution into these structures, which leads to proliferation of fibroblasts and formation of new collagen.[58] The final result is increased stability of the disc fragment because the two vertebrae become less mobile. Before this procedure is undertaken, full reduction must be achieved.

Occasionally, the same technique can be employed for arthritis of the facet joint or for ligamentous lesions. In these cases triamcinolone is used.

The sclerosant infiltrations are given at weekly intervals and the greatest effect is normally obtained after 3 weeks; exceptionally it may take up to 2 months. Usually, one full treatment suffices; if there is further recurrence, it can be repeated.

Technique: infiltration of the interspinal and supraspinal ligaments (Fig. 27.17)

A 5 mL syringe is filled with 3 mL of sclerosant solution and 1 mL of lidocaine 2%, and a 4 cm needle is fitted to it; 2 mL of this solution are used for the interspinal and supraspinal ligaments, the rest for the facet joints.

The relevant spinous processes are marked and the needle is inserted halfway in between them at the midline. At about 1 cm deep it is changed into an almost horizontal position, pointing cranially and aiming at the inferior part of the upper spinous process. Once it hits bone, 0.5 mL of the solution is infiltrated dropwise into the supraspinal ligament and the same

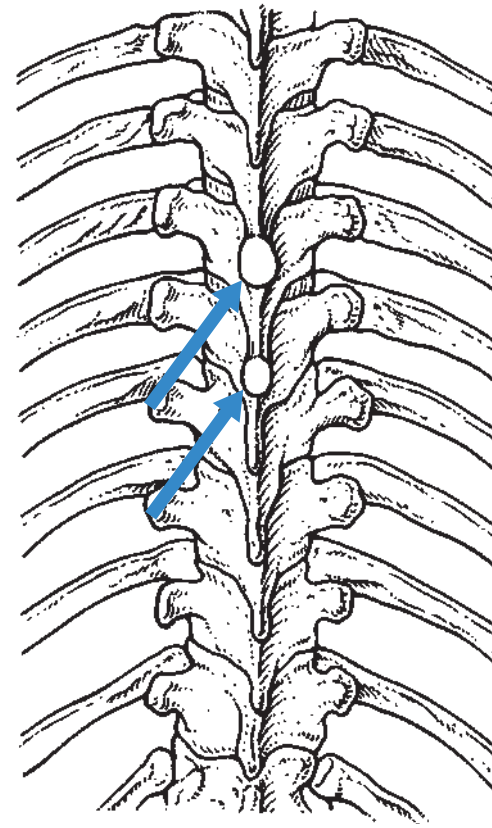

Fig 27.17 • Infiltration of the interspinal and supraspinal ligaments.

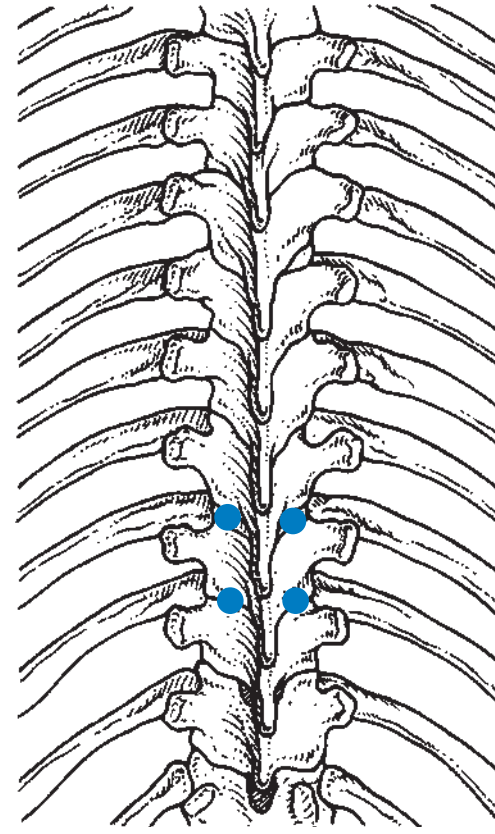

Fig 27.18 • Infiltration of the capsule of the facet joint.

quantity a little deeper down in the interspinal ligament. Infiltration is only given with the tip of the needle in bony contact. The needle is then half-withdrawn and brought into a more vertical position towards the insertions of the ligaments on the upper aspect of the lower spinous process, which are infiltrated in the same way. When the supraspinal ligament is infiltrated, it offers tough resistance, whereas infiltration of the interspinal ligament is much easier.

Technique: infiltration of the facet joint (Fig. 27.18)
A 4 cm needle is used. The patient remains prone and the transverse processes corresponding to the most painful consecutive spinous processes are marked. The needle is inserted at about 1.5 cm from the midline halfway in between the two transverse processes. It is thrust in vertically downwards until it touches the articular process at about 3 cm depth. Capsular resistance to the needle tip is sought by minor repositioning of the needle. The infiltration is given mainly into the capsule with the tip of the needle always in bony contact and considerable resistance is usually felt during the whole infiltration. This is done at both sides using 1 mL of the solution at each side.

The interspinous and supraspinous ligaments and the facet joints are infiltrated at the same time, repeated three times at weekly intervals.

Disorders of the thoracic spine: non-disc lesions

CHAPTER CONTENTS

Introduction 403
Warning symptoms and signs 403
Symptoms 403
Signs 404
Pathology: see the online content

Introduction

Non-disc lesions of the thoracic spine comprise the following disorders:

- Tumours
- Extradural haematoma
- Spinal cord herniation
- Spinal canal stenosis
- Vertebral fracture
- Chest deformities
- Fracture of a transverse process
- Spinal infections
- Lateral recess stenosis
- Localized lesion of costovertebral and costotransverse joints
- Localized lesion of a facet joint
- Paget's disease.

Very often, the signs and symptoms of the non-discal lesions of the thoracic spine resemble those of discodural disorders.

Some of the lesions mentioned are serious and even life-threatening. Therefore examiners must be on their guard and should immediately request further investigation whenever there is doubt about the exact diagnosis.

Warning symptoms and signs that warrant the examiner's attention are listed here and are summarized in Box 28.1.

Warning symptoms and signs

Symptoms

Progressively increasing pain

In disc lesions the pain may increase over a short period or come and go. In expanding lesions the pain tends to increase continuously. This may occur quickly over days (extradural haematoma), weeks to months (malignant diseases) or even longer periods (benign tumours).

Expanding pain

Pain that not only increases in intensity but also expands to occupy a larger area is very likely to be caused by an expanding lesion, most commonly a malignant disease or an extradural haematoma.

Continuous pain, not changed by posture or activity

Although this symptom is less alarming than the previous ones, a mechanical disorder is unlikely in the absence of variation of symptoms on movement. Nevertheless, the situation in the thoracic spine is slightly different from the rest of the spine because its rigidity sometimes results in a lack of change in pain with activity. Pain that is worse at night is seldom caused by a disc lesion, and is more suggestive of a rheumatic disorder, infection or trauma.

Increasing postoperative thoracic backache

Surgery correctly indicated and performed, but which is still followed by continuous pain, demands a fresh diagnostic evaluation. A clear relationship between what is found on further investigations and the patient's symptoms must be established. Local infection and a tumour must be excluded.

Box 28.1

Summary of warning signs

History

- Progressive increasing pain
- Expanding pain
- Continuous pain, not changed by posture or activity
- Increasing postoperative thoracic backache
- First symptoms and signs in people over 50 years of age
- Central pain radiating bilaterally and spreading anteriorly

Examination

- Gross limitation of both side flexions and rotations
- Gross limitation of extension
- Pain and limitation of side flexion away from the painful side as the only positive finding
- Flexion with a rigid thoracic segment
- Presence of one of following neurological signs:
  - Signs of involvement of multiple nerve roots
  - Band-shaped area of numbness
  - All signs of cord compression
  - Muscle spasm
  - Local paravertebral mass

First symptoms and signs in the thoracic area in patients over 50 years of age

Because both intra- and extraspinal tumours occur mainly over the age of 50, symptoms that first appear beyond middle age arouse suspicion. Moreover, disc lesions become less frequent with increasing age because of increasing stiffness of the spine.

Central pain radiating bilaterally around the thorax and spreading anteriorly towards the epigastrium

Although a posterocentral disc protrusion may provoke this type of pain, a tumour or an extradural haematoma should always be excluded.[1]

Signs

The following may draw attention to non-discal lesions.

Gross limitation of both side flexions and rotations

In older patients it is normal for these movements to be diminished in range, although the limitation should not be major. In younger patients gross limitation is never normal; if present, it usually points to a non-mechanical disorder, such as ankylosing spondylitis or a tumour.

Gross limitation of extension

In an ordinary disc lesion it is usually anteflexion or one of the rotations that is most painful and limited. If active extension is severely limited and painful, attention is drawn to the possibility of a fracture of a vertebral body, an infection or a tumour. There is only one type of thoracic disc lesion in which severe limitation of active extension can occur: acute thoracic lumbago. In acute thoracic lumbago, other movements are, of course, also limited and/or painful.

Pain and limitation of side flexion away from the painful side as the only positive finding

This pattern suggests that a lesion is being stretched to such an extent that the pain becomes so severe such that the movement is arrested involuntarily. This may indicate a neoplasm in the lung or abdomen, or a thoracic neurofibroma.

Flexion with a rigid thoracic segment

Absence of movement at the thoracic level indicates a disorder other than a disc lesion. Ankylosing spondylitis is a possibility, as are advanced osteoarthrosis, fracture, tumour or a vertebral infection.

Neurological signs

The presence of one of the following neurological signs should always put examiners on their guard.

- Signs of involvement of multiple nerve roots
- A band-shaped area of numbness related to one or more dermatomes
- All signs of spinal cord involvement[2–4] (see p. 390).

A large space-occupying process, or a large disc protrusion which cannot and may not be manipulated, is very likely and a myelogram or magnetic resonance imaging (MRI) should be ordered immediately.

Muscle spasm

If one of the passive movements is stopped by an involuntary muscular contraction, a serious disorder should be suspected.

Local paravertebral mass

A local paravertebral mass may be caused by extraspinal invasion of a tumour.[5]

Differential diagnosis 406
Diffuse idiopathic skeletal hyperostosis 406
Osteoarthritis 407
Treatment 407

About 0.1% of the total population has ankylosing spondylitis (AS). It affects mainly the attachment of ligaments to the axial skeleton. Solitary involvement of the thoracic spine and cage is seldom encountered because this is normally part of a generalized ankylosing spondylitis. Only 2–5% of all patients have chest pain as an initial symptom.[1,2]

The condition usually starts in the sacroiliac joints and extends upwards to the spine, often to the thoracolumbar junction first, and then later to the lumbar, thoracic and cervical spines. Although involvement of the sacroiliac joints may remain silent, spinal localization of AS without sacroiliitis is very rare.[3]

Clinical findings

Ankylosing spondylitis of the thoracic spine

Patients complain of a chronic stiff back, especially early in the morning and easing with activity. Periods of worsening pain and stiffness come on spontaneously and are not provoked by activity or exercise. During the pain-free periods, the patient is effectively normal. Only slight radiation to the sides is present. Because several levels are usually involved and little referred pain is present, the pain is distributed in the vertical axis. All these are important differences from disc lesions, in which pain is usually referred horizontally, is worse during the daytime and is brought on by activity.

The findings on inspection depend on the duration of the disorder. Initially, a rigid lumbar segment is present, which later becomes flat, together with a slight accentuation of the thoracic kyphosis. This develops further to a thoracic hyperkyphosis with hyperextension of the upper cervical spine and flexion of the hip.[4] Chest expansion may be diminished.

On functional examination, a clear capsular pattern is present with an equal amount of pain and limitation of both side flexions and rotations, more pain and limitation on extension, and only slight discomfort on flexion. The end-feel on rotation and extension is typically hard. The range of rotation has a significant negative correlation with the duration of the disease.[5] Pain provoked by pressure on the spinous processes is usually much more severe than in an ordinary disc lesion.[6] At a later stage, the vertebrae are much more vulnerable to fractures, because of loss of normal capsular and ligamentous elasticity.

The capsular pattern with hard end-feel, chronic prolonged morning stiffness and pain with periods of spontaneous exacerbations, together with other localizations of the same

disorder, all in young patients (mainly 18–30 years), strongly indicates AS.

A radiographic examination should be done at once and must always include the sacroiliac joints.

Ankylosing spondylitis of the anterior longitudinal ligament

Involvement of the anterior longitudinal ligament gives rise to pain felt only at the sternum or in the epigastrium, without central dorsal pain. The pain has the same characteristics as in other localizations of AS at the thoracic spine.

Ankylosing spondylitis of the thoracic facet joints

The apophyseal joints are usually involved, together with the intervertebral joints. The former are mainly responsible for bilateral paravertebral pain. AS may lead to total fusion of the facet joints.

Ankylosing spondylitis of the costovertebral joints

Costovertebral and costotransverse joints are often affected in AS. Computed tomography (CT) scans usually show the classic lesions: erosions, sclerosis, joint widening and bridging.[7] It is accepted that these changes provide the anatomical basis for the understanding of the thoracic pain in AS patients.[8] Although the pain is usually rather dull, it may sometimes be severe, even mimicking renal colic.[9] Chest expansion is diminished. Therefore chest expansion should always be assessed when AS is suspected. It is measured level with the nipples. The normal difference between inspiration and expiration is at least 7 cm; less than 4 cm is regarded as abnormal.[10] Surprisingly enough, reduced chest expansion seldom interferes with normal lung and heart function, because of normal diaphragmatic mobility.[11] If it does, chronic cor pulmonale is to be expected, with shortness of breath. The latter may also be the result of upper lobe fibrosis from involvement of the lung by AS.

Ankylosing spondylitis of the manubriosternal joint

This joint is affected in 50% of all cases.[12] Forced inspiration may be painful. Palpation reveals a precise area of local tenderness together with swelling of the ligaments.

Further investigations

Laboratory tests

The erythrocyte sedimentation rate may be elevated in active disease. A mild anaemia may be present. HLA-B27, although not diagnostic as such, is present in over 90% of cases, whereas in a normal population it is only found in 8%.[6]

Radiography

Sacroiliac joint

Early confirmation of AS is based mainly on radiography of the sacroiliac joints. A single anteroposterior pelvic radiograph is sufficient. AS is characterized by loss of distinctness of the subchondral bone in the iliac portion of the joint, which shows as loss of outline and pseudo-widening. Later, subchondral sclerosis and joint bridges may develop, ultimately with total fusion of the joint.

Spinal changes

Plain radiography of the spine may show the following changes:

- *Erosion*: loss of bone cortex at the corner of the vertebral body, called the 'shiny corner sign' or 'Romanus lesion'.[13]
- *Squaring* of the vertebral body: another characteristic feature of AS. It is caused by a combination of corner erosions and periosteal new bone formation along the anterior aspect of the vertebral body.
- *Syndesmophyte* formation: refers to the process in which ossification of the outer fibres of the annulus fibrosus leads to bridging of the corners of one vertebra to another.
- *Ossification* of the adjacent paravertebral connective tissue fibres: posterior interspinous ligament ossification, combined with linking of the spinous process, produces an appearance of a solid vertical dense line in the midline on frontal radiographs.
- The *apophyseal and costovertebral joints*: these are frequently affected by erosions and eventually undergo fusion.
- *A bamboo spine*: results from complete fusion of the vertebral bodies by syndesmophytes and other related ossified areas.

Manubriosternal joint

The earliest information that can be gained on AS is sometimes a radiograph of the manubriosternal joint. Normally, the joint surfaces of the manubriosternal joint are flat but in AS they may become biconcave.[14]

Differential diagnosis

Diffuse idiopathic skeletal hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is a condition characterized by calcification and ossification of ligaments, mainly of the thoracic spine. This condition was described by Forestier over 50 years ago and was termed senile ankylosing hyperostosis.[15] It affects middle-aged and elderly persons and is often asymptomatic, or is associated with mild dorsolumbar pain and/or some restriction of spinal mobility. Prevalence

studies based on the radiological characteristics have shown that between 2.4 and 5.4% of those over 40 years of age have DISH, as well as 11.2% of those over 70.[16]

The diagnosis of DISH is usually based on the definition suggested by Resnick and Niwayama[17]:

- The presence of flowing ossification along the anterolateral aspect of at least four contiguous vertebral bodies. The anterior margins of the vertebral bodies are usually distinct and separated from the hyperostosis by a vertical linear radiolucent zone.[18]
- The presence of relative preservation of the intervertebral disc height in the involved vertebral segment and the absence of radiographic changes of degenerative disc disease.
- The absence of apophyseal joint bone ankylosis and sacroiliac joint sclerosis, erosion and fusion.

Unlike in AS, there is no association with HLA-B27.

Osteoarthritis

In osteoarthritis, the disc spaces are narrowed. Osteophytes arise from the anterior and lateral margins of the vertebral bodies and have a horizontal, beak-like orientation. There are also obvious signs of osteoarthritis of the facet joints and costovertebral joints.

Treatment

The aim of treatment is to keep pain and stiffness under control, to maintain mobility and a straight spine, and to preserve as satisfactory a respiratory excursion as possible.

The basic treatment is administration of anti-inflammatory drugs and a daily exercise programme. Exercises, sports and swimming are strongly recommended.

Significant involvement of the costovertebral joints may affect their mobility, and care should be taken to prevent this. Deep breathing should be practised regularly and can be assisted by a therapist. Mobilization exercises to increase joint movement on inspiration and expiration must also be performed.

30

Introduction to the lumbar spine

There is much confusion about the meaning of commonly used words such as backache, sciatica and lumbago. In this book they are defined as follows:

- *Backache*: pain in the lower back, central, unilateral or bilateral with or without radiation to the gluteal region and iliac crest.
- *Lumbago*: acute and severe 'backache', causing twinges on attempted movement together with some degree of fixation and/or trunk deviation. The pain reference is wider and sometimes involves the legs in an extrasegmental distribution.
- *Sciatica*: pain in the leg, radiating segmentally to L4, L5, S1 and S2. Pain felt along the anterior aspect of the thigh, as a result of L3 root compression, is not true 'sciatica', although patients may describe it as sciatica.

During recent decades, syndromes related to the lower back have been identified by many epidemiological studies. As a result, the incidence of low back pain, and its socioeconomic impact, are well known.[1] Low back pain is so common that only a minority of individuals escape it. Eighty percent of the general population will at some time suffer from low back pain and 20% are suffering at any given time.[2,3] In Western countries, the 1-year incidence rate for backache is between 24 and 36%.[4–6] In the United States, a study of Veteran Affairs outpatients found a 3-year incidence rate of 67%.[7] Knepel reported that in general practice every tenth patient had back complaints.[8]

Backache and sciatica have also become an increasing socioeconomic problem in industrialized countries: back disorders account for between 1 and 2% of all working days lost[9–13] and for 12.5% of all sickness absence days.[14] They are the most common cause of disability among younger adults in the USA.[15] The number of working days per year lost because of low back pain is 1400 per 1000 workers in the USA,[16] and 2600 per 1000 workers in some British factories.[17,18] In the United Kingdom, low back pain was the largest single cause of absence from work in 1988 and 1989 and accounted for 12.5% of all sick days and over £11 billion in direct and indirect costs in 2000.[19] The cost of treatment and compensation for low back syndromes is enormous and increases every year. In 1976, in the USA, the total cost of spinal disorders was approximately $14 billion. By 1983, this figure had risen to $20 billion,[20] and by 1991 to more than $50 billion[21]; for 1998, estimates and patterns of direct healthcare expenditures among individuals with back pain in the USA had reached $90.7 billion.[22]

Backache and sciatica are complaints rather than specific diagnoses. Although most of these symptoms stem directly or indirectly from lesions of the intervertebral discs, it is widely accepted that low back pain spans a group of disorders with varying causes.

As many as 80% of all cases of low back syndromes relate to the lumbar intervertebral discs; the posterior support structures (facets, ligaments, laminae and fasciae) are directly responsible for less than 20% of cases of back disorders.[23] The evidence for this statement is derived from anatomical and imaging studies, but Cyriax[24] came to the same conclusion almost 50 years ago, purely on careful clinical observations: 'In my experience lumbar disc lesions are responsible for more continuing – yet avoidable – annoyance, frustration, semi-invalidism, general misery and bad temper than any other tissue in the body. In our view, lumbar disc lesions are responsible for well over 90% of all organic symptoms attributable to the back.'

It is remarkable that, in disorders that affect both individuals and society so much, there is so little agreement about possible pathogenesis and pathological entities. Despite the advanced technology available for diagnosis and treatment, the number of patients suffering from backache and sciatica continues to increase.[25] It has even been suggested by both the lay press and professionals that the epidemic increase in disability is partly caused by unnecessary technical investigations and too much surgical treatment.[26]

The main reason for ineffective diagnosis and treatment is that patients are submitted to technical investigations and tests before careful clinical assessment has been made. A basic

© Copyright 2013 Elsevier, Ltd. All rights reserved.

knowledge of anatomy, histology and behaviour of the tissues involved is necessary to be able to understand a patient's symptoms and to interpret the signs found during the clinical examination. These skills are not widely taught nowadays. Students are trained in the interpretation of discograms, myelograms and magnetic resonance images (MRI), but they do not learn how to take a history and make a clinical examination effectively nor how to interpret the clinical picture that emerges from the findings, how this can be translated into a diagnosis and what is the natural history of the detected disorder.

As for other parts of the body, the information gained from the history and physical examination is the first and most important requisite for correct diagnosis. If the clinical assessment is properly done, technical investigations add little information and scarcely improve diagnostic precision. If clinical assessment is omitted, the results of radiographs, myelograms, discograms, computed tomography (CT) scans and MRI will pose more questions than they solve, simply because these investigations, although very sensitive, are not sufficiently specific to guarantee that the detected lesions are indeed the source of the pain. Indeed, CT investigations have a false-positive rate of 15.5% and a false-negative rate of 40%; MRI has a false-positive rate of 13.2% and a false-negative rate of 35.7%.[27] These rates are far too high for imaging alone to be decisive in the diagnosis of an individual patient's problem. In spite of this, many surgeons base their decision to carry out surgery solely on the outcome of these investigations.

With a good understanding of the applied anatomy and a clear insight into the way that tissues behave, it is possible to translate the symptoms and signs found during clinical assessment into a deduction about the anatomical changes that have taken place in a patient's back. The true art of clinical investigation is to organize all the clinical data in such a way that the typical patterns are easily recognized. There are, in fact, only a few symptom patterns and patients' descriptions are frequently strikingly similar.

The *dura mater* is the most important pathway by which an intervertebral disc produces pain. It is the link between the macroscopic changes at the posterior aspect of the intervertebral joint and the symptoms: backache or lumbago result when the dural sac is irritated; sciatica occurs when the dural investment around the spinal nerve is pinched. This 'dural concept', in which both disc and dura have a particular role, accounts for most of the low back syndromes, and is discussed in the chapter on the dural concept (Ch. 33).

Changes in the disc can also have consequences for the *posterior support structures* and result in other signs and different findings. We discuss these in the chapter on the ligamentous concept (Ch. 34).

Increasing degeneration of the spine usually remains painless and is, in fact, a normal event which does not signify any particular disease. Sometimes increasing degeneration can account for acquired *stenosis of the vertebral canal or the lateral recess*. The resulting symptoms and signs are discussed in the chapter on the stenotic concept (Ch. 35).

There are also a number of pain syndromes not related to mechanical problems, such as spondylolisthesis, infectious and rheumatological diseases, and diseases of the osseous structures. These are discussed in the chapter on *non-mechanical spinal disorders* (Ch. 39).

The treatment administered for lumbago, backache and sciatica depends on the diagnosis, i.e. on the data obtained during history taking and clinical examination. A 'standard' treatment for backache does not exist; treatment procedures depend entirely on the underlying disorder. For example, if backache is caused by a small posterior displacement of the intervertebral disc, irritating the dura mater, attempts are made to shift the protruded fragment back into place, either by manipulation or by traction. If this proves impossible, attempts are made to desensitize the dura with an epidural injection. If the protrusion is unstable, and the patient has a history of recurrent back trouble, prophylactic measures against further disc displacements should be taken. If backache is caused by a sprained posterior ligament or an inflamed facet joint, local sclerosing injections or infiltrations with triamcinolone should be used.

Human posture

The human spine is a self-supporting construction of skeleton, cartilage, ligaments and muscles. Erect, there are four sagittal curves, which are the result of man's evolution from quadruped to biped. This began in Africa 3 million years ago with *Homo australo-pithecus*, which had a pelvis strong enough to support an erect posture. After a further 1.5 million years, the definitive erect posture had been adopted – *Homo erectus*.[1] The four curves resulted: cervical lordosis, thoracic kyphosis, lumbar lordosis and sacrococcygeal kyphosis. This S form seems to be a compromise between the static and the dynamic qualities of the spine[2]; theoretical considerations suggest that the S form is the shape an elastic bar adopts when it is subjected to axial compression.[3]

The phylogenetic evolution from the large thoracolumbar kyphotic spine of a quadruped into two kyphotic and lordotic curves is also reflected in the spine's ontogeny. In intrauterine life and during the first 5 months after birth, the spinal curves are absent and there is only one slight kyphosis of the whole spine. At 13 months the lumbar spine is straight, at 3 years some lumbar lordosis is present, and by 8 years the lumbar spine has attained its normal adult posture (Fig. 31.1).[4]

As a result of the lumbar lordosis, the intervertebral space is larger in front than behind, which has some consequences for the intervertebral disc. It is clear that axial pressure exerted on the disc in a lordotic spine will result in a forward strain on the disc, whereas increased axial pressure during trunk flexion will force the disc backwards. A backward shift of the disc is a very undesirable event because nerve roots and dura mater emerge at the posterior aspect of the vertebral column. Indeed, these very sensitive structures lie at the weakest and most unprotected part of the column, and it is good posture, rather than any ligamentous device, that protects them against a posterior or posterolateral shift of the disc. Maintaining normal physiological lordosis is therefore important in the prophylaxis of low back syndromes.

The development of the erect posture is recent and it seems that, apart from the compensatory lordosis, not much in the way of structural adaptation has taken place. Comparative anatomical evidence suggests that the spine has evolved as a hanging structure between the anterior and the posterior parts of the body. However, during development from quadruped to biped, the function of the spine had to alter completely (Table 31.1); this has serious consequences. In an upright position, the spine is submitted to axial load, which probably leads to

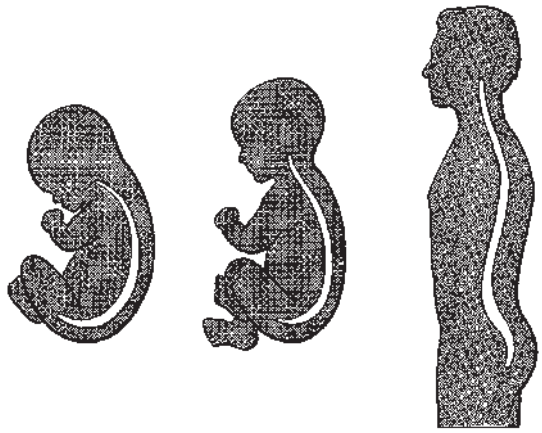

Fig 31.1 • Development of the lumbar lordosis.

Table 31.1 Comparison of the quadruped and biped lumbar spines

	Quadruped	Biped
Structure	Horizontal	Vertical
Load	Horizontal	Axial
Curve	Slight kyphosis	Lordosis
Strength	Against extension	Against flexion
Strong structures	Anterior	(Posterior?)

the premature disc degeneration from which humans are apt to suffer. In the upright position, the lumbar spine has to resist flexion, whereas the quadruped spine has to resist extension because it is structurally undesirable for a 'bridge' to sag in the middle. The change to an upright position, however, has not yet been followed by anatomical adaptation, and the human spine has an anatomy that more readily withstands extension than flexion: the anterior part of the annulus fibrosus is stronger and thicker than the posterior, and the anterior longitudinal ligament is almost twice as thick and broad as the posterior.[5]

Conclusion: the spine was originally designed as a horizontal, slightly kyphotic, hanging structure, strong in resistance to extension. Once the erect posture was achieved, the spine became submitted to axial and flexion stresses. Slight lordosis prevents lumbar discs from shifting backwards and keeps them away from painful and vital structures, such as dura and nerve roots.

Vertebrae

Embryologically, the lower half of a vertebra and the upper half of the one below it originate from the same segment. Between them is the disc, which is partly a remnant of the notochord.

Vertebral bodies

Each vertebral body is more or less a cylinder with a thin cortical shell which surrounds cancellous bone. From L1 to L5, the posterior aspect changes from slightly concave to slightly convex, and the diameter of the cylinder increases gradually because of the increasing loads each body has to carry. At the upper and lower surfaces, two distinct areas can be seen: each is a peripheral ring of compact bone – surrounding and slightly above the level of the flat and rough central zone – which originates from the apophysis and fuses with the vertebral body at the age of about 16. The central zone – the bony endplate – shows many perforations, through which blood vessels can reach the disc. A layer of cartilage covers this central zone, which is limited by the peripheral ring. This is the cartilaginous endplate, forming the transition between the cortical bone and the rest of the intervertebral disc. A sagittal cut through the vertebral body shows the endplates to be slightly concave, which consequently gives the disc a convex form.[6]

Pedicles

The two pedicles originate posteriorly and attach to the cranial half of the body. Together with the broad and flat lamina, they form the vertebral arch. From L1 to L5, the pedicles become shorter and broader, and are more lateral. This narrows the anteroposterior diameter and widens the transverse diameter of the vertebral canal from above downwards. Together with the increasing convexity of the posterior aspect of the vertebral body, these changes in the position of the pedicles alter the shape of the normal bony spinal canal from an ellipse at L1 to a triangle at L3 and more or less a trefoil at L5 (Fig. 31.2).

Laminae

Each lamina is flat and broad, blending in centrally with the similarly configured spinal process, which projects directly backwards from the lamina. The two transverse processes project laterally and slightly dorsally from the pediculolaminar junction. The superior and inferior articular processes originate directly from the lamina.

The part of the lamina between the superior and inferior articular processes is called the 'pars interlaminaris'. It runs obliquely from the lateral border of the lamina to its upper medial border. This portion of the lamina is subjected to considerable bending forces, as it lies at the junction between the vertically oriented lamina and the horizontally oriented pedicle. This 'interlaminar part' will therefore be susceptible to fatigue fractures or stress fractures (spondylolysis) (see Ch. 39).[7]

Intervertebral discs

Two adjacent vertebral bodies are linked by an intervertebral disc. Together with the corresponding facet joints, they form the 'functional unit of Junghans' (Fig. 31.3).[8]

The disc consists of an annulus fibrosus, a nucleus pulposus and two cartilaginous endplates. The distinction between annulus and nucleus can only be made in youth, because the consistency of the disc becomes more uniform in the elderly.

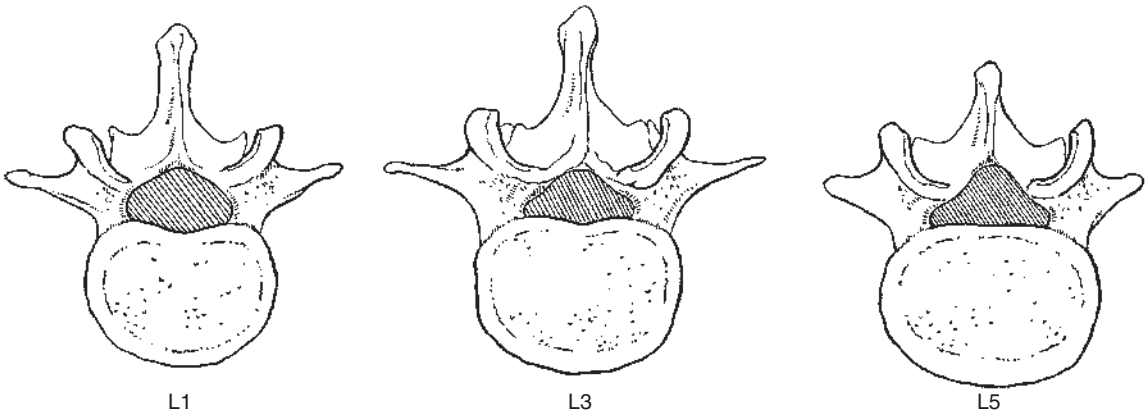

Fig 31.2 • L1, L3 and L5 from above, showing the changes in the diameter of the spinal canal.

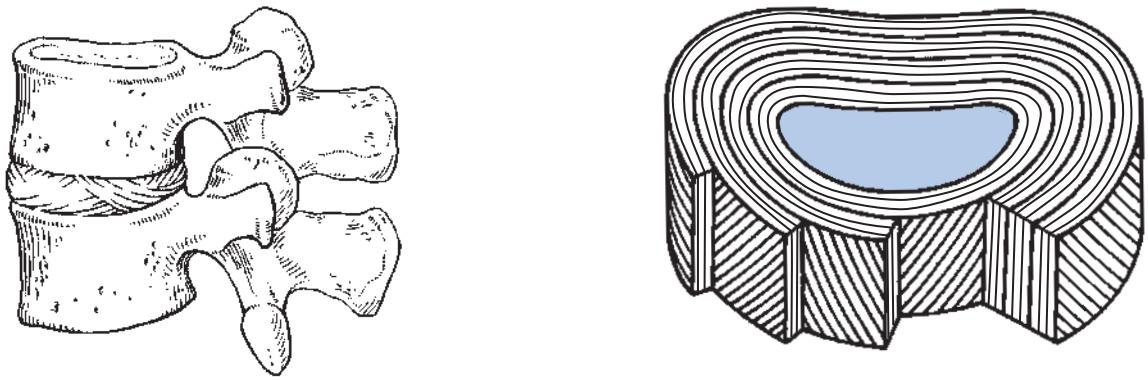

Fig 31.3 • Lateral view of two vertebrae: the 'functional unit'.

For this reason, nuclear disc protrusions are rare after the age of 70. From a clinical point of view, it is important to consider the disc as one integrated unit, the normal function of which depends largely on the integrity of all the elements. That means that damage to one component will create adverse reactions in the others.

Endplates

An upper and a lower *cartilaginous endplate* (each about 0.6–1 mm thick) cover the superior and inferior aspects of the disc. They are plates of cartilage that bind the disc to their respective vertebral bodies. Each endplate covers almost the entire surface of the adjacent vertebral body; only a narrow rim of bone, called the ring apophysis, around the perimeter of the vertebral body is left uncovered by cartilage. That portion of the vertebral body to which the cartilaginous endplate is applied is referred to as the vertebral endplate. The endplate covers the nucleus pulposus in its entirety; peripherally it fails to cover the entire extent of the annulus fibrosus.[9] The collagen fibrils of the inner lamellae of the annulus enter the endplate and merge with it, resulting in all aspects of the nucleus being enclosed by a fibrous capsule.[10]

The endplate permits diffusion and provides the main source of nutrition for the disc.[11,12] Up to the age of 8 years, the cartilaginous endplates are penetrated by blood vessels

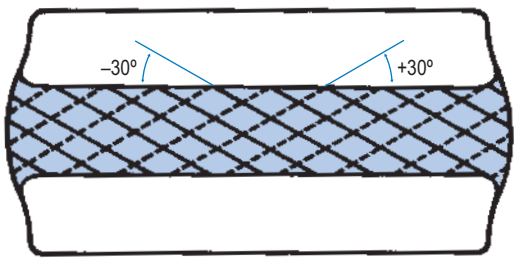

Fig 31.4 • Lamellar construction of the annulus fibrosus.

which pass into the peripheral layers of nucleus and annulus. Thereafter, the disc's nutrition is achieved by diffusion through the endplate. The hyaline endplate is also the last part of the disc to wear through during severe disc degeneration.[13]

Annulus fibrosus

This is made up of 15–25 concentric fibrocartilaginous sheets or 'lamellae' (Fig. 31.4), each formed by parallel fibres, running obliquely at a 30° angle between the vertebral bodies.[14] Because the fibres of two consecutive layers are oriented in opposite directions, they cross each other at an angle of approximately 120°.[15] This arrangement of the annular fibres gives the normal

disc great strength against shearing and rotational stresses,[16] while angular movements remain perfectly possible.[17,18] The outermost fibres are attached directly to bone, around the ring apophysis, and for that reason they are referred to as the ligamentous portion of the annulus fibrosus. The inner third merges with the cartilaginous endplate and is referred to as the capsular portion of the annulus fibrosus (Fig. 31.5).

Nucleus pulposus

This consists of a gelatinous substance, made of a meshwork of collagen fibrils suspended in a mucoprotein base which contains mucopolysaccharides and water.[19] With advancing age, the amount of mucopolysaccharides diminishes, as does that of the water they bind. A young nucleus is 85% water, whereas it is only 65% water in the elderly.[20] These biological changes are mirrored in the macroscopic aspects of the nucleus. In the second and third decades the nucleus is clear, firm and gelatinous but subsequently it becomes drier and more friable. In the elderly, the nucleus has the texture of thickened cream cheese, and is dry, brownish and friable.

At birth the nucleus pulposus occupies the centre of the intervertebral space. As the anterior part of the vertebral body grows faster than the posterior part, the nucleus comes to lie more posteriorly. Consequently, the anterior part of the annulus will have thicker and stronger fibres,[21] which means that the annulus gives better protection against anterior than posterior displacements of the nucleus; this is disadvantageous with respect to the contiguous nerve roots and dura.

Cartilage is devoid of nerves and it has been conventional to draw the same conclusions about the disc. However, over the last few decades, there has been a great deal of research on the possibility that there is some innervation. The presence of free nerve endings has been demonstrated as far as one-third of the way into cadaveric annuli fibrosi,[22] and as far as halfway into annuli fibrosi obtained during posterior fusion operations.[23] Other research has shown a few nervous elements in the periphery of the annulus fibrosus.[24,25]

More recent studies have demonstrated mechanoreceptors to be present in the outer two or three lamellae of the human intervertebral disc and the anterior longitudinal ligament.[26] Although the presence of substance P – generally accepted as an important nociceptive neurotransmitter – has so far not been demonstrated in human intervertebral discs,[27] other neuropeptides have.[28,29] The exact relationship between the existence of small nerve endings in the outer layers of the disc and back pain therefore still remains controversial.

The lack of blood supply to the intervertebral disc has been shown by microangiographic studies.[30] There is some vascularization of the vertebral borders of the disc in children but by the age of 8 years all cartilaginous penetration by blood vessels has disappeared. Vascular buds in the bony endplate remain during adulthood as a vascular bed under the cartilaginous endplate, and diffusion from these through the endplates remains the main nutritional pathway for the disc during adult life,[31,32] although some nutrition via contact with the intimate anterior and posterior longitudinal ligaments is also possible (Fig. 31.6).[33] The disc is thus the largest non-vascular structure in the body, which causes difficulties in healing and regeneration after damage.

Functions of the disc

The primary function of the disc is to join the vertebrae and allow movement between them. The other functions are typical of the erect spine: a shock absorber; a load distributor; and a separator of the posterior facets to maintain the size of the intervertebral foramen.

Behaviour of the disc

The disc as an osmotic system

The main structural components of the intervertebral disc are collagen, proteoglycans (PGs) and water. The water is not free

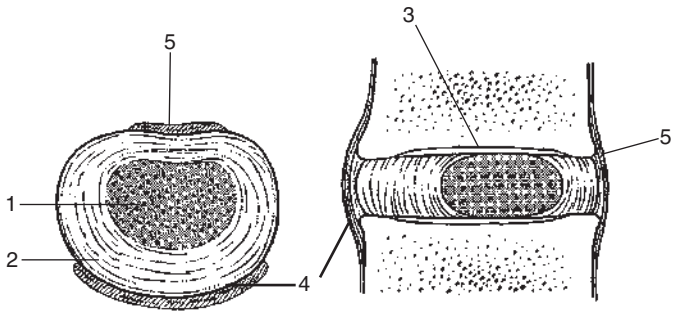

Fig 31.5 • The intervertebral disc: 1, nucleus; 2, annulus; 3, cartilaginous endplate; 4, anterior longitudinal ligament; 5, posterior longitudinal ligament.

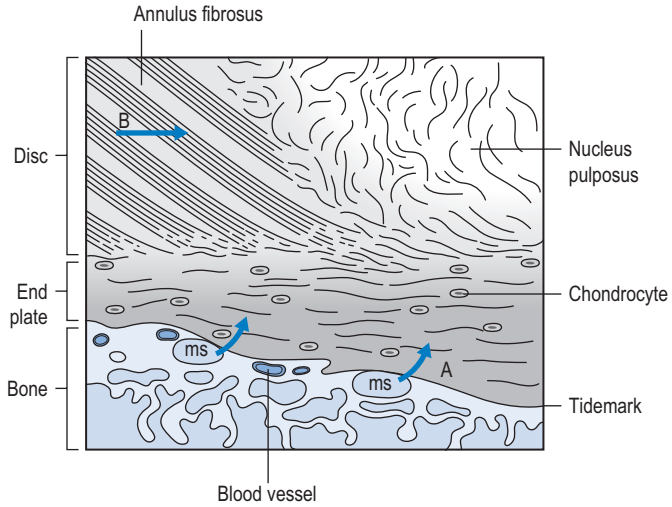

Fig 31.6 • The vertebral endplate, consisting of a hyaline cartilage layer, loosely bonded to a plate of perforated cortical bone. The two routes of metabolite transportation are: A, through the marrow spaces (ms) of the endplate; B, through the annulus. Reproduced from Adams M, Bogduk N, Burton K, Dolan P. *The Biomechanics of Back Pain*, 2nd edn. Churchill Livingstone, Edinburgh, 2006: Fig 7.15 (p. 90).

but is bound by the PGs,[34] which, because of their pronounced osmotic properties, maintain the hydration and turgor of the disc. The proportion of the three constituents varies across the disc. Fluid and PG concentrations are highest in the nucleus and lowest in the annulus, whereas the reverse is true for collagen.

Proteoglycans are complex chemical structures, existing as monomer subunits and aggregates. The former are made up of a central protein molecule with an attached long-chain glucosaminoglycan; the latter consist of monomers, attached to a long hyaluronic acid filament (see Ch. 3). The synthesis of PGs is performed by the cartilage cells and is a continuous process, demanding a well-balanced metabolism.[35] For its nutrition, the disc, devoid as it is of any penetrating vascular structure, depends entirely on diffusion through the central portion of the endplates and the outer annulus (see Fig. 31.6).[11,36] Consequently, the disc is vulnerable and changes in its composition are inevitable as age advances. Although the total collagen content remains fairly constant during adult life,[37] the PG concentration falls.[38,39] The result is that the osmotic properties and the turgor of the disc will also decline as age advances (see p. 438).[40]

Proteoglycans play a key role in the osmotic system of the intervertebral joint, which incorporates the nucleus, annulus and cartilaginous endplates, and also the cancellous bone of the vertebrae. Two compartments – nucleus and paravertebral tissues – are separated by the semipermeable barrier formed by the cartilaginous endplate and the annulus fibrosus, which permits the transport of small molecules only: water, ions and substances of low molecular weight. Diffusion tests with dye demonstrate that only substances with a molecular weight under 400 can pass the disc tissue barrier.[41] The PGs of the inner compartment take up water, until the hydrostatic pressure that results is in balance with the physical tension that arises from the tensile forces of the annulus and the loads applied by muscles, ligaments and gravity (Fig. 31.7).

At this point, there is no net fluid loss or gain. If the external stress is increased – say, by an increase in load – the balance will be disturbed and fluid is expressed from the nucleus (Fig. 31.8a). This loss of fluid has two consequences: tensile stress in the collagen network falls and the concentration of PGs in the nucleus and thus the osmotic pressure rise. In other words, loss of fluid increases the internal swelling pressure, until the latter has risen to the physical stress and a new balance is achieved.[43] The reverse happens when the external load decreases: the internal osmotic pressure is momentarily higher than the external load and fluid is attracted (Fig. 31.8b). The concentration of PGs and the swelling pressure decrease until external and internal pressures again reach an equilibrium.

Conclusion: the fluid content of the disc is not an intrinsic property of the tissue but depends on changes in the external load. Fluid flow is caused by pressure changes on the disc: increased load causes fluid to be expelled, whereas low pressure allows PGs in the disc to absorb fluid from the surrounding tissues.[44]

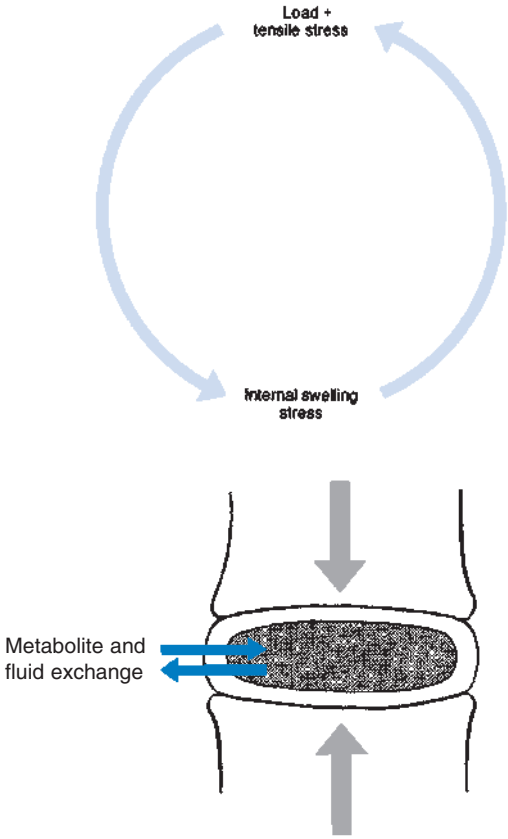

Fig 31.7 • The intervertebral disc as an osmotic system, as described by Krämer.[42]

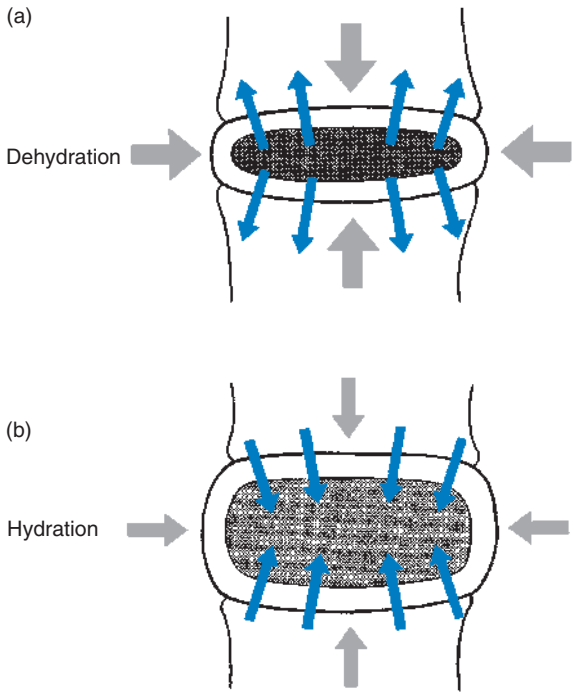

Fig 31.8 • (a) Increase in external stress causes dehydration of the nucleus; (b) decrease in external stress causes hydration of the nucleus.

Influence of the external load on hydration of the disc

Using diffusion techniques with dye and with radioactive substances, Krämer was able to show that in normal non-degenerated discs there is an extravasation of fluid when a load of more than 80 kPa is applied. Absorption takes place when the load is lower than 80 kPa.[45]

From 1966 on, Nachemson and co-workers demonstrated the relationship between body posture and intradiscal pressure by intravital recordings.[46–51] They demonstrated that the pressure in an L3 disc of a healthy individual, weighing 70 kg, is 30 kPa in a supine lying position. Standing and walking around sets up a pressure between 70 and 85 kPa, whereas sitting raises the pressure to 100 kPa and slightly bending forwards to 120 kPa. Lifting a 20 kg object with a bent back and straight legs increases the intradiscal pressure to a surprising 340 kPa.

These findings suggest the dehydration–hydration point, found by Krämer to be around the standing and walking position (Fig. 31.9). The supine position causes hydration of the disc, whereas sitting, bending or lifting squeezes fluid out of the disc.

Since the transport processes in the disc depend largely on fluid flow, continuous change in intradiscal pressure could be of utmost importance for the nutrition of the disc.[53] Load and de-load acts as a pump, and transports water and metabolites from and to the intervertebral disc.[54] In order to protect discs against early degeneration, it is therefore important to keep the intradiscal pressure as low as possible during daily activities. This can be achieved by adopting a slight lordosis at the lumbar spine which protects the disc against excessive pressure. Also, regular changes in position continuously alter the intradiscal pressure, so causing a nutritional fluid flow to and from the disc.[55] The prophylactic measures derived from these findings will be discussed in the section on back schools (see p. 582).

Biomechanical properties of the disc

The fibroelastic annulus provides the disc with hydraulic properties and provides resistance to tensile forces. Retained by this fibroelastic mesh, the nucleus pulposus acts like a fluid-filled balloon. During load, it distributes the axial pressure equally over the cartilage plates and the annulus fibrosus (Fig. 31.10). The annular fibres are under a constant slight stretch, because of the turgor of the nucleus. McNab[56] compares the annulus with a coiled spring that pulls the vertebral bodies together against the turgor of the nucleus. If the load is axial and symmetrical, the nucleus pulposus distributes the force to all sides and therefore perpendicularly on the stretched annular fibres. In this position the disc is very strong and, during high compressive loads, outward herniation of the nucleus is not seen but there is a collapse of the cartilaginous endplates.[57,58]

Asymmetrical loading, however, simultaneously involves tension, compression and shear stresses at different locations in the disc. Bending results in a tensile stress on the convex side and a compressive stress on the concave side: that under tension stretches, while that under compression bulges.[59,60] Tensile stresses on the convex side are increased by the migration of the nucleus. During such asymmetrical loading, the nucleus pulposus is pushed away from the area of compression, following the simple mathematical parallelogram of forces (Fig. 31.11). This means that, in bending forwards, the nucleus will move posteriorly, and therefore greater stress will fall on the posterior annular fibres, which are already subjected to a strong tensile stress.

The posterior migration of the nucleus pulposus in bending has been demonstrated experimentally by putting a metal pin

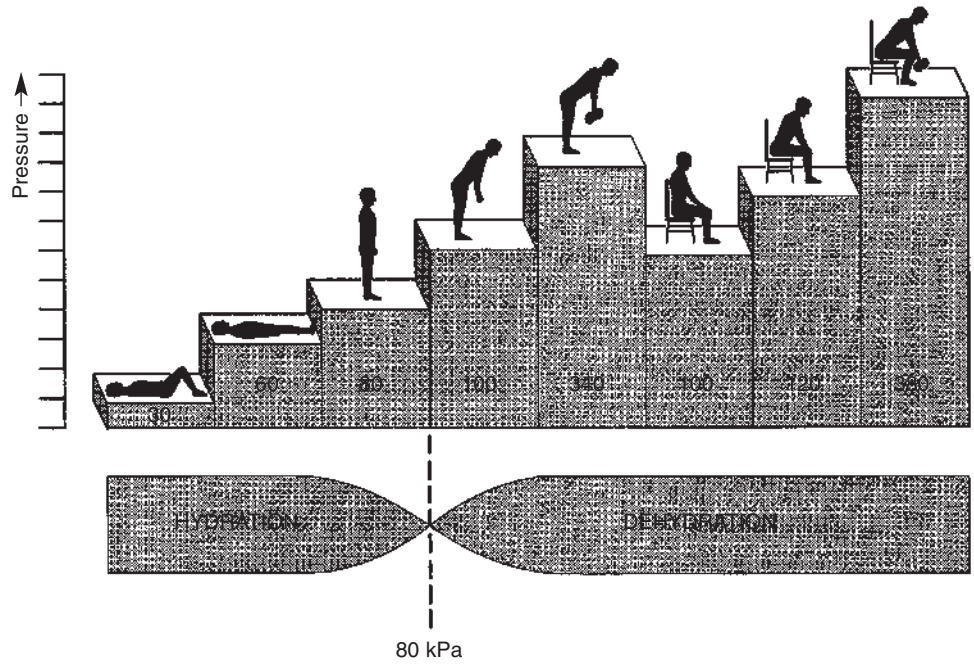

Fig 31.9 • Intradiscal pressure is related to position.[52]

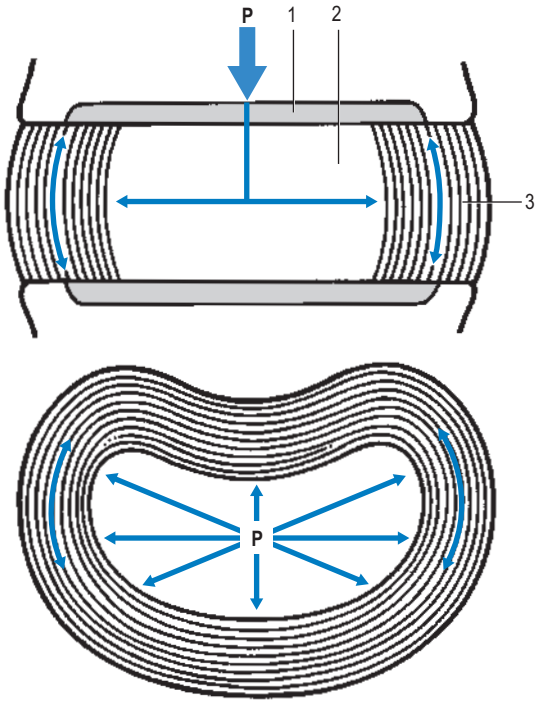

Fig 31.10 • During an axial and symmetrical load, the nucleus pulposus distributes the force to all sides and therefore perpendicularly on the stretched annular fibres. P, load; 1, endplates; 2, nucleus; 3, annular fibres.

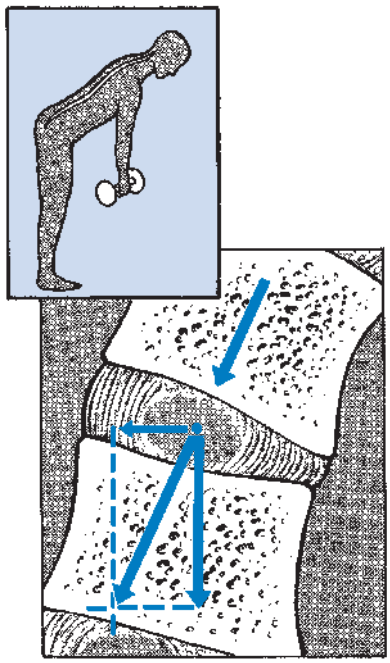

Fig 31.11 • Asymmetrical loading.

in the nucleus pulposus.[61] On continuous forward bending, the nucleus migrated backwards at a speed of 0.6 mm/min during the first 3 minutes and this continued very slowly during the next hour. After bending ceased, the nucleus regained its original position only very slowly. These findings have been confirmed by discography[62] and by magnetic resonance imaging (MRI) studies.[63–65] Biomechanical studies, conducted *in vitro*, have also demonstrated that the normal nucleus moves posteriorly in kyphosis and anteriorly in lordosis.[66–68]

The weak zone of the disc

Several anatomical, biochemical and biomechanical properties make the posterior aspect of the disc the most critical and vulnerable part of the whole intervertebral joint.[69,70]

- The posterior annular fibres are sparser and thinner than the anterior.
- Because the area available for diffusion is smaller posteriorly than anteriorly, the posterior part of the nuclear–annular boundary receives less nutrition and again the posterior part of the disc is the most strained part.[71]
- The posterior longitudinal ligament affords only weak reinforcement, whereas the anterior fibres are strengthened by the powerful anterior longitudinal ligament.
- Because of the special mechanical arrangements of the annular fibres, the tangential tensile strain on the posterior annular fibres is 4–5 times the applied external load.[72]

All these elements explain the predominance of the posterior part of the disc in the development of weakening, radiating ruptures and posterior nuclear displacements. This is unfortunate, because most nociceptive tissues responsible for backache and sciatica (nerve roots and dura mater) emerge just beyond the posterior aspect of the disc.

In order to prevent early degeneration and internal derangement, the erect body has developed only one adequate defence system: namely, a slightly lordotic lumbar posture. Cyriax was the first clinician to point out the importance of the lumbar lordosis. Long before biomechanical experiments, such as those of Nachemson, and purely on clinical findings, he demonstrated the importance of correct posture in the avoidance of backache and sciatica.[73] This is the physiological lumbar lordosis, which diminishes the intradiscal pressures and protects the disc against backward displacements of the nucleus pulposus. 'Keep your back hollow' is still the best advice against recurrent discogenic backache, even more so in recent decades because of the more sedentary jobs many people have. A sitting position not only increases the intradiscal pressure but also forces the lumbar spine into kyphosis by a backwards inclination of the sitting pelvis.[74] Increased sedentary work is probably one of the reasons for the rising rate of lumbar syndromes.

Facet joints

The joints between the lower and upper articular processes are called zygapophyseal joints, apophyseal joints or 'facet' joints. They are true synovial joints, comprised of cartilaginous

articular surfaces, synovial fluid, synovial tissue and a joint capsule (Fig. 31.12). The superior articular surface is slightly concave and faces medially and posteriorly. The convex inferior articular surface points laterally and slightly anteriorly. In general terms, there is a change from a relatively sagittal orientation at L1–L3, to a more coronal orientation at L5 and S1 (Fig. 31.13).[75,76]

Unlike the disc, the facet joints normally do not bear weight and during normal loads they are not subjected to compression strain.[72] In degenerative fragmentation of the disc, however, intervertebral height diminishes and the articular surfaces are subjected to abnormal loading, setting up spondylarthrosis.[77] The main function of the facet joints is to guide lumbar movements and keep the vertebrae in line during flexion–extension and lateral flexion. Because of the more sagittal slope of the articular surfaces, very little rotation takes place at the four upper lumbar levels. More distally, at the lumbosacral level, the joint line has a more coronal plane, which makes rotational movements potentially possible, but these are limited by the iliolumbar ligaments (see p. 424).[78] The total range of rotation in the lumbar spine is therefore very limited, although not completely zero.[79]

The capsule of the joints is well developed and thick and elastic at the dorsal, superior and inferior aspects. At rest, the fibres run slightly diagonally from lateral–caudal to medial–cranial. As the articular excursion is about 0.5 cm at each level, the capsule must have a considerable laxity to follow the points of insertion during flexion. It therefore possesses capsular recesses of varying size, at the superior and inferior poles of the joint, which gives the joint the appearance of a dumb-bell during arthrographic examinations.[80] In extension the posterior capsule can become pinched between the apex of the inferior facet and the lamina below. In order to prevent this, some fibres of the multifidus blend with the posterior capsular fibres and keep the capsule taut.[81] The ventral aspect of the capsule is an extension of the ligamentum flavum. It is very thin[82] and may rupture during intra-articular injections.[83]

During flexion, the inferior articular process slides upwards on the superior articular process. The lower part of the latter loses contact and becomes exposed. Similarly, the lower part of the inferior articular process becomes exposed ventrally. In order to protect these exposed surfaces, and to maintain a film of synovial fluid over the articular cartilages, the facet joints are endowed with small intra-articular 'meniscoids'.[84–86] These small fibro-adipose crescent wedges have a base attached to the joint capsule and an apex that projects into the capsular pouches.[87] Stretching of the capsule during flexion makes them disappear. Some believe that these fibro-adipose enlargements could become pinched between the articular surfaces, constituting a probable source of backache.[88–91]

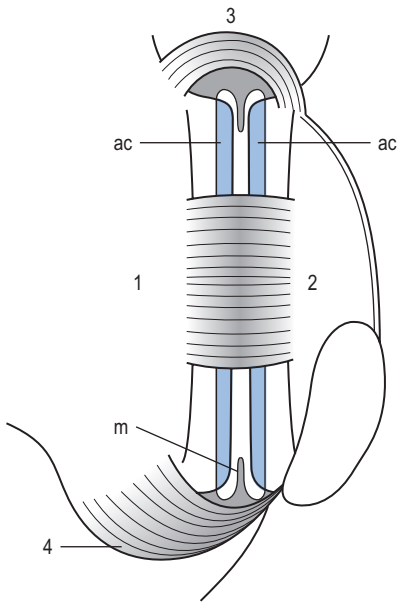

Fig 31.12 • Lateral view of the facet joint with the capsule partly removed. 1, Inferior articular process; 2, superior articular process; 3, superior capsule; 4, inferior capsule; ac, articular cartilage; m, meniscoid.

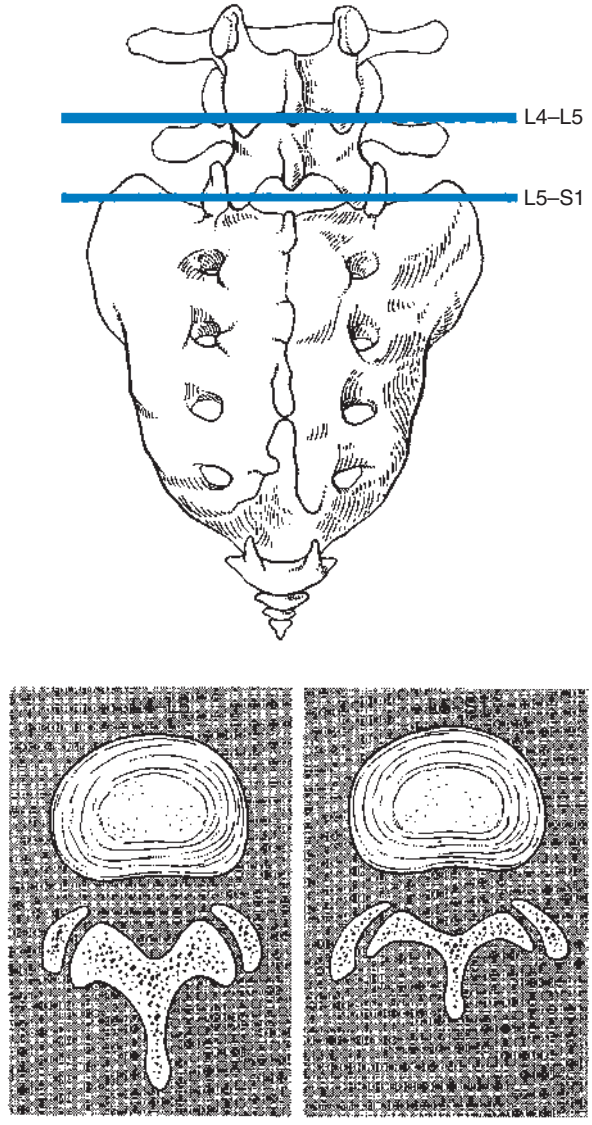

Fig 31.13 • Facet joints at L4–L5 and L5–S1.

The facet joints are innervated by fibres of the medial branch of the dorsal root. The same nerve supplies the inferior aspect of the capsule and the superior aspect of the joint below.[92]

Ligaments

The broad, thick *anterior longitudinal ligament* (Fig. 31.14) originates from the anterior and basilar aspect of the occiput and ends at the upper and anterior part of the sacrum. It consists of fibres of different lengths: some extend over 4–5 vertebral bodies; the short fibres attach firmly to the fibres of the outermost annular layers and the periosteum of two adjacent vertebrae.

The posterior longitudinal ligament (Fig. 31.15) is smaller and thinner than its anterior counterpart: 1.4 cm wide (versus 2 cm in the anterior ligament) and 1.3 mm thick (versus 2 mm). This is another fact in favour of the theory that the lumbar spine was originally designed to be a horizontal hanging structure: to withstand extension strains, the back had to be stronger anteriorly than posteriorly.[5] The posterior longitudinal ligament is narrow at the level of the vertebral bodies, and gives lateral expansions to the annulus fibrosus at the level of the disc, which bestow on it a denticulated appearance.[93]

Although the posterior ligament is rather narrow, it is important in preventing disc protrusion.[94] Its resistance is the main factor in restricting posterior prolapse and accounts for the regular occurrence of spontaneous reduction in lumbago. This characteristic is also exploited in manipulative reduction, when a small central disc displacement is moved anteriorly when the ligament is tightened. The fact that the ligament occupies only the midline of the vertebral column is one of the predetermining factors in the progression of sciatica: as a central protrusion enlarges, it tends to move in the direction of least resistance – lateral to the ligament. Once free from ligamentous resistance, it further enlarges and starts to compress the nerve root. This anatomical evolution is mirrored by the change in the clinical picture: a central backache is replaced by a unilateral sciatica.

The ligamentum flavum (Fig. 31.16) connects two consecutive laminae and has a very elastic structure with an elastin content of more than 80%.[82] The lateral extensions form the anterior capsule of the facet joints and run further laterally to connect the posterior and inferior borders of the pedicle above with the posterior and superior borders of the pedicle below. These lateral fibres form a portion of the foraminal ring and the lateral recess.[95,96]

The interspinous ligament (see Fig. 31.14) lies deeply between two consecutive spinal processes. Unlike the longitudinal ligaments, it is not a continuous fibrous band but consists of loose tissue,[97] with the fibres running obliquely from posterosuperior to anteroinferior.[98] This particular direction may give the ligament a function over a larger range of intervertebral motion than if the fibres were vertical.[99] The ligament is also bifid, which allows the fibres to buckle laterally to both sides when the spinous processes approach each other during extension.[97]

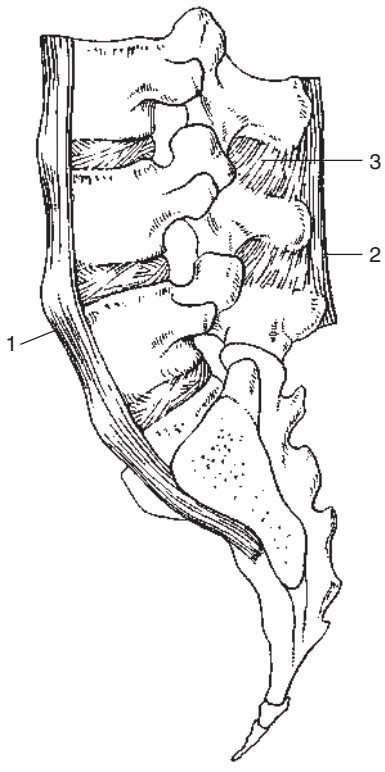

Fig 31.14 • Anterior longitudinal (1) and supraspinous and interspinous ligaments (2 and 3, respectively).

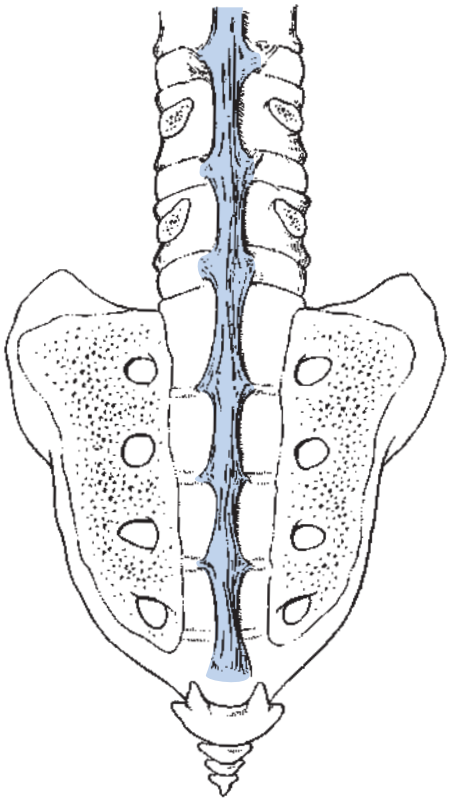

Fig 31.15 • Posterior longitudinal ligament.

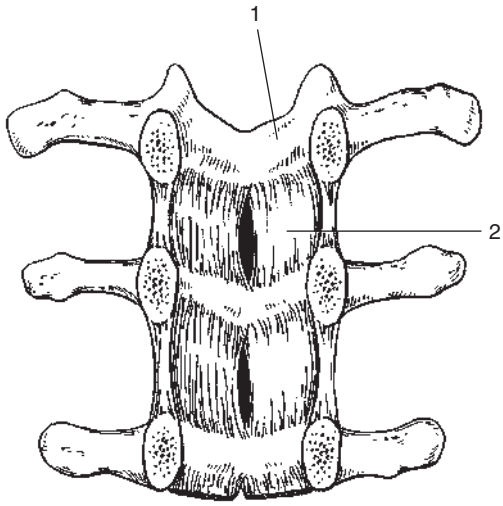

Fig 31.16 • Lamina (1) and ligamentum flavum (2).

The supraspinous ligament is broad, thick and cord-like. It joins the tips of two adjacent spinous processes, and merges with the insertions of the lumbodorsal muscles. Some authors consider the supraspinous ligament as not being a true ligament, as it seems to consist largely of tendinous fibres, derived from the back muscles.[100] The effect of the supraspinous ligaments on the stability of the lumbar spine should not be underestimated.[101] Because the ligament is positioned further away from the axis of rotation and due to its attachments to the thoracolumbar fascia,[102] it will have more effect in resisting flexion than all the other dorsal ligaments. Pearcy[103] showed that the distance between the tips of the spinous processes increases during full flexion by 360% at L3–L4 and 129% at L5–S1. By contrast, the posterior longitudinal ligament only increases by 55% at L3–L4 and 34% at L5–S1. This demonstrates the limiting effect of the ligament on the increasing posterior disc height during stooping. The importance of a strong supraspinous ligament in the prophylaxis of recurrent disc protrusions will be discussed later.

The intertransverse ligaments are thin membraneous structures joining two adjacent transverse processes. They are intimately connected to the deep musculature of the back.

The iliolumbar ligaments (Fig. 31.17) are thought to be related to the upright posture.[104] They do not exist at birth but develop gradually from the epimysium of the quadratus lumborum muscle in the first decade of life to attain full differentiation only in the second decade.[105] The ligament consists of an anterior and a posterior part.[106–108] The anterior band of the iliolumbar ligament is a well-developed, broad band. Its fibres originate from the anterior–inferior part of the L5 transverse process from as far medially as the body of the L5 vertebra to the tip of the transverse process, and expand as a wide fan before inserting on the anterior part of the iliac tuberosity. The posterior band of the iliolumbar ligament originates from the apex of the L5 transverse process and is thinner than the anterior. It inserts on the iliac crest, behind the origin of the quadratus lumborum.[108]

The iliolumbar ligaments play an important role in the stability of the lumbosacral junction by restricting both side flexion and rotational movement at the L5–S1 joint and forward sliding of L5 on the sacrum.[104,109,110] One clinical consequence of this is that posterolateral disc protrusions at the L5–S1 level will not be followed by large lateral flexions of L5 on the sacrum. Marked adaptive deformity will therefore be absent here. Consequently, a large lateral tilt in a patient with acute backache means a displacement at L3–L4 or L4–L5, since these intervertebral joints can open up more easily. Also, stabilization of the lumbosacral junction by the strong iliolumbar ligaments may explain the fact that L5–S1 pars defects are more stable than L4–L5 lesions (see spondylolisthesis, Ch. 58).[111,112]

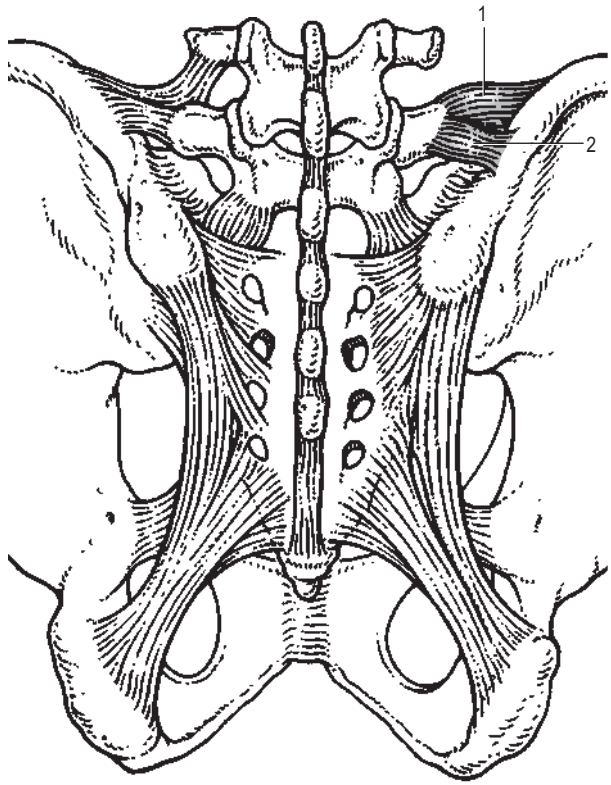

Fig 31.17 • Iliolumbar ligaments: 1, anterior band; 2, posterior band.

Muscles and fasciae

The spine is unstable without the support of the muscles that power the trunk and position the spinal segments.[113] Back muscles can be divided in four functional groups: flexors, extensors, lateral flexors and rotators (Fig. 31.18).

The extensors are arranged in three layers: the most superficial is the strong erector spinae or sacrospinalis muscle. Its origin is in the erector spinae aponeurosis, a broad sheet of tendinous fibres attached to the iliac crest, the median and lateral sacral crests and the spinous processes of the sacrum and lumbar spine.[114] The middle layer is the multifidus. The fibres of the multifidus are centred on each of the lumbar spinous processes. From each spinal process, fibres radiate inferiorly to insert on the lamina, one, two or three levels

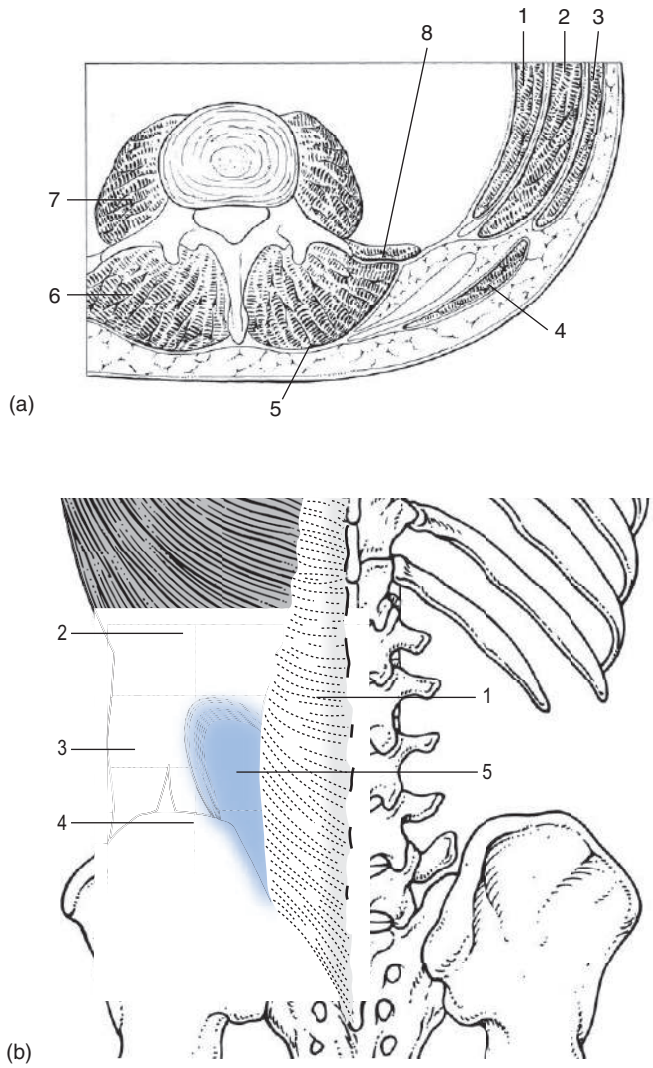

Fig 31.18 • (a) Muscles of the lumbar spine: 1, transversus abdominis; 2, internal oblique; 3, external oblique; 4, latissimus dorsi; 5, lumbar fascia; 6, erector spinae; 7, psoas; 8, quadratus lumborum. (b) Posterior layer of the thoracolumbar fascia: 1, thoracolumbar fascia; 2, fascia latissimus dorsi; 3, fascia of external oblique; 4, posterior superior iliac spine; 5, lateral raphe.

below. The arrangement of the fibres is such that it pulls downwards on each spinal process, thereby causing the vertebra of origin to extend.[115] The third layer is made up of small muscles arranged from level to level, which not only have an extension function but are also rotators and lateral flexors.

The extensor muscles are enveloped by the *thoracolumbar fascia* (Fig. 31.18b), which in turn consists of three layers. The anterior layer is quite thin and covers the anterior surface of the quadratus lumborum. Medially, it is attached to the anterior surfaces of the lumbar transverse processes, and in the intertransverse space it merges with the intertransverse ligaments. The middle layer lies behind the quadratus lumborum muscle. Medially, it also continues into the intertransverse ligament to attach to the lateral border of the lamina. The posterior layer covers the back muscles. It arises from the lumbar spinous processes and from the supraspinous ligaments to envelop the back muscles and blend with the other layers of the thoracolumbar fascia along the lateral border of the iliocostalis lumborum. The union of the fasciae is quite dense and forms a strong raphe (the lateral raphe[116]) which fuses with the fibres of transversus abdominis, internal oblique and latissimus dorsi muscles. The lateral raphe further inserts at the posterior segment of the iliac crest and the posterior superior iliac spine.[117]

The flexors of the lumbar spine consist of an intrinsic (psoas and iliacus) and an extrinsic group (abdominal wall muscles).

Lateral flexors and rotators are the internal and external oblique, the intertransverse and quadratus lumborum muscles. It is important to remember that pure lateral flexion is brought about only by the quadratus lumborum.

Spinal canal

The spinal canal is made up of the canals of individual vertebrae so that bony segments alternate with intervertebral and articular segments. The shape of the transverse section changes from round at L1 to triangular at L3 and slightly trefoil at L5 (see Fig. 31.2).[118]

The margins of the canal are formed by an anterior wall and a posterior wall, connected through pedicles and intervertebral foramina.

The anterior wall consists of the alternating posterior aspects of the vertebral bodies and the annulus of the intervertebral discs. In the midline these structures are covered by the posterior longitudinal ligament, which widens over each intervertebral disc.

The posterior wall is formed by the uppermost portions of the laminae and the ligamenta flava. Because the superoinferior dimensions of the laminae tend to decrease at the L4 and L5 levels, the ligamenta flava consequently occupy a greater percentage of the posterior wall at these levels.[95] The posterolateral borders of the posterior wall are formed by the anterior capsule of the facet joint and the superior articular process, which is located well anterior of the articulating inferior articular process.

The spinal canal contains the dural tube, the spinal nerves and the epidural tissue.

Dura mater

The dura mater is a thick membranous sac, attached cranially around the greater foramen of the occiput, where its fibres blend with the inner periosteum of the skull, and anchored distally to the dorsal surface of the distal sacrum by the filum terminale. The latter descends to the coccyx, where its fibres merge with the connective tissue of the sacroiliac ligaments.[119] The dural sac itself ends blind, usually at S2. There is an inconstant dural attachment, the 'Hofmann complex',[120] made up of bands of connective tissue and loosely joining the anterior dura to the vertebral column (Fig. 31.19). Ventral meningovertebral ligaments pass from the ventral surface of the dura to the posterior longitudinal ligament. They are variable in structure and may present either as tight bands, bifurcations

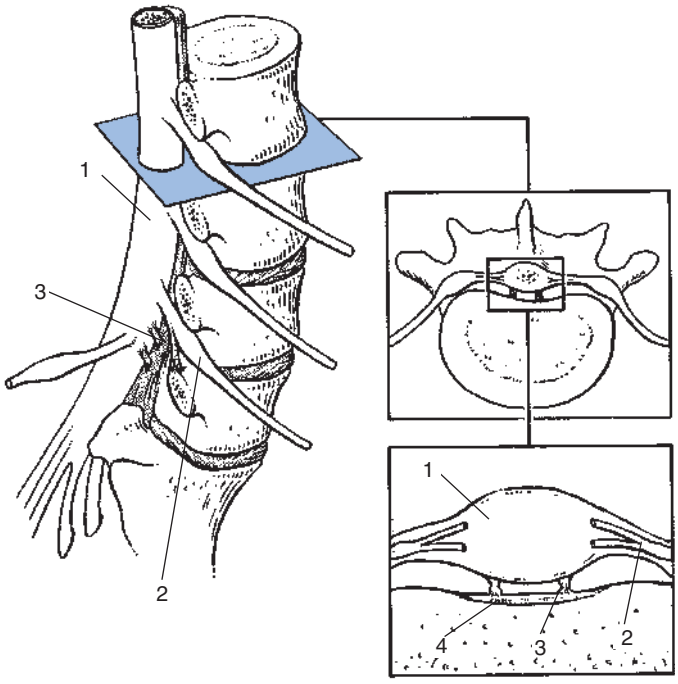

Fig 31.19 • 1, Dura mater; 2, nerve root in the nerve root sleeve; 3, meningovertebral ligaments; 4, posterior longitudinal ligament.

in a Y shape or paramedian bands.[121–123] Others reported on more lateral ligaments, passing from the lateral surface of the dural sac and blending with the periosteum of the pedicles.[124–127]

At the lumbar level, the dura contains the distal end of the spinal cord (conus medullaris, ending at L1), the cauda equina and the spinal nerves, all floating and buffered in the cerebrospinal fluid. The lumbar roots have an intra- and extrathecal course. Emerging in pairs from the spinal cord, they pass freely through the subarachnoid space before leaving the dura mater. In their extrathecal course and down to the intervertebral foramen, they remain covered by a dural investment. At the L1 and L2 levels, the nerves exit from the dural sac almost at a right angle and pass across the lower border of the vertebra to reach the intervertebral foramen above the disc. From L2 downwards, the nerves leave the dura slightly more proximally than the foramen through which they will pass, thus having a more and more oblique direction and an increasing length within the spinal canal. The practical implications of this oblique course of the roots are discussed later.

The dura mater has two characteristics that are of cardinal clinical importance: mobility and sensitivity.

Dural mobility

During spinal movements, the canal is subject to variations in its length and shape. It is obvious that all variations in dimensions of the vertebral canal will influence its contents.

The vertebral canal lengthens considerably during flexion: O'Connell[128] showed by radiological measurements that in full flexion the length of the cervical canal increases by 3 cm, compared with its neutral position. The dura mater, a structure situated in the vertebral canal but anchored at the top and at the bottom, will consequently move in the spinal canal. Breig[129] suggests that the dura mater unfolds and stretches. Other authors have found a gliding of the dural sac in relation to the spinal canal during flexion and extension.[130–133] Using gas myelography, Decker[134] showed that the dura moved towards the front of the canal during flexion: like a rubber band, it shifts towards a position of less tension, and is pulled against the anterior wall. Klein[135] demonstrated an upward displacement of the dura by more than 5 mm at L3 level during full flexion of the spine.

Straight leg raising can put considerable traction on the dural sac. During this manœuvre the L4, L5, S1 and S2 nerve roots are dragged downwards and forwards (Fig. 31.20). At the level of the intervertebral foramen, the degree of downward movement is between 1 and 4 mm.[136–138] As the root is connected through its dural investment with the distal part of the dura, the latter will also be involved in the downward movement. Therefore, straight leg raising drags on the dura mater and pulls it caudally, laterally and forwards.[135,139]

During neck flexion and straight leg raising, the dura thus moves slightly in relation to the anterior wall of the spinal canal, despite some loose attachments between the posterior longitudinal ligament and the dural sac. Anatomical changes at the anterior walls – for instance, a disc protrusion bulging dorsally into the canal – compress the dura. Conversely it can be pulled against this protrusion, whether from below during straight leg raising or from above during neck flexion. The observation that the dura is mobile thus has considerable clinical significance, since an increase of lumbar pain during neck flexion or during straight leg raising implicates the dura mater as the source. In fact, these signs have been accepted for decades as being positive in meningeal irritation (Kernig's sign and neck retraction), but this mechanism of dural pain was not elucidated until Cyriax's paper was published in 1945.[140] In the differential diagnosis of lumbar pain syndromes, 'dural signs' are extremely important in distinguishing a lesion in which the anterior part of the dura mater is involved (disc displacements) from possible lesions at the posterior wall (facet joints and ligaments).

Dural sensitivity

Clinical experiments have shown that the anterior part of the dura is sensitive to both mechanical and chemical stimulation.[141,142] Back pain is also well known in the context of neurological diseases in which the dura becomes inflamed[143] or compressed.[144] Further evidence for dural pain comes from neurosurgical studies that report relief of postlaminectomy pain after resection of the nerves to the dura.[145]

From the 1950s on, numerous neuroanatomical studies have been conducted that describe the innervation of the dural tube.[146] Several authors have shown that the ventral half of the dura mater is supplied by small branches of the sinuvertebral nerve.[147,148] Further work has confirmed that the innervation is from the sinuvertebral nerves and is confined to the anterior part of the dura only.[149,150]

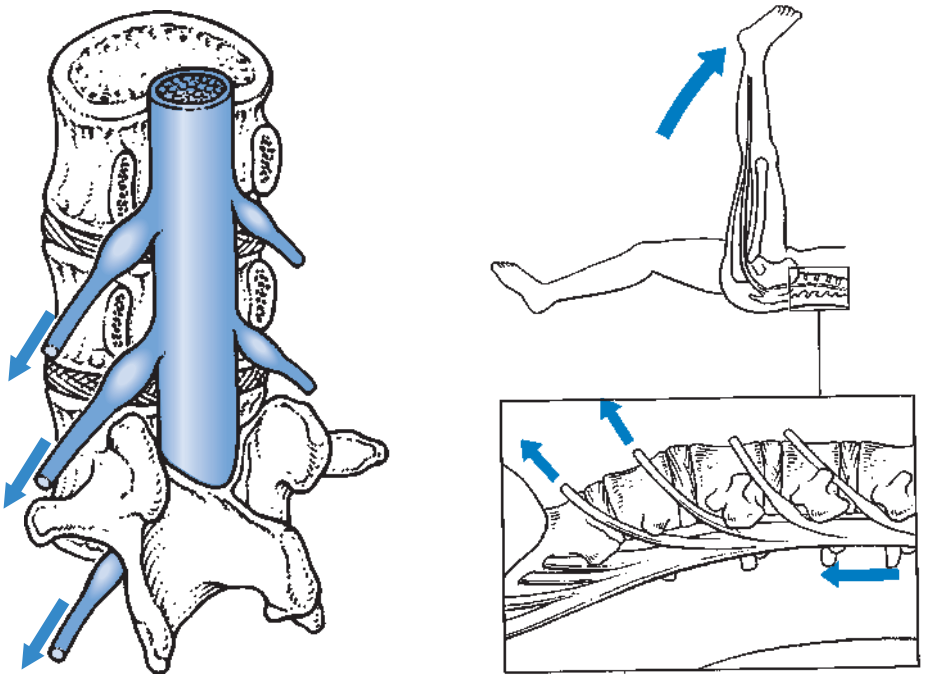

Fig 31.20 • Movement of nerve root and dura mater during straight leg raising.

During the last decade, immunohistochemical studies clearly demonstrated a significant number of free nerve endings, containing substance P, calcitonin-generated peptides and other neurotransmitters contributing to nociception.[151,152] All these findings have been confirmed and extended recently so that the present concept is of a dense, longitudinally orientated nerve plexus in the ventral spinal dura, extending over up to eight segments, showing a great deal of overlap between adjacent levels and crossing the midline.[153,154] The anterior part of the dura mater is thus innervated by a mesh of nerve fibres which belong to different and consecutive sinuvertebral nerves (Fig. 31.21). This probably explains the phenomenon of 'dural pain', which is a pattern of large and broad reference of pain covering different dermatomes, commonly found in low back syndromes. The patient then describes lumbar pain, radiating to the abdomen or up to the chest, to the groin or to the front of both legs.[155]

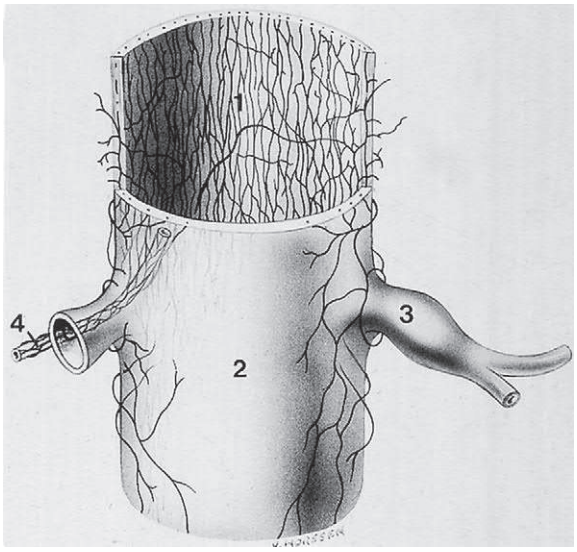

Fig 31.21 • The anterior part of the dura mater is innervated by a mesh of nerve fibres belonging to different and consecutive sinuvertebral nerves. 1, anterior part of the dura; 2, posterior part of the dura; 3, nerve root; 4, sinuvertebral nerve. Reproduced with permission from Groen.[154]

Nerve roots

Definition

The spinal cord terminates at the level of T12–L1. Consequently the lower lumbar and sacral nerve roots must run within the vertebral canal. The motor (ventral) and dorsal (sensory) rootlets that take their origin in an uninterrupted series of attachments at the ventrolateral and the dorsolateral aspects of the cord, run freely downwards through the subarachnoid space of the dural sac.

The rootlets that form one 'nerve root' are gathered into pairs before they leave the dural sac. They do so by taking with them an extension of dura mater and arachnoid mater, referred to as a 'dural sleeve'. The pair of roots covered by dura mater is called the *intraspinal, intrathecal part* of the spinal nerve.

The pairs of spinal roots join at the level of the foramen. Immediately proximal to its junction with the ventral root, the dorsal root forms an enlargement – the dorsal root ganglion – which contains the cell bodies of the sensory fibres in the dorsal

root. Distal to the junction at the foramen, the dura mater merges with the epineurium of the spinal nerve. From here the *extraspinal part* of the spinal nerve begins.[125]

Boundaries

The entire course of the intraspinal part of the spinal nerve is enveloped by the *radicular canal*[156] or *spinal nerve root canal*.[157] The term 'lateral recess' has been applied to the bony boundaries of this radicular canal.[158]

The radicular canal is a small, cone-shaped, osteofibrous space, which begins at the point where the nerve root leaves the dural sac and ends at the lateral border of the intervertebral foramen. It thus shelters the complete extrathecal nerve root in its dural sheath. The direction of the canal is caudal, lateral and slightly anterior. The anterior wall is formed by the posterior aspects of the vertebral body and intervertebral disc, both partly covered by the posterior longitudinal ligament. The posterior wall is the ligamentum flavum, the lamina and the corresponding superior articular facet. The medial wall is the dura mater. The lateral aspect of the radicular canal is formed by the internal aspect of the pedicle and is continuous with the intervertebral foramen.

The length of the radicular canal increases from L3 to S1, so making the L5 and S1 roots more liable to compression. The L3 nerve root travels behind the inferior aspect of the vertebral body and the L3 disc. The L4 nerve root crosses the whole vertebral body to leave the spinal canal at the upper aspect of the L4 disc. The L5 nerve root emerges at the inferior aspect of the fourth lumbar disc and crosses the fifth vertebral body to exit at the upper aspect of the L5 disc (Fig. 31.22).[159,160] Further clinical applications of this downward direction of the nerve roots are:

- At L4 level, a disc protrusion can pinch the fourth root, the fifth root or, with a larger protrusion, both roots.
- At L5 level, a disc can compress the fifth root, the first sacral root or both.
- Root L5 can be compressed by an L4 or an L5 disc.

It is, however, important to remember that aberrant courses and anastomoses exist between the lumbar nerve roots,[161] which may be present in about 4% of the population.[162]

The intervertebral foramen[163] is the point where the spinal nerve emerges from the canal (Fig. 31.23). It is located in a sagittal plane, so it can be demonstrated perfectly on a plain lateral radiograph. The foramen is limited cranially by the upper pedicle and caudally by the pedicle below. The anterior wall corresponds to the posterior aspect of the vertebral body and the disc. The posterior wall of the intervertebral foramen is formed by the articular facets. The size of the foramen increases from T12–L1 to L4–L5, but the foramen L5–S1 is the smallest of all and is located slightly more anteriorly.

Anatomy

The radicular canal contains the intraspinal extrathecal nerve root. The nerve root consists of a sheath (dural sleeve) and fibres. Each structure has a specific behaviour and function,

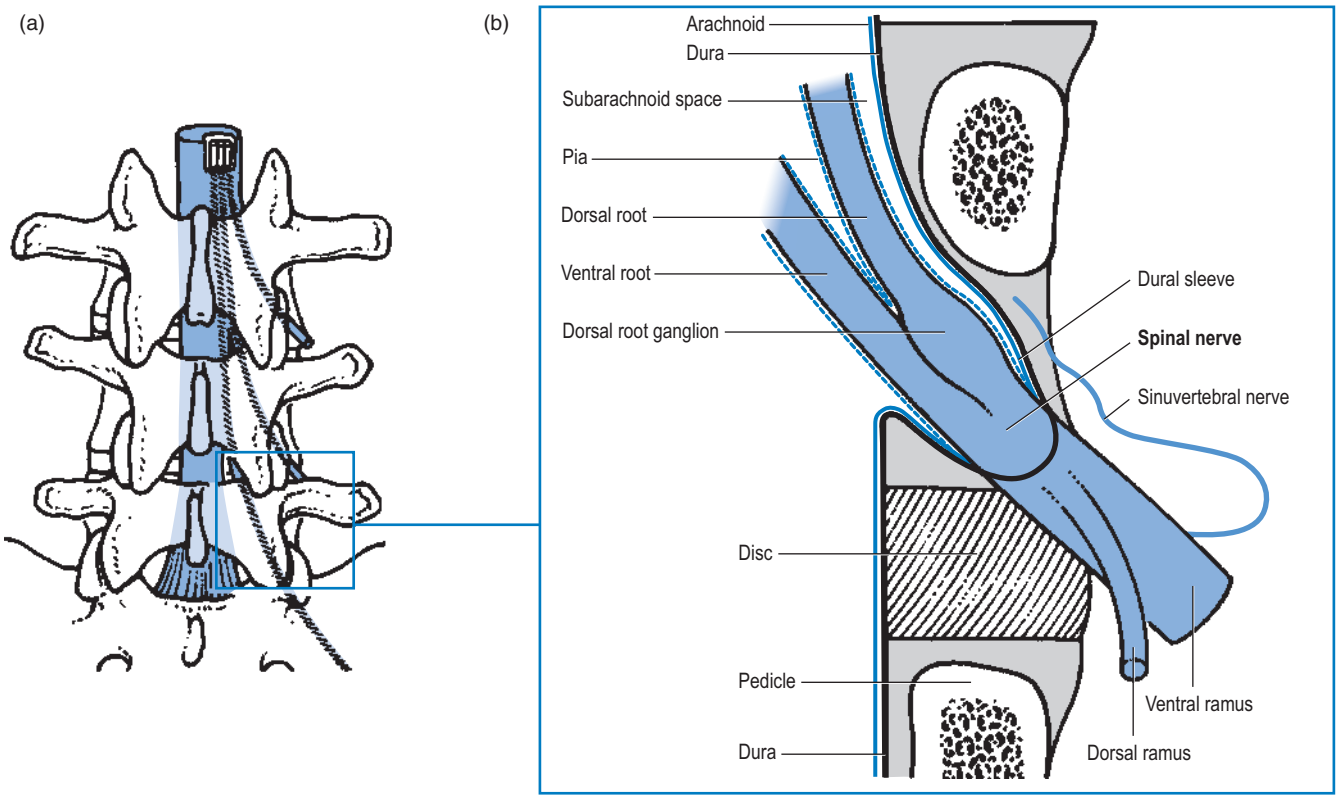

Fig 31.22 • (a) Course of the lumbar nerve roots; (b) anatomy of the nerve root.

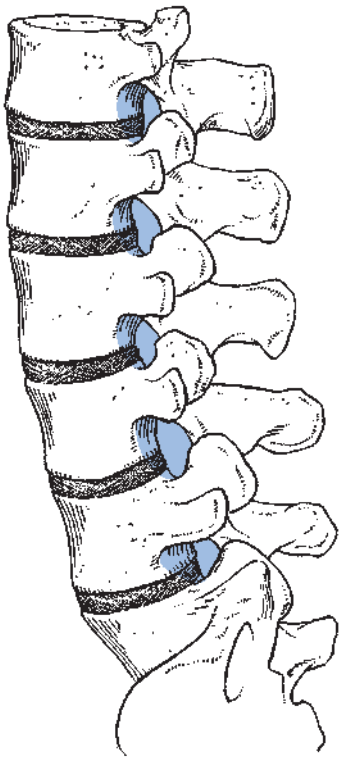

Fig 31.23 • Intervertebral foramina.

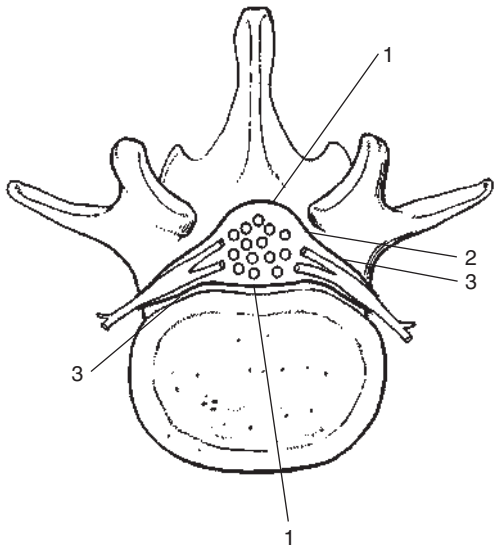

Fig 31.24 • The relationship between the nerve root and dural sheath: 1, dura mater; 2, dural pouch; 3, dural sleeve of nerve root.

Box 31.1

• Segmental pain	• Paraesthesia
• Mobility	• Conductivity

responsible for typical symptoms and clinical signs (Box 31.1). This has some clinical consequences: slight pressure and inflammation only involve the sleeve and provoke pain and impaired mobility. More substantial compression of the root will also affect the nerve fibres, which leads to paraesthesia and loss of function.

The dural sheath

The dural sheath (Fig. 31.24) starts as a funnel-shaped pouch, enclosing the anterior and posterior roots at their exit from the dural sac. The dural nerve root sleeve proper is formed at the end of this short pouch and continues distally to the foramen, where it merges with the connective tissue sheath of the ganglion and the spinal nerve. The dural investment of the nerve root therefore does not extend beyond the lateral border of the vertebral foramen. In this sleeve, the anterior and posterior roots no longer lie free but are firmly bound to the dural sleeve by the arachnoid membrane. In other words, the subarachnoid space forms a bilaminar tube within the root sleeve as a whole.[164]

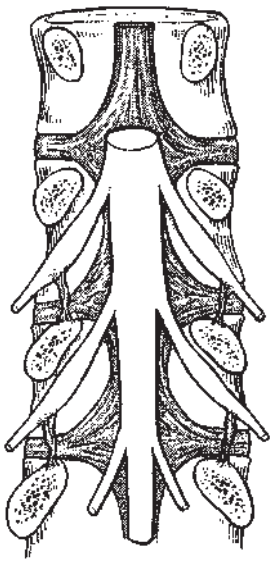

Fig 31.25 • The lateral root ligament.

At the foramen, the epidural tissue becomes more condensed and forms a loose ligamentous fixation of the epineural sheath to the bony boundaries of the intervertebral foramen.[165,166] A stronger ligament (the so-called 'lateral root ligament'; Fig. 31.25), connecting the epineural sheath to the pedicle, has also been described.[167] It has been suggested that the fixation of the dural sleeve, together with the anterior attachment of the dura to the posterior longitudinal ligament, could be of some importance in the mechanism of sciatica.[168] Simple mechanical analysis suggests that pressure applied to the nerve root by a disc protrusion is determined by the extent of the dural ligament fixation rather than by compression of the root against the posterior wall.[169]

The dural investment of the nerve root is sensitive and mobile, like the dural sac.

Mobility

Although the intervertebral foramen represents a point of relative fixation of the nerve, some caudal migration of the latter remains possible.[170] Distal traction on the sciatic nerve and lumbosacral plexus thus pulls the nerve root downwards and drags on the dural sheath and the dura. This occurs during straight leg raising, when the nerve roots of L4, L5, S1 and S2 are moved downwards at the level of the intervertebral foramen.[136,171,172] The main range of motion of the S1 root is 4 mm, of L5 3 mm and of L4 1.5 mm. Straight leg raising does not pull directly on the L3 root. This structure can only be moved caudally during knee flexion in the prone position, which stretches the femoral nerve.[173] It is not possible to test the mobility of the S3 and S4 roots because they do not reach the lower limb.

Because of the downward and anterior direction of the nerve roots and the relative fixation of the dural investment at the anterior wall, a downward movement of the nerve always involves anterior displacement, which pulls the root against the posterolateral aspect of disc and vertebra. Restriction of nerve root mobility therefore always means anterior compression of the root. Internal rotation of the hip during straight leg raising adds more tension to the lumbosacral plexus and nerve roots.[174] To clinicians this is not surprising, because it is common to see patients with considerable limitation of straight leg raising actively rotating their hips laterally when it is performed, thus protecting the inflamed root against further traction.

Cyriax drew attention to two interesting phenomena in relation to the mobility of the nerve root sheath: namely, the existence of a painful arc and the aggravation of the pain during neck flexion.[175]

- It is a common clinical finding that patients with sciatica show momentary pain during straight leg raising: there is pain only in a certain sector of movement (usually between 45 and 60°). The most acceptable explanation for this curious sign is that a small discal bulge exists over which the root slips and thereafter the rest of the movement is painless. This painful arc during straight leg raising always implies a small disc displacement and is a good indication that reduction by manipulation or traction is possible.
- The dural sheath can also be stretched from above. As we have seen previously (in the section on dural mobility), the dura can slip upwards during neck flexion. If pain brought on by straight leg raising is aggravated by neck flexion, the tissue thus stretched must run in a continuous line from the lumbosacral plexus to the neck. Only the dura mater and its continuations, the dural investments, can possibly be stretched from above and below at the same time.

Sensitivity of the dural investment

Dural root sheaths are innervated by the sinuvertebral nerve,[149] and each sheath receives branches from the nerve of the corresponding side and level only. In contrast to the anterior aspect of the dural sac, anastomoses between branches of adjacent sinuvertebral nerves do not exist. Pain originating from the dural sheath is therefore strictly segmental and follows the corresponding dermatomes in the limb.[176]

Compression of the spinal nerve beyond the intervertebral foramen does not generate pain but only pins and needles, numbness and paresis. This is the case when a disc protrusion has passed very laterally, when the fifth lumbar nerve is compressed between a corporotransverse ligament and the ala of the sacrum,[56] or in some spondylolytic compressions of the nerve root. Experience during the performance of a sinuvertebral block also confirms the insensitivity of the nerve root fibres. When the needle, just before touching the posterior aspect of the vertebral body, brushes against the nerve root, no pain but a sharp 'electric' shock results. As the dural investment of the root ends at the same level, it must be concluded that the latter is responsible for the radicular pain in sciatica.[175]

Nerve root

The structure of the nerve root differs from that of the peripheral nerves in three ways: the epineurium is less abundant, the fasciculi do not branch and the perineurium is missing. Thus, compared with a peripheral nerve, the parenchyma of the nerve root is more susceptible to injury, by either mechanical or chemical irritation.[177]

Irritation of the parenchyma leads to *paraesthesia*. Unlike 'radicular' pain, which is merely a symptom of compression of the dural sheath, pins and needles indicate that the nerve fibres are irritated as well. Paraesthesia is thus a symptom of direct involvement of the nerve root. Further irritation and destruction of the neural fibres leads to interference with conduction, resulting in a *motor and/or sensory deficit*. The fact that the motor and sensory components of the nerve root remain completely separated during the course of the nerve root along the radicular canal has some clinical consequences: it is possible for a nerve root compression to cause a pure motor paresis or a pure sensory deficit. If pressure is exerted from above, sensory impairment may result, whereas an impingement from below can induce a motor paresis. A larger protrusion, pressing between two roots, can result in a motor palsy of the root above, together with a sensory deficit of the nerve root below (Fig. 31.26).

Controversy still exists over the mechanism of nerve root compression by a protruded disc. Inman and Saunders[178] stated that the nerve root is rarely 'compressed' between anterior and

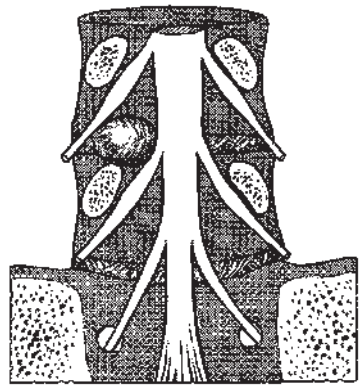

Fig 31.26 • Protrusion pressing between two roots.

posterior walls, but is merely brought under tension by the disc herniation. Others have observed that the extrathecal, intraspinal nerve root is relatively fixed to the anterior wall and the intervertebral foramen by the dural ligamentous complex and the foraminal complex (see p. 429).[171,179] Therefore, this particular part of the root cannot easily slip away from a disc protrusion and is tethered over it, and a pressure-induced nerve lesion can develop.[168]

These anatomical findings probably help to explain why the magnitude of signs and symptoms in sciatica does not necessarily correspond to the magnitude of the disc protrusion, and also why many asymptomatic protrusions exist. The amount of interference with conduction is related to the degree of the compressing force, which in turn depends not only on the magnitude of the protrusion but also on the tightness of the dural fixation to anterior wall and intervertebral foramen.

The involvement of nerve fibres is tested during clinical examination: resisted movements and the reflexes test the integrity of the motor fibres, while cutaneous analgesia indicates loss of sensory conduction. Interference with conduction suggests that an attempt to achieve reduction by manipulation or traction will fail. In general, a disc lesion affects only one nerve root and the neural effects are rather subtle. As described above, combinations of sensory and motor effects or their independent existence may occur. It is also possible for two roots to be pinched by one disc protrusion, which can be the case at the L4 level where a combined fourth–fifth palsy can arise, probably resulting in drop foot, or at the L5 level where a combined fifth lumbar–first sacral deficit can occur.

Massive pressure may finally cause ischaemic root atrophy and then complete loss of sensitivity of the sheath. Reflex hamstring contraction to protect the nerve root no longer takes place and straight leg raising becomes full-range, despite the massive disc protrusion and the complete lesion.

Conclusion

For clinical purposes it is as well to divide the components of the nerve root into an external aspect (the sheath), which is mobile and is responsible for pain, and an internal aspect (the nerve fibres), which serves conduction only. This helps to distinguish the symptoms and signs of each, so permitting proper assessment of the location of a lesion, the magnitude of compression and the degree of functional incapacity (Box 31.2).

In nerve root compressions by a displaced disc, the development of symptoms and signs allows the anatomical changes in the radicular canal to be followed: slight pressure will only involve the sheath of the root (Fig. 31.27), giving rise to pain in the corresponding dermatome and probably impaired mobility, reflected by alterations in straight leg raising. Greater pressure will result in pressure on nerve fibres, reflected in paraesthesia at the distal end of the dermatome. Clinical examination will now reveal not only interference of mobility but also impaired conduction – a sensory deficit and/or loss of motor power. Greater pressure causes root atrophy, which results in loss of sensitivity of the dural sheath and gives a painless straight leg raising test. At the same time the sensory deficit and motor palsy become complete (Fig. 31.28).

Box 31.2

Neurological deficit at each level

L1 Compression of the L1 root produces neither paraesthesia nor muscle weakness and cutaneous analgesia is only found below the inner half of the inguinal ligament

L2 Involvement of the L2 root causes paraesthesia and analgesia over the anterior aspect of the thigh, from the groin to the patella. Muscle weakness is found in the psoas

L3 Interference of conduction in the L3 root causes paraesthesia at the anterior aspect of the leg from the distal third of the thigh, over the knee and the lower leg, down to the ankle. Cutaneous analgesia extends from the patella along the front and the inner aspects of the leg, and ends just above the ankle. The weak muscles are psoas and quadriceps and the knee jerk is sluggish or absent

L4 Compression of L4 has the following clinical signs: paraesthesia at the outer leg and the big toe, sensory deficit at the lateral aspect of the lower leg, over the foot up to the big toe, and weakness of the extensor hallucis and the tibialis anterior muscles

L5 Involvement of the L5 root results in paraesthesia at the outer leg, the front of the foot and the big and two adjacent toes, and cutaneous analgesia of the outer leg, the dorsum of the foot and the inner three toes. Weakness is found at the extensor hallucis longus, the peroneal and gluteus medius muscles

S1 Compression of the S1 nerve root shows the following signs: paraesthesia at the two outer toes, numbness at the calf, the heel and the lateral aspect of the foot. The weak muscles are the calf muscles, the hamstring, the gluteus maximus and the peronei

S2 Involvement of the S2 root results in paraesthesia at the heel and cutaneous analgesia at the posterior aspect of the thigh, the calf and the heel. The calf muscles, the hamstrings and the gluteal mass are weak

S3 Neural deficits cannot be detected in S3 lesions

S4 Parenchymatous lesions of the S4 root result in paraesthesia in the perineum, vagina or penis, anal analgesia, and functional disorders of the bladder and rectum, usually incontinence

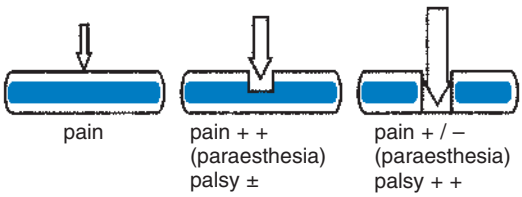

Fig 31.27 • Symptoms and signs of a compressed nerve root vary according to the intensity of compression.

Epidural space

The virtual space between the dural sac, the dural sheaths of the nerve roots, and the spinal canal is the epidural space. This space is quite narrow because the dural sac lies very close to the boundaries of the vertebral canal and is filled with a network of loose connective tissue, fat, arteries and a dense network of veins.[180]

Fig 31.28 Symptoms and signs of nerve root compression at each level (continued). SLR, straight leg raising.

The sinuvertebral nerve is in the anterior half of the epidural space. The venous system is extensive and valveless, with multiple cross-connections. Batson[181] has described retrograde venous flow from the lower pelvis to the lumbosacral spine, which probably provides the route for metastases and infections spreading from the pelvic organs to the spine.

Innervation

The spine is innervated by the sinuvertebral nerve and the posterior primary ramus. All the tissues lying posterior to the plane of the intervertebral foramina at each level (i.e. the facet,

the vertebral arch, the related tendinous and aponeurotic attachments and the flaval and interspinous ligaments) are innervated from the posterior primary rami. Those anterior to the intervertebral foramina (longitudinal ligaments, anterior dura and dural sleeves) are supplied by branches of the sinuvertebral nerves (Wyke, cited by Cyriax[182]).

Sinuvertebral nerve

The sinuvertebral nerve was first described by Luschka in 1850.[183] It emerges from the anterior aspect of the spinal nerve, distal to the nerve ganglion, and receives some sympathetic branches from the ramus communicans[22] (Fig 31.29). In the fetus the nerve is composed of several filaments which may become bound together during later life, to form the adult sinuvertebral nerve.[146] The composite nerve is between 0.5 and 1 mm thick,[184] passes through the intervertebral foramen and points upwards around the base of the pedicle, to pass along the cranial side of the corresponding disc to reach the medial aspect of the posterior longitudinal ligament. Here it divides into ascending, descending and transverse branches, which anastomose with the sinuvertebral nerves of the contralateral side and with those from adjacent levels. Therefore, instead of a recognizable nerve trunk, the sinuvertebral nerve is represented by a network of overlapping fine filaments from different levels and from both sides (Fig. 31.30).[185]

Branches of the sinuvertebral nerve supply the vertebral body, the outermost layers of the annulus fibrosus, the posterior longitudinal ligament, the anterior aspect of the dural sac and the dural investments around the nerve roots.[186] Branches of the sinuvertebral nerve also surround the blood vessels of the vertebral canal. The posterior aspect of the dura is devoid of nerve endings. There is still disagreement as to whether the ligamentum flavum and the lamina are innervated by the sinuvertebral nerve.

Posterior primary ramus

Distally from the intervertebral foramen, the spinal nerve divides into a large anterior branch and a smaller posterior ramus (Fig. 31.31). The latter divides almost immediately into a medial and a lateral branch,[187] although a smaller intermediate branch has also been identified.[92]

The medial branch descends posteriorly to the transverse process, where it lies in a groove formed by the junction of the superior articular and transverse processes. A strong fibrous

band transforms this osseous groove into an osteofibrous tunnel. At this level a branch innervates the inferior part of the articular capsule of the facet joint. The nerve continues its course caudally on the lamina, to supply the dorsal muscles and the superior part of the articular capsule of the facet joint of the level below.[188]

Each medial branch thus supplies the facet joints above and below its course. Consequently, each facet joint is innervated by two consecutive medial branches.[189,190]

The lateral branch of the posterior ramus emerges between the deep layer of the lumbodorsal fascia and the lateral edge of the lamina. It supplies the muscles and the fascia. The lateral branches of the ramus posterior have cutaneous nerves and reach distally as far as the greater trochanter.[148]

Introduction

The human spine functions in a reverse way to that for which it was originally developed: instead of a hanging bridge connecting the anterior to the posterior limbs of a quadruped, it has become a vertical column of a biped, fundamentally changing the biomechanics and imposing larger loads on the lower lumbar discs. Humans' upright posture has long been blamed as the main cause of the development of early disc degeneration: 'intervertebral disc disease is the price we pay for the gift of the erect posture.'[1]

Disc degeneration in animals is very unusual.[2] Neither have localized bulging and Schmorl's nodules ever been observed in quadrupeds.[3] However, a quadruped forced to adopt an erect position quickly develops structural changes in the annulus fibrosus and nucleus pulposus.[4–6] Large disc herniations at the lumbosacral level also occur in 25% of bipedal rats.[7] It seems obvious, therefore, that the upright position and the consequent increase in static loading of the disc[8] are the main causes of the early and progressive development of degeneration in the human lumbar spine.

Degenerative changes in the intervertebral discs are so common that they can be regarded as normal physiological processes. Therefore we do not use the term intervertebral disc 'disease' but prefer to speak of intervertebral disc 'ageing'.

Degeneration of the lumbar discs starts very early in life. Clear microscopic signs of degeneration have been demonstrated in a 4-year-old.[9] Several reports of prolapsed discs in children and adolescents show that major disc degeneration appears at or before puberty[10–14] and it has been maintained that after the age of 30 years there is no lumbar disc which does not show some degenerative changes.[15] There seems to be no way to escape this degeneration because it affects all, whatever their weight, physical build or athleticism.[16]

Ageing of the disc

Mechanism

Both the erect posture, which imposes heavier mechanical stresses on the spine, and the decreased regenerative capacity of the disc make it very vulnerable. As has been described (see Ch. 31), the disc depends for its nutrition on diffusion through the endplates and annulus, which can only take place as an outcome of change in intradiscal pressure within a physical range (Fig. 32.1). Consequently, both excessive forces and immobilization will have deleterious effects on disc tissue.[17] A modern, mostly sedentary lifestyle, for example, puts continuous increased

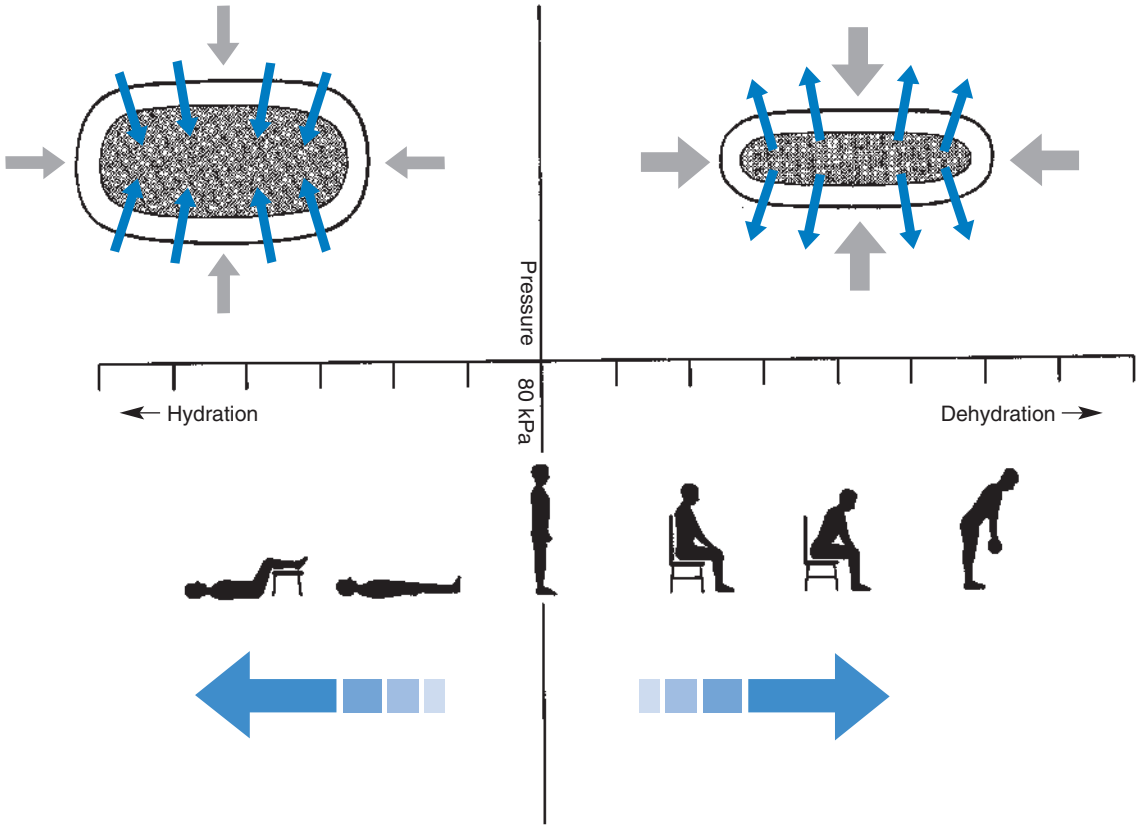

Fig 32.1 • Hydration–dehydration changes with load and consequently with activity and posture.

pressure on the disc; it is then constantly kept low in water content, which prevents the transport of nutrients. As the cells are undernourished, the fibrils and ground substance become damaged and their chemical composition changes.[18] Enzymatic depolymerization of collagen and mucopolysaccharide causes a decrease in weight and content that results in a drop in oncotic pressure, which leads to further loss of water.[19] The drying out of the disc is the most characteristic sign of intervertebral degeneration. The loss of hydrostatic pressure in an ageing disc is also reflected in the change in daily variations in body height: in adolescence the difference in body height between morning and night is 2%, but this drops to 0.2% in adults.[20] The mature disc is thus permanently dried out and lacks the osmotic elasticity of the young disc.

Loss of water-binding capacity is also responsible for the decrease of disc turgor and loss of endurance. The disc does not sustain the normal loads and the hydration–dehydration curve shifts in the direction of further dehydration (Fig. 32.2). A vicious circle of further degeneration, further decrease in molecular weight and further fall in water-binding capacity is set up (Fig. 32.3).[21]

With advancing age, the permeability of the vertebral endplates also decreases. The accompanying calcification compromises the nutrient supply to the adjacent nucleus, so enhancing further disc degeneration.[22,23] The early stage of the changes in vertebral bone structure is first seen on magnetic resonance imaging (MRI).[24] Vertebral endplate sclerosis later becomes radiographically visible.[25]

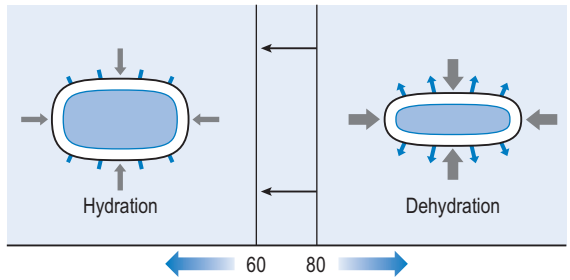

Fig 32.2 • Loss of water-binding capacity leads to loss of endurance; the disc cannot sustain normal loads and the hydration–dehydration curve shifts further in the direction of dehydration.

Another consequence of the decrease of oncotic pressure is loss of disc height and narrowing of the intervertebral space, which in turn influences the function of the facet joints and the anatomical relationships of the intervertebral foramina.

Structural changes

The intervertebral disc is characterized by a tension-resisting annulus fibrosus and a compression-resisting nucleus pulposus. As the nucleus pulposus dries out, it becomes less able to exert fluid pressure. The annular fibres, no longer under constant tension in relation to the nucleus, bear a greater share of vertical load and are subjected to bulk deformations and shear

strains.[26] This leads to tears in the annular fibres.[27] The posterior annulus, especially the area between annulus and nucleus, is subjected to most of the mechanical strain.[28] As this posterior boundary zone is also most exposed to nutrient deficiency,[29] it will be the first to wear through, so that small radial fissures appear.[30,31] Further softening and loosening of annular tissue leads to expansion of these fissures and the formation of cavities and cysts, which are radiographically seen as air pockets.[32] Nuclear displacements through these fissures will lead to a further decrease in disc height. As a result, the intervertebral joint becomes unstable and is subjected to more bulk deformation and more shear strain. Ruptures permit further migration of the disc material in the direction of least resistance (mostly backwards). The result is intradiscal displacements, bulging beyond the vertebral borders and disc prolapses (see Ch. 33).

Ageing of the disc also involves structural changes in the endplate. Between the ages of 20 and 65, the endplate becomes thinner and cell death occurs in the superficial layer of the cartilage.[33] The vascular channels in the subchondral bone of the endplate are gradually occluded, finally leading to complete endplate sclerosis. As the endplate plays an important role in the nutrition of the disc, changes in it will contribute to further degeneration of the whole intervertebral disc. Also, the strength of the vertebral endplate decreases with age, which renders it more liable to (micro)fractures. Microscopic defects may be followed by invasion of the disc by young blood vessels and connective tissue cells.[34] The latter undergo metaplasia into cartilage cells and granulation tissue, and adult connective tissue also forms.[35] This 'invading' connective tissue can spread out into the disc, create zones of decreased resistance and cause further weakness and instability. It has even been hypothesized that this 'new' proliferative tissue plays a part in disc herniations.[36]

The macroscopic degeneration of the disc was divided into four grades by Friberg and Hirsch[37] and later by Nachemson.[38] This scheme for assessing the gross morphological changes in the lumbar intervertebral discs has recently been improved by Thompson *et al*,[39] who consider five morphological grades (Table 32.1 and Fig. 32.4).

Macroscopic grades of disc degeneration have been correlated with age, sex and spinal level for 600 lumbar intervertebral discs from 273 cadavers in a review by Miller *et al*.[40] Their conclusion was that, by the age of 50 years, 97% of all lumbar discs exhibit degeneration and that the L3–L4 and L4–L5 levels usually contain the most severely degenerated discs. Another study demonstrated that there is disc degeneration in at least one lumbar level in 35% of subjects between 20 and 39 years of age, and that all subjects 60–80 years of age show disc degeneration.[41]

These figures establish that disc degeneration is a normal age-dependent pathophysiological process; it therefore cannot be regarded as a 'disease' but is a normal biological event from which no one will escape.[42]

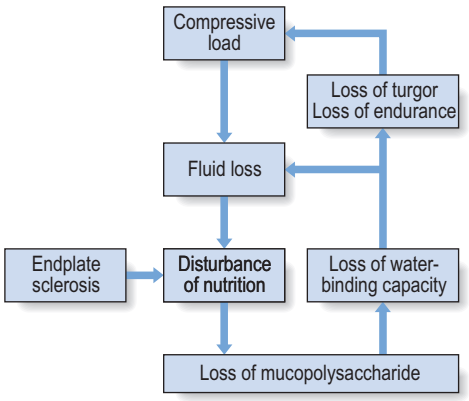

Fig 32.3 • Vicious circle of disc degeneration.

Disc displacements

Fissures in the annulus fibrosus will inevitably lead to changes in the biomechanical behaviour of nucleus and annulus, which can then result in intradiscal nuclear displacements, protrusions and prolapses (Fig. 32.5).

The nucleus and inner annulus do not contain free nerve endings. Displacements of these structures are therefore painless, except when they irritate other more sensitive tissues, such as the outer annulus, the dura and the nerve root sleeves.

Table 32.1 Description of the morphological grades

Grade	Nucleus	Annulus	Endplate	Vertebral body
I	Bulging gel	Discrete fibrous lamellae	Hyaline, uniformly thick	Margins rounded
II	White fibrous tissue peripherally	Mucinous material between lamellae	Thickness irregular	Margins pointed
III	Consolidated fibrous tissue	Extensive mucinous infiltration; loss of annular–nuclear demarcation	Focal defects in cartilage	Early chondrophytes or osteophytes at margins
IV	Horizontal clefts parallel to endplate	Focal disruptions	Fibrocartilage extending from subchondral bone; irregularity and focal sclerosis in subchondral bone	Osteophytes less than 2 mm
V	Clefts extend through nucleus and annulus		Diffuse sclerosis	Osteophytes greater than 2 mm

Reproduced with pernission from Thompson *et al*.[39]

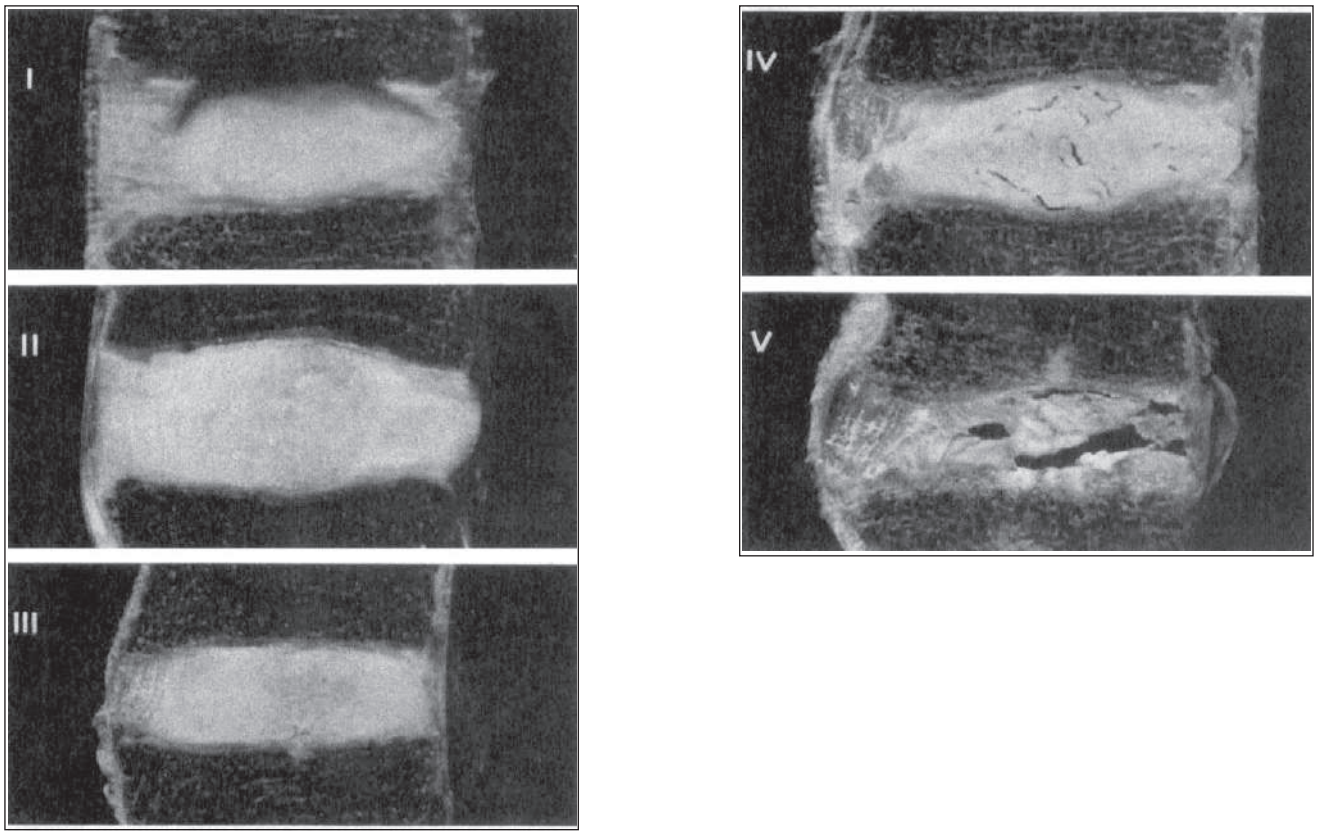

Fig 32.4 • The appearance of a typical disc of each grade. From Thompson *et al*,[39] with permission.

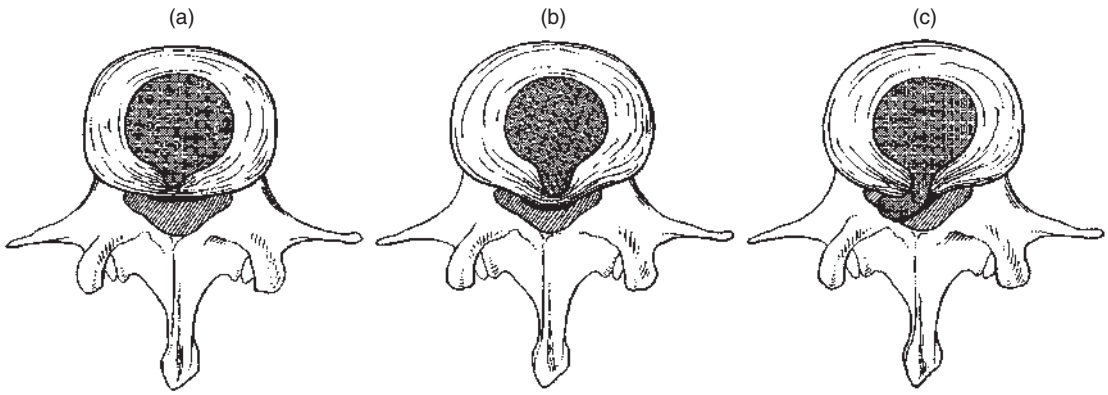

Fig 32.5 • Disc displacement: (a) displaced tissue within the disc; (b) bulging of the intervertebral disc without perforation of the annulus fibrosus; (c) herniation of intervertebral disc tissue through the annulus fibrosus into the spinal canal (prolapse).

Therefore it is not the size of the migration that is important but the degree of irritation of the pain-sensitive tissues. Because imaging techniques (computed tomography (CT), CT discogram and MRI) can only detect the size and localization of the bulges, and not always their effect on surrounding tissues, many more disc displacements are detected during imaging than actually cause symptoms.[43,44] More than 50% of asymptomatic patients over 40 years of age have either alterations in or displacements of disc.[44] Single or multilevel disc bulging is visible on the MRIs of between 28 and 85% of the adult population who do not have activity-limiting low back pain.[45–48]

Cyriax[49] listed five different directions in which discal tissue can move: posterior, posterolateral, anterior, vertical and circular. Each type of displacement occurs during a specific period in the degeneration of the disc. Posterior and posterolateral displacements are typical in the third, fourth and fifth decades. Anterior displacement resulting in osteochondrosis is a disorder of teenagers, whereas anterior displacement in combination with disc resorption is a lesion of the elderly and is seldom

seen below the age of 50. It is surprising to find that low back syndromes (lumbago, backache, sciatica) are age-related,[50,51] whereas the incidence of fissures, ruptures and degeneration of the disc increases linearly during the whole of life. Extensive pressure within the nucleus pulposus is higher in individuals between 30 and 50 years of age than in the elderly (Fig. 32.6).[52] The conclusion is that posterior displacement of the disc will be more likely to appear when increased intradiscal pressure coincides with some damage to the posterior annular fibres. In other words, the combination of intradiscal pressure and lowered resistance of the annulus fibrosus is the main biomechanical factor contributing to protrusion–prolapse. When the expansive forces of the nucleus pulposus decrease and, because of the loss of water, the disc gradually deflates, the tendency to displacement diminishes.[53,54] Other factors protecting the ageing disc against displacements are increasing stiffness of the posterior ligaments, which limit spinal mobility, and the formation of osteophytes, which distribute the load over a larger area.

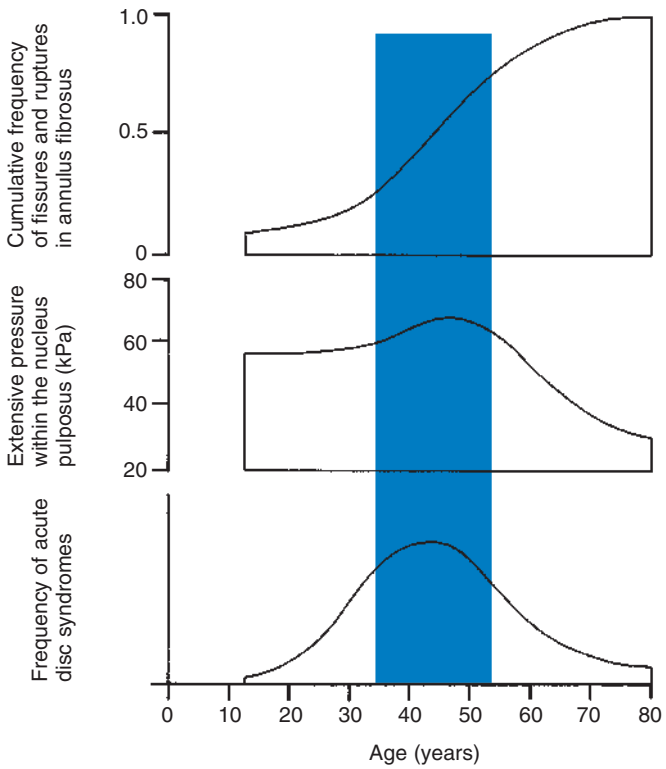

Fig 32.6 • The relationship of age to acute disc syndromes. From Krämer J. *Intervertebral Disc Diseases, Causes, Diagnosis, Treatment and Prophylaxis*, 1981, Elsevier, Stuttgart, with permission.

Posterior displacement

The posterior boundary zone between the annulus and the nucleus is the first part to develop areas of degenerative change and fissures (see p. 438). In sitting and forward bending, the disc is asymmetrically loaded, with a compression strain anteriorly and a tensile stress dorsally. Because of the increase of intradiscal pressure, the nucleus pulposus is pushed dorsally and applies more stress to the weakened posterior fibres, which are already subjected to the strong tensile stress imposed by the flexion.[55]

Posterior migration of disc tissue beyond the posterior limits of the intervertebral joint space causes tension on the outer annulus and the posterior longitudinal ligament. Irritation of ligament, dura mater and the Hofmann complex combines to produce *backache* (Fig. 32.7a). The patient's history usually suggests the type and localization of the displacement and the degree of dural irritation: progressively increasing backache usually stems from a nuclear displacement. A sudden shift indicates that the material that has moved is of harder, annular consistency. If the bulge irritates the dura centrally, the pain is central, probably with some bilateral gluteal radiation. If it lies more to one side, unilateral pain and pain in one buttock result.

Further irritation of the dura mater results in a clinical picture that is called *acute lumbago* (Fig. 32.7b). In a cartilaginous displacement, the patient states that bending, lifting or standing, after sitting for a while, resulted in acute and severe pain. Alternatively, the pain and disability have come on gradually, some hours after a period of stooping or sitting, which suggests protrusion of part of the nucleus. In both events, a constant ache is experienced which forces a pain-avoiding

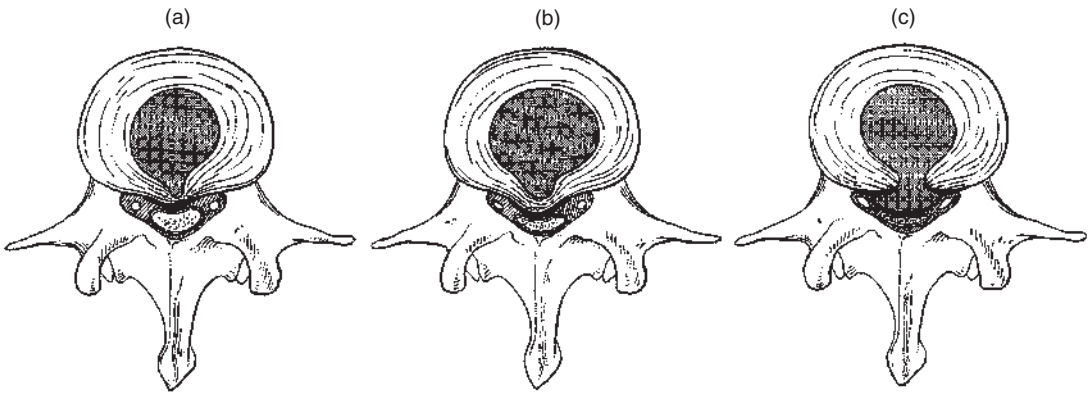

Fig 32.7 • Posterior disc displacement in (a) backache; (b) acute lumbago; (c) massive posterior protrusion (S4 or cauda equina syndrome).

position, usually in flexion and/or lateral deviation. The pain is agonizing and radiates to one or both legs in an extrasegmental way. Dural symptoms (pain on coughing and sneezing) are positive, as are dural signs (limited straight leg raising and lumbar pain on full neck flexion), indicating that the dura is under constant and severe stress.

In backache and lumbago, the posterior displacement puts the posterior longitudinal ligament under tension, which causes counterpressure on the bulge. This explains why acute lumbago usually ceases after a lapse of time, especially when the intradiscal pressure is reduced by lying down and avoiding sitting or bending.

A *massive posterior protrusion* may cause a rupture of the posterior longitudinal ligament. The entire cauda equina will then be compressed between the protrusion and the laminae. This not only squeezes the nerve roots on both sides but also causes compression and atrophy of the centrally localized S3 and S4 roots, with disturbance of bladder and rectal function (the S4 syndrome or cauda equina syndrome) (Fig. 32.7c).[56,57]

Posterolateral displacement

Root pain results from pressure of the prolapsed or protruded disc against the dural sleeve of the nerve root and subsequent irritation of the latter (Fig. 32.8). This may be primary or secondary.

Secondary posterolateral protrusion

This is more common. The root pain starts after the patient has suffered a number of attacks of lumbago or backache. After the most recent attack, the counterpressure exerted by the posterior longitudinal ligament has not resulted in the usual reduction of the bulge but rather in a lateral shift which impinges on the nerve root. The back pain will have passed, to be replaced by pain in the limb. According to the severity of irritation, which is determined not only by the degree and consistency of the bulge but also by the tightness of the 'tethering ligaments', the size of spinal canal and the degree of inflammatory response, the symptoms and signs are related to impairment of mobility of the dural sleeve (pain and limitation of straight leg raising) alone, or interference with conduction (paraesthesia, numbness and motor deficit).

Primary posterolateral protrusion

In this case, the pain usually begins in the calf and the posterior thigh; the absence of previous backache indicates that the dura has not been previously compressed. This condition usually affects young adults (aged 18–35 years). The signs are radicular, with pain and paraesthesia in the affected dermatome and limitation of straight leg raising. Signs of impaired conduction at the affected root are exceptional.

Anterior displacement in adolescents

Because of its high oncotic and hydrostatic pressure, the young disc sometimes invades the vertebral endplates. This occurs particularly in the regions where the endplates have low resistance against increased anterior loading.[58,59] The nucleus pulposus may then move forwards between the cartilaginous endplate and the bone of the vertebral body, causing injury to the growth zone of the vertebra (Fig. 32.9). The result is a developmental deformity of the anterior part of the vertebra. During the course of this, protrusion may separate a small triangle of bone at the anterior corner of the vertebral body (limbus vertebra).[60] If the osteochondrosis involves several consecutive vertebrae, a kyphotic deformity results (Scheuermann's disease).[61]

Such deformities occur only during the period of spinal growth and are asymptomatic. Care must therefore be taken not to overemphasize the significance of incidental radiological findings.[62]

Anterior displacement in the elderly

Tears at the anterior and anterolateral part of the disc lead to both anterior and anterolateral herniation. Anterior displacement of the disc causes dissection of the anterior longitudinal ligament from its bony attachments, which stimulates bony outgrowths along the anterior and anterolateral aspects of the vertebral body. These first appear in a horizontal direction and then vertically, following the course of the anterior longitudinal ligament (see p. 423). In advanced cases, the whole disc is displaced anteriorly. On a lateral radiograph this can be seen

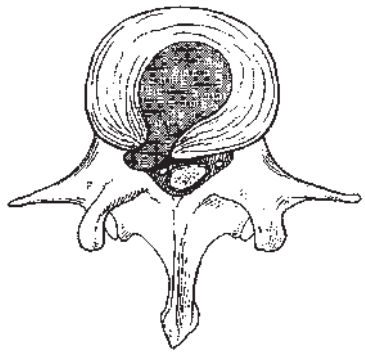

Fig 32.8 • Posterolateral disc displacement.

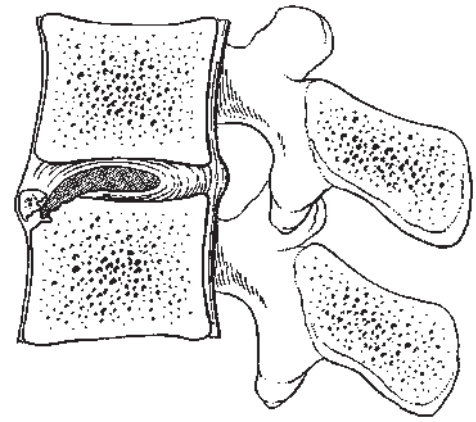

Fig 32.9 • Intravertebral herniation in adolescence.

as two 'beaks' containing the disc, while the intervertebral space is so narrowed that the vertebral bodies come to lie in apposition.[63] Cyriax called this situation the 'mushroom' phenomenon, because of the characteristic appearance of the osteophytes, surrounding a 'mushroom' – the anteriorly displaced disc (Fig. 32.10).[64] The formation of the protrusion itself is completely painless but the gross narrowing of the intervertebral space, the folding of the posterior longitudinal ligament and the enlarged arthrotic posterior joints can cause considerable narrowing of the spinal canal and the lateral recess, which may result in compression of dura or nerve root when the spine is subjected to an axial load.

Vertical displacement

There are two types of vertical displacement: Schmorl's node and biconvex disc.

A herniation of the nucleus through the cartilaginous endplate is known as Schmorl's nodes (Fig. 32.11),[65] although it was first described by von Luschka in 1858.[66] After the nuclear material has invaded the cancellous bone, a reactive osseous shell forms, visible on a radiograph from the age of 17; this does not alter over the years. The disorder is very common at the lower thoracic and upper lumbar levels. Schmorl reported an incidence of 13% on radiographic examination of an adult and asymptomatic population but postmortem studies reported nodes in more than 75% of ordinary individuals.[67]

Biconvex discs appear as the result of traumatic or degenerative changes in the cartilaginous or bony endplates. Osteoporosis or osteomalacia causes a weakening of the bone and the disc balloons between two adjacent and slightly collapsed vertebrae.[68]

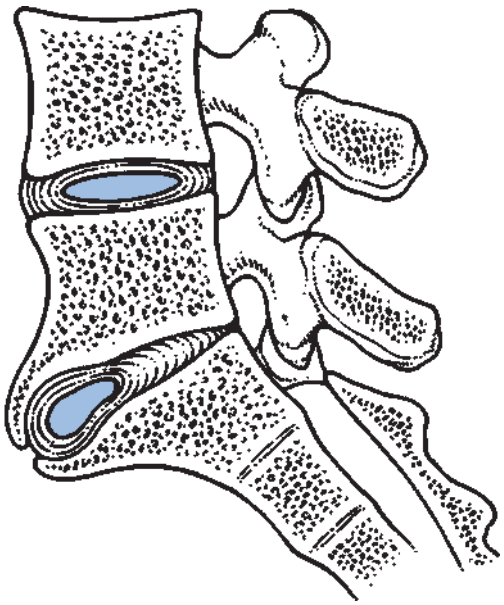

Fig 32.10 • Anterior displacement in the elderly: the 'mushroom' phenomenon.

Circular displacement

As a result of degeneration, weakening and drying out, the disc may bulge out all the way round the joint. The outward pressure pulls on the ligaments and lifts the periosteum off the bone. Formation of osteophytes at the anterior and lateral aspects of the vertebra results. These bony outcrops encircle the damaged disc. Mechanically, the presence of osteophytes is beneficial because they increase the weight-bearing surface and decrease the load per unit area.[69] They also decrease mobility. Both effects augment the stability of the joint.

Ageing of the surrounding tissues

Effects on the ligaments

The adjacent vertebral endplates develop poorly demarcated sclerotic densities, probably as the result of changed load distribution on the disc.[30] However, the most commonly observed radiographical manifestation of disc degeneration is osteophyte formation in the vertebral bodies.

The first sign of degeneration and instability of the disc is the formation of small *traction spurs*[70] which project horizontally to about 2 mm above and below the vertebral body (Fig. 32.12a). Their formation is explained as follows: decrease in turgor in the disc and the increasing anteroposterior instability which results cause the outermost fibres of the annulus, firmly attached to the undersurface of the epiphyseal ring, to exert traction on the periosteum. A horizontal lifting of the periosteum results in the formation of traction spurs.[71]

Spondylitic spurs (Fig. 32.12b) or claw spurs are very common in the elderly and there is a positive correlation between osteophyte size and patient age.[72] They have been reported to occur most frequently at L3–L4 in men who carry out heavy physical activity and in obese patients.[73] The claws form as the result of subperiosteal ossification at the anterior and anterolateral aspect of the vertebrae and their aetiology is considered to be follows: a softened and dehydrated disc bulges easily under the influence of external load and lifts the

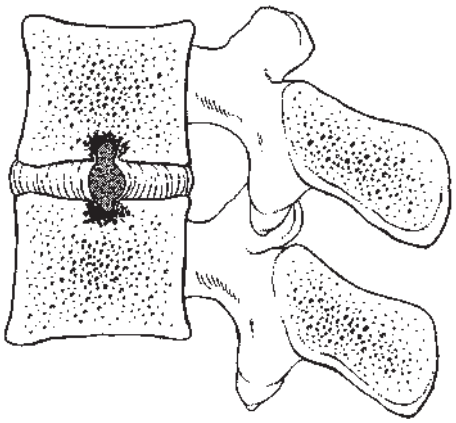

Fig 32.11 • Vertical displacement: Schmorl's nodes.

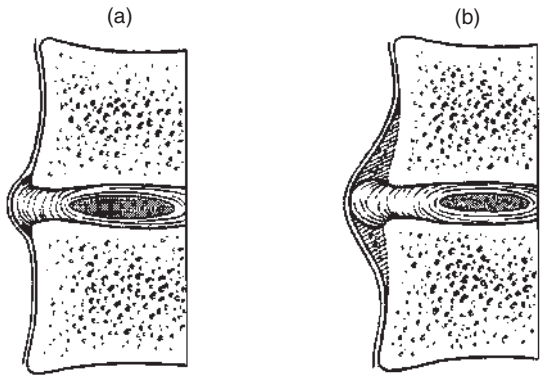

Fig 32.12 • Traction spur (a) and spondylitic spur (b).

longitudinal ligament and the periosteum from the vertebral margin. Osseous reaction takes place, provoking the formation of new bone in a beak-like protuberance.[74] This process can be viewed as if the vertebral body were trying to expand its articular surface area. By distributing axial loads over a wider area, the vertebral body lessens the stress applied to the annulus fibrosus and the spinal column becomes more stabilized.[75]

Effects on the facet joints

The disc and facet joints form a 'three-joint complex'. Degenerative changes affecting the disc are followed by increasing changes in the posterior joints. Arthrosis of a facet joint is thus always secondary to changes in mechanical load, induced by disc degeneration.[76,77] Like disc degeneration, facet arthrosis is a universal finding in the human lumbar spine. Evidence of arthrosis begins early, with more than one-half of adults younger than 30 years demonstrating arthritic changes in the facets. The most common arthritic level appears to be L4–L5.[78]

Initially, alterations in the height and volume of the disc result in positional changes of the facet joints. Axial compression on a degenerated and narrowed disc causes subluxation of the posterior joints: they move telescopically in relation to each other and slide past the normal range of movement, sometimes to such a degree that the tip of the inferior articular facet impinges on the adjacent lamina.[79]

A height reduction in the functional unit results in changes in the orientation of capsular fibres: they become stretched during axial loading, which gives the capsule a load-bearing function in the upright position.[80] The apophyseal joints resist about 16% of the intervertebral compressive forces in the erect standing posture if the disc is thinned.[81]

Another consequence of disc degeneration is that flexion–extension movement in the functional unit becomes disturbed. In a normal disc with adequate turgor, the instantaneous axis of rotation remains more or less in the region of the nucleus. In full flexion, it moves immediately anterior to the nucleus and in full extension it lies posterior to it.[82] In a normal joint, the vertebral bodies thus rock over the nucleus and the facet joints serve only to guide the movement. When disc degeneration is present, the axis of movement becomes irregular and completely unpredictable: sliding and anteroposterior

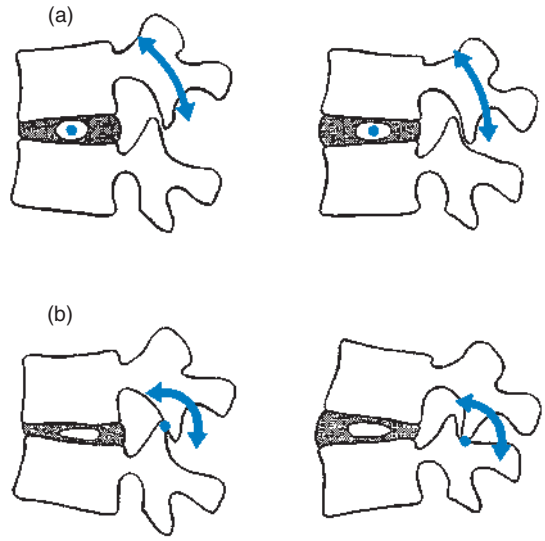

Fig 32.13 • In a normal functional unit the vertebral bodies roll over the nucleus and the facet joints only guide the movement (a). When disc degeneration is present, the facet joints are subject to rocking movements, resulting in compression and distraction (b).

movements, or tilting of the upper vertebra during flexion, become possible. Alternatively, the axis of rotation remains constant in position through or behind the posterior joints.[83] Then the facet joints not only guide and steady motion but are also subjected to a rocking movement, which results in compression of the articular surfaces and distraction of the capsule (Fig. 32.13).

These abnormal stresses cause laxity of the facet joints and the posterior ligaments. Together with the increasing laxity of the disc, the final result is instability of the functional unit, which in turn favours the development of internal derangement at the intervertebral disc.[84] This instability of the three-joint complex most commonly appears during a particular period in the cycle of degeneration, which normally falls between the third and fifth decades, when backache is most likely to occur.[50]

At the facet joints, the repeated pressure results in erosion and thinning of the cartilage. Where cartilage is lost, fibro-fatty intra-articular inclusions may increase in size to fill the space vacated by the cartilage.[85] Other regions may exhibit swelling, with subsequent formation of subperiosteal osteophytes and periarticular fibrosis.[86] Osteoarthrotic changes in the apophyseal joints finally result in gross enlargements of both inferior and superior facets, giving them a bulbous aspect. All these degenerative changes cause a substantial decrease in motion of the facet joints and, together with the stabilizing changes in the disc, they provide, at the end of the degeneration cycle, the ultimate stabilization of the functional unit.

Effects on the spinal canal and intervertebral foramen

Because of the change in pressure and volume of the lumbar disc, the position of the intervertebral joints changes so that

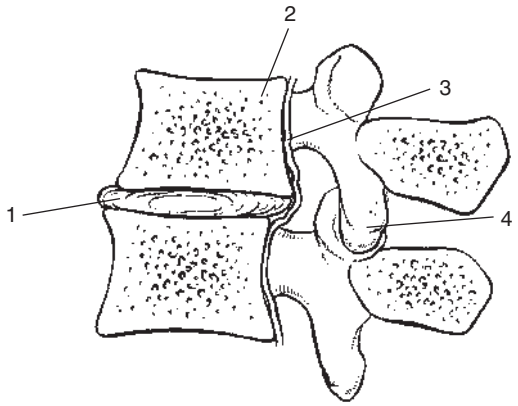

Fig 32.14 • Effects on the spinal canal and the lateral recess. 1, The vertebral bodies approach; 2, owing to the inclination of the joint surfaces, the upper vertebra is displaced backwards and produces a retrospondylolisthesis; 3, the posterior longitudinal ligament buckles; 4, the facet joints become hypertrophied and develop a bulbous aspect.

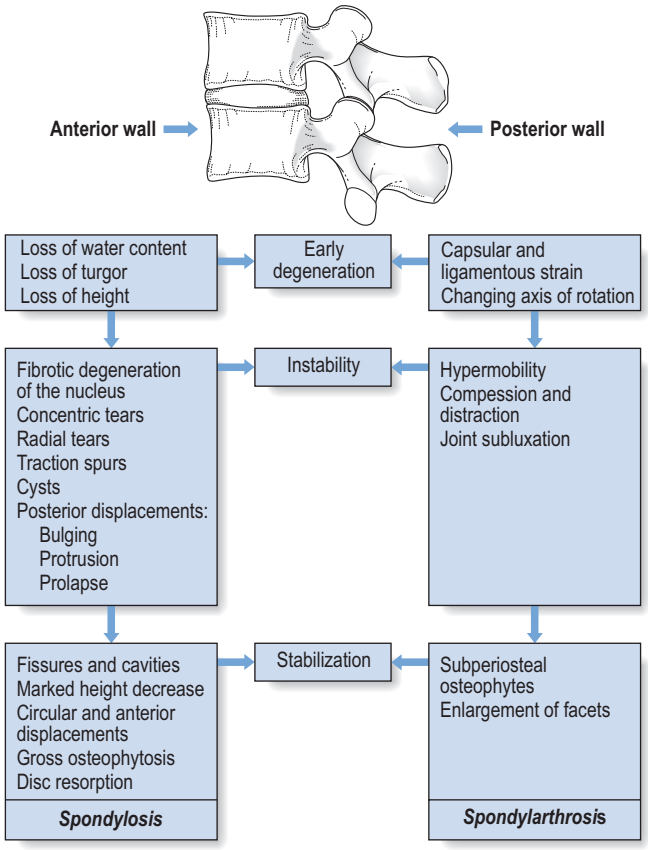

Fig 32.15 • Natural history of degeneration of the lumbar spine.

the articular processes override each other. As the vertebral bodies approach each other and because of the inclination of the joint surfaces, the upper vertebra moves backwards (retrospondylolisthesis) to the intervertebral foramen (Fig. 32.14). With increasing approximation of the vertebrae, both the ligamentum flavum and the posterior longitudinal ligament may buckle, so further narrowing the lumbar canal.[87] Further, hypertrophied and bulbous arthrotic apophyseal joints commonly project into the intervertebral foramina, where they may add to compression on the dural sac and nerve roots.[76]

The natural history of degeneration of the lumbar spine is summarized in Figure 32.15.

Radiological changes

The direct radiological signs of disc degeneration include disc space narrowing, gas within the disc space, vertebral sclerosis and osteophytes. Radiological signs of apophyseal joint degeneration are the same as seen in other degenerative joint diseases elsewhere in the body (joint space narrowing, sclerosis, osteophytosis and subluxation).

An ageing disc loses height because of a loss of water and altered biomechanics. Consequently, narrowing of the intervertebral disc space is the first radiographic sign of lumbar degeneration.

The presence of air pockets, located in discrete cavities within the nucleus, is evidence of long-standing disc degeneration.[88] The mechanism by which the gas is produced has been ascribed to a vacuum phenomenon.[89,90]

Alterations of adjacent vertebral bodies frequently accompany disc degeneration. Increased and poorly demarcated bone density of the adjoining vertebral endplates is clearly visible on plain radiographs and is often referred to as 'discitis'.

Two types of osteophyte are commonly seen. *Traction spurs*, which project horizontally from the corner of the vertebral body, are located about 5 mm from the vertebral margin (see Fig. 32.12a). They are believed to be caused by degenerative disc disease, allowing abnormal motion between the vertebrae. Traction spurs are therefore thought to be associated with segmental instability. *Claw osteophytes* are larger and arise from the margin of the vertebral body. These bone formations are thought to be a response to increased mechanical loading which arises in deficient discs (see p. 443).

The radiological signs of degeneration in the apophyseal joints include joint space narrowing, sclerosis of the subchondral bone and osteophyte formation. Increasing narrowing of the intervertebral space also provokes some subluxation of the zygapophyseal joints. On a lateral view, the tip of the superior articular facet is then seen to extend more than a few millimetres beyond the posteroinferior border of the vertebral body above.[91] Further damage to the posterior joints results in retrolisthesis. Oblique projections of the lumbar spine can detect more malalignment of the articular surfaces and the onset of arthrotic deformity.

The end result of disc degeneration is radiologically characterized by an almost complete loss of disc, which is now represented only by a thin intervertebral space between the dense and sclerotic vertebral endplates.[92] Gross beak-like osteophytes are seen at the anterior aspect of the vertebrae. The intervertebral foramen is narrowed, the facet joints are subluxated and enlarged, and retrolisthesis may be visible (Table 32.2).

Table 32.2 Radiological changes in apophyseal and intervertebral joints

	Apophyseal joint	Intervertebral joint
Early changes	Joint space narrowing Beginning subluxation	Intervertebral disc space narrowing Traction spurs Beginning endplate sclerosis
Late changes	Joint space narrowing Subchondral sclerosis Osteophyte formation Enlargement of articular facets Joint subluxation	Considerable disc space narrowing Air pockets (vacuum phenomenon) Endplate sclerosis Claw osteophytes Retrolisthesis

Relationship between degeneration and symptoms

Although disc degeneration and its radiographic appearances progressively increase with age, it cannot be too strongly emphasized that low back pain and disability do not. It is well known that backache peaks in the middle working years of life (40 years),[93–96] which establishes that disc degeneration as such does not produce symptoms *per se*. It is therefore unwise to rely on radiographic appearances for the diagnosis of lumbar disorders. It has been shown repeatedly in controlled studies that there is absolutely no relationship between clinical symptoms and the radiographic changes of degeneration.[97–104] To take but one example, a prospective study on 536 patients by Sanders *et al* compared the radiological findings in patients with backache and disablement (n = 270) with those in an asymptomatic control group (n = 266): there was not the slightest radiographic difference between the two. Their conclusion was that radiography afforded little or no help in the diagnosis of mechanical lumbar disorders[105] and remains a very poor method to indicate past, present or future low back pain.[106]

In contrast, the practitioner must constantly be aware of the problems that can be induced by the interpretation that the clinician, the radiologist or the patient places on a radiograph. The results of radiographic examinations should never be given to the patient *as a diagnosis*. Since there is no evidence of a correlation between the radiographic appearances and the actual complaints, it is vital to be extremely careful in discussing the results of radiology with the patient. Telling the patient that the back shows 'a marked degree of arthrosis' may mean incurability to the patient, and may conjure up a picture of a hopelessly crumbling spine. The radiograph, instead of helping the patient, will increase the disability. Many patients become depressed when they hear that the back is 'worn out'.

Symptoms are produced by a more complex pathway than simple and uncomplicated arthrosis. Making a specific diagnosis and designing a specific treatment are only possible if symptoms and signs are meticulously assessed. The interpretation of the data obtained is based on knowledge of the mechanical behaviour of the tissues involved and the mechanism of pain production. In this way, it is possible to classify activity-related spinal disorders under three major concepts: the dural, the ligamentous and the stenotic (Chs 33–35). These three appear in a specific age group, have a certain correlation with the natural ageing of the lumbar spine and are clinically distinct. Classification of a particular patient's backache into one of these types thus depends on the information obtained from the history and clinical examination, and not on interpretation of radiographs.

Clinical evidence for sensibility of the dura mater 447
The mechanism of dural pain is dual 448
The dural concept in the natural history of the ageing disc 449
Clinical syndromes 450
Lumbago 450
Backache 454
Sciatica 459

Hypothesis

The dural concept was first defined by James Cyriax in 1945.[1] His hypothesis was that lumbago and backache originate when a subluxated fragment of disc tissue impinges on the sensitive dura mater. This concept – lumbar pain may be of dural origin – is based on two premises:

- Disc degeneration and disc displacements are of themselves painless events.
- The dura mater is sensitive and translates deformations of the posterior border of the disc into pain.

Clinical evidence for insensibility of the disc

The most important evidence for the first premise (insensibility of the disc) is the poor correlation between obvious disc lesions and lumbar pain:

- Data obtained from postmortem studies show the existence of large, symptomless disc protrusions in almost 40% of the cadavers.[2]
- Several controlled studies have failed to show a relationship between radiological changes seen in disc degeneration and the existence of clinical syndromes.[3–5]
- Myelograms in asymptomatic patients show defects in 37% of cases,[6] and the incidence of asymptomatic disc herniations demonstrated by computed tomography (CT) in subjects over 40 years of age is more than 50%.[7]
- Recent magnetic resonance imaging (MRI) studies[8–11] have demonstrated anew the high incidence of disc degeneration and displacement in an asymptomatic group of patients.

These observations permit the conclusion that degenerated or displaced disc tissue is not itself the source of lumbar pain, which only appears when other, more sensitive structures are involved.

Clinical evidence for sensibility of the dura mater

The second premise was deduced from clinical observations on the natural course of backache and sciatica.

One of the most striking clinical features to support the pain-mediating role of the dura is the chronological evolution from backache to sciatica. Almost every instance of sciatica starts with a period of central or unilateral backache, but once leg pain supervenes, the backache usually disappears. Since the work by Mixter and Barr,[12] it has been widely accepted that most radicular pain is caused by a disc protrusion compressing the dural investment around the nerve root and, if this is so, it is logical to argue that the earlier backache was brought about by the same disc lesion. If sciatica is referred pain from the dural sleeve, by analogy the prior backache must have originated from the dura mater. Sciatic pain is thus only the final

© Copyright 2013 Elsevier, Ltd. All rights reserved.

stage of a progression. A small posterior protrusion, bulging out of the intervertebral joint, lifts the posterior longitudinal ligament, touches the dura mater and causes backache. Kept under control by the posterior ligament, the bulge can recede, resulting in spontaneous recovery, or stay unaltered, causing chronic backache. If it increases, however, the counterpressure exerted by the stretched posterior longitudinal ligament pushes it laterally. No longer subject to any resistance, it immediately swells and compresses the nerve root. At the same time, pressure against the dural tube is released and backache ceases (see p. 459).

Another proof of the role of the dura in lumbar pain syndromes is the effect of diagnostic local anaesthesia. A weak solution of procaine, induced via the sacral hiatus into the epidural space, and thus forced between the dural tube and the boundaries of the neural canal, causes contact anaesthesia of the dura mater (see p. 556). Because procaine 0.5% is too weak to penetrate the ligaments or the dural membrane, it acts as a surface anaesthetic, thus only desensitizing the structures with which it comes into contact. If the patient had backache before the injection, and anaesthesia affords temporary relief of symptoms and signs, the dura is most likely to be the source of pain. In all cases of acute lumbago and in most cases of acute or recurrent backache, epidural local anaesthesia immediately abates the pain, thus strongly suggesting a dural origin.

During the last few decades, numerous neuroanatomical studies have shown that the ventral half of the dura mater is supplied by small branches of the sinuvertebral nerve.[13,14] Immunohistochemical studies further demonstrate a significant number of free nerve endings in the dura that contain substance P, calcitonin gene-related peptides and other neurotransmitters contributing to nociception.[15,16]

The mechanism of dural pain is dual

The original concept was quite simple: a subluxated (but of itself painless) component of the disc impinges on the dura or the dural sleeves of the nerve roots. These pain-sensitive structures translate the anatomical changes into back pain or root pain, respectively (Fig. 33.1).

However, recent anatomical and biochemical studies have slightly changed this original concept:

- *The outer border of the disc is innervated*. Although earlier anatomical studies demonstrated the disc to be totally deprived of innervation,[17] more recent research could detect sparse nerve fibres and free nerve endings in the three outer lamellae of the annulus fibrosus,[18–20] penetrating to a maximum depth of 0.9 mm into the annulus. This means that, except at the surface, a normal intervertebral disc remains almost without innervation.
- *Dura mater attachments exist between the anterior part of the dura and the posterior longitudinal ligament* (Fig. 33.2). Recent anatomical and MRI studies have demonstrated that the dura mater is not totally disconnected from the vertebral column but also attached to the posterior longitudinal ligament by connective tissue, consisting of ventral and lateral fibrous bands.[21–24] Although these ligaments are sufficient to allow for

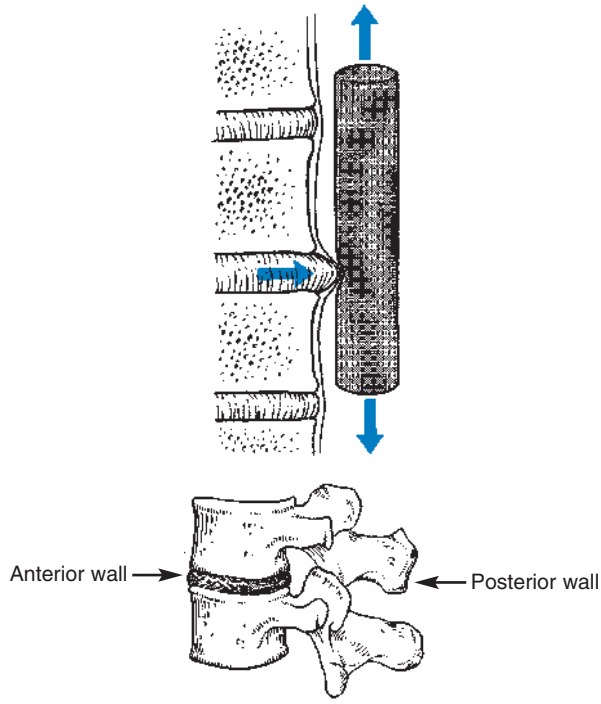

Fig 33.1 • Interaction between displaced disc tissue and the dura mater.

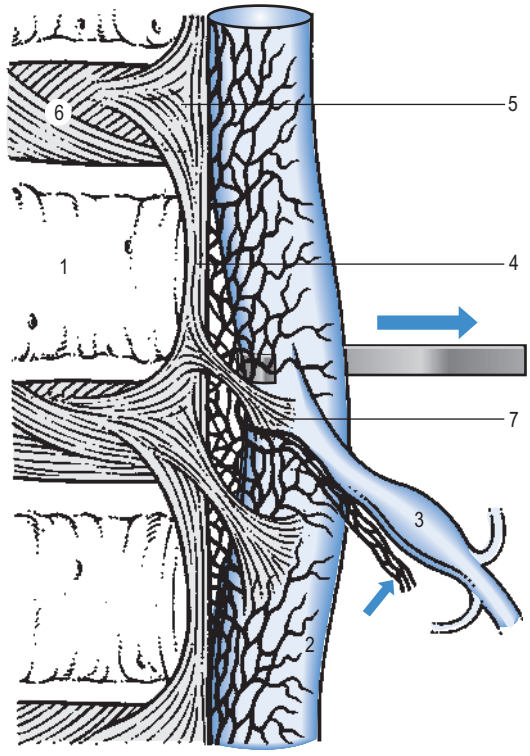

Fig 33.2 • Dura mater attachments: 1, vertebra; 2, dura mater; 3, nerve root; 4, posterior longitudinal ligament; 5, lateral expansion of posterior longitudinal ligament; 6, intervertebral disc; 7, dural ligaments. Small arrow: sinuvertebral nerve, anterior to the nerve root (3).

displacement of the dural sac during movement, they could act to place traction on the dural sac in the event of nuclear bulge or herniation.[25]

- Pain is not only mechanical: inflammatory mechanisms are also involved. Apart from being stimulated mechanically, nociceptors in dura mater may also be activated chemically. An increasing number of experimental studies suggest that disc lesions and/or displacements may induce sufficient chemical changes to irritate the dura mater and to elicit dural pain.[26–31]

Although these new anatomical and histochemical developments have improved understanding of the discodural relation, the original (Cyriax) concept has not changed. From a clinical point of view, the mechanism of discodural interactions is still that of a conflict between an inert and mostly painless structure (nucleus and inner part of the annulus) and a pain-sensitive duroligamentous complex (outermost rim of annulus, posterior longitudinal ligament, dura mater and dural ligaments), all innervated by the sinuvertebral nerves. Discodural pain therefore has a multisegmental behaviour with a broad reference that involves multiple dermatomes and crosses the midline. The interaction is not just a mechanical impingement of discal tissue on the dura mater but also involves inflammatory reactions of the pain-sensitive tissue.

This hypothesis has important clinical consequences. Because the mechanism is dual, the symptoms and the physical signs are also dual. Therefore both 'discal' (articular) signs and symptoms and 'dural' signs and symptoms should be looked for during history taking and functional examination.

- Articular signs and symptoms are those that are related to the mechanical behaviour of the disc: certain postures and movements create biomechanical changes, which force the protrusion against the dura mater.
- Dural signs and symptoms are those that are related to the increase of dural irritation: traction exerted from a distance (straight leg raising and neck flexion) pulls on the inflamed dura or, via the dural ligaments, on the posterior longitudinal ligament or outer annular rim. Also, a sudden increase in spinal fluid pressure pushes the dura against the protrusion (painful coughing and sneezing).

The duality is also important in drawing up a therapeutic strategy. The first measure is to attempt to alleviate the pain by removing the subluxated disc from contact with the dura, which can be achieved by manipulation or traction. If this fails, attempts can be made to desensitize the dura by epidural local anaesthesia.

The dural concept in the natural history of the ageing disc

One of the factors involved in the dural concept is a subluxated portion of the disc and so the biomechanical conditions to allow such a displacement must be present. First, there must be some degeneration of the disc, leading to weakness of the annular fibres and to radiating fissures. These changes are present very early in the degeneration cycle and, for a number of biomechanical and biochemical reasons, occur most frequently at the rear side of the disc. Second, repeated wear and tear, together with shearing forces and slight decrease of disc height, creates some ligamentous laxity which results in an instability of the whole 'motion segment'. Third, through enzymatic depolymerization of macromolecules in the disc, the oncotic pressure temporarily rises.[32] This means that during a particular period of life (between the ages of 20 and 50 years), the osmotic pressure within the nucleus pulposus increases.

Raised intradiscal pressure together with increased segmental laxity is the perfect foundation for disc displacement. A kyphosis imposed on such a predisposed intervertebral joint not only increases the intradiscal pressure but also tends to shift disc material backwards in the direction of the convexity.[33] The intensity of the contact between disc and dura determines whether lumbago or backache will result. When the protrusion is more posterolateral, the dural investment and the content of the nerve root, rather than the dural tube, are compressed, with the symptomatic outcome of root pain.

Further degeneration of the disc results in its 'deflation' and a decline of intradiscal pressure. Decrease in disc height leads to reactive changes at the intervertebral joint and at the posterior structures, which stiffen and stabilize the segment and so diminish the tendency for disc displacements during the later stages of ageing of the spine (Fig. 33.3).

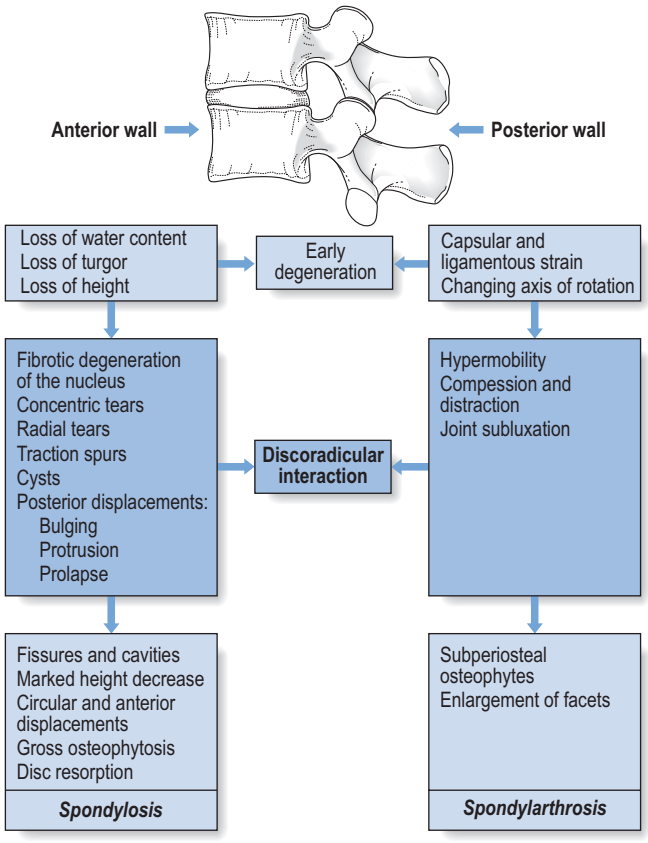

Fig 33.3 • Position of discodural interactions in the degeneration of the lumbar spine.

Conclusion: acute lumbar clinical syndromes of dural origin occur during a specific period of life. This has been established by epidemiological studies, which place the peak incidence between the ages of 30 and 60 years.[34,35]

Clinical syndromes

Lumbago

The most striking example of a discodural interaction is acute lumbago – a sudden attack of severe and incapacitating backache, with obvious limitation of movement, together with gross dural signs and symptoms, summarized in Box 33.1.

History

The history is typical and depends largely on the composition of the protruded disc tissue: annular, nuclear or combined.

Annular lumbago

The patient states that, during some trivial activity, a sudden 'snap' was felt and agonizing pain in the back immediately followed. Very often, this acute event has occurred during a simple movement: coming up after bending, rising from a chair or picking up a light object. Initially, the pain is central and spreads bilaterally over the lower lumbar area and the buttocks. Later, it often tends to radiate more and more unilaterally. Although centralized in the lumbar and/or gluteal area, it spreads to the groin and abdomen, downwards to one or both legs as far as the ankles, or upwards in the trunk as far as the inferior aspect of the scapulae (Fig. 33.4).

Box 33.1

Summary of lumbago

Definition	a sudden attack of severe and incapacitating backache, caused by a large posterior shift of disc material, with dural contact	
Acute onset	Annular	
Slow onset	Nuclear	
	Articular	**Dural**
Symptoms	Twinges Pain on sitting/bending	Extrasegmental pain Pain on coughing/sneezing
Signs	Deviation: forwards sideways Gross partial articular pattern	Pain on neck flexion Limited straight leg raising
Treatment	Manipulation Mobilizations Relative rest	Epidural injections

Differential diagnosis from radicular pain must be made if the ache spreads to one leg only. In such a 'pseudoradicular' dural pain, the distribution is vague, covers several dermatomes and never spreads into the feet. The lumbar or gluteal component also remains more pronounced than the vague and poorly localized referred pain in the limb.

A typical statement in acute lumbago is that the pain is aggravated by sitting and bending forwards, the latter even being impossible. Also, changing from sitting to standing or raising the trunk after lying down for some time is extremely painful and often takes considerable time. The most characteristic sensations in acute lumbago are sharp *twinges*. For fear of these, lumbar movements are executed very cautiously and in 'slow motion'.

The spine is held in the position of least pain by reflex spasm of the trunk muscles and every attempt to straighten the back is associated with severe twinges; the patient walks with the trunk largely immobile, leaning forwards or sideways, keeping the hips and knees slightly bent. Coughing and sneezing are extremely painful and some patients find that even taking a deep breath increases their pain.

Usually, the patient retires to bed, which is probably the only place where a greater or lesser degree of freedom from pain can be assured. Characteristically the 'psoas position' is adopted: supine, with hips and knees flexed to 90°. The pain eases gradually and in most cases all symptoms have gone after a few days or weeks.

An attack of acute annular lumbago is caused by posterior subluxation of part of the annular rim, pressing the posterior longitudinal ligament against the dura mater (Fig. 33.5a). It is obvious that a history of sudden pain, immediately followed by a 'locking' in flexion, indicates some internal derangement,

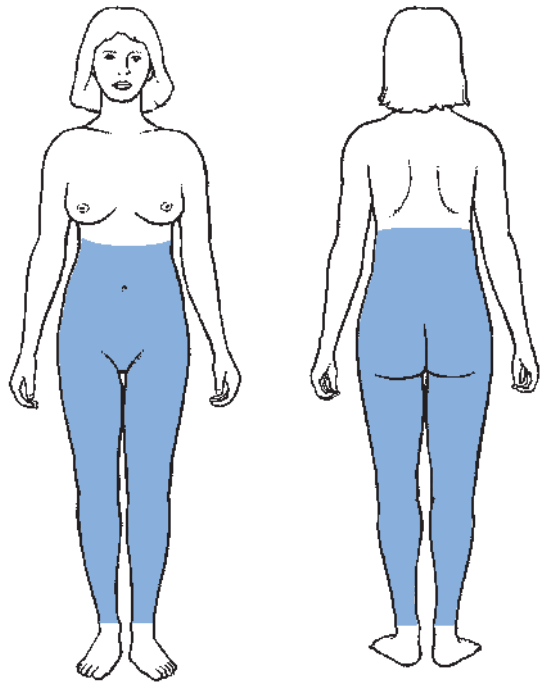

Fig 33.4 • Possible reference of dural pain caused by an L5 protrusion.

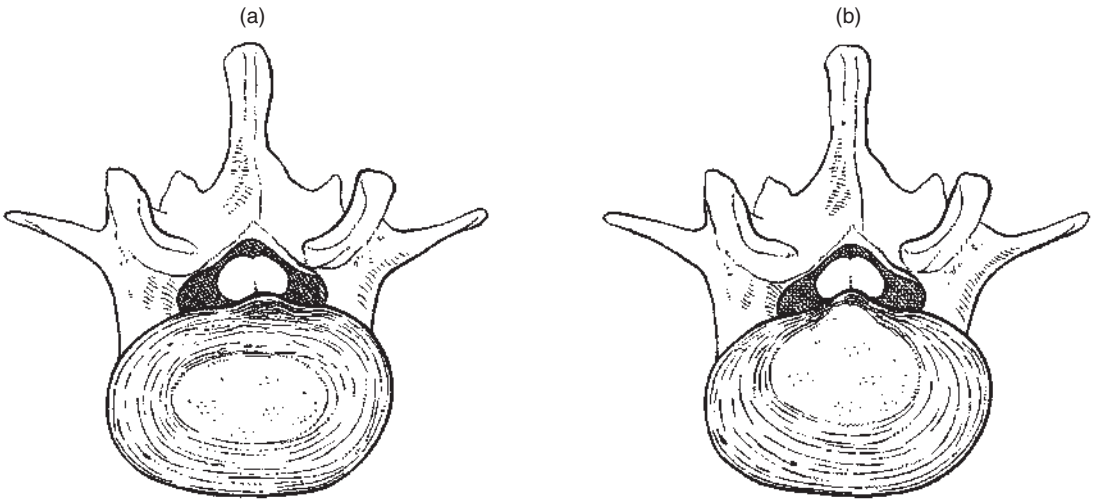

Fig 33.5 • (a) Annular and (b) nuclear lumbago.

just as a sudden pain in the knee, followed by inability to straighten it, indicates subluxation of a meniscus. The dural extrasegmental reference of the pain, together with pain on coughing and sneezing, implicates the dura mater and therefore excludes locking of the posterior facet joints. In displacement at the back of the intervertebral joint, the lumbar spine is held in flexion because extension squeezes the protrusion, which in turn increases the painful pressure on the dura. In order to keep the protrusion away from the dura and as immobile as possible, the patient adopts a flexed position. Muscle spasm prevents any further movement at the lumbar spine.

Nuclear lumbago

The pain, although equally incapacitating, does not appear suddenly but gradually increases over the course of a number of hours or days. Alternatively, after heavy work involving much stooping and lifting or sitting for an unusual length of time in an uncomfortable position, slight backache is felt but is initially regarded as trivial. However, by the next morning the backache is sufficiently severe to make getting out of bed impossible. The pain radiates in a way that is typical of dural involvement (see Fig. 33.4). The patient is immobilized in flexion or side flexion and every attempt to straighten the back is followed by an agonizing twinge in the lumbar area and the buttocks. Sometimes even simple neck flexion is impossible or coughing or sneezing creates a twinge. As in an attack of annular lumbago, the patient has to go to bed to cope with the pain. As a rule the pain eases after a few days or weeks.

In gradually increasing lumbago, the protrusion presumably consists of soft and pulpy nuclear material, oozing slowly backwards. This typically happens during the maintenance of a kyphotic posture (sitting, bending or lifting). The displaced nuclear material gradually presses more and more against the outermost layers of the annulus and the posterior longitudinal ligament and makes them protrude (Fig. 33.5b). This provokes dural irritation, resulting in the typical dural pain in lumbar area, buttocks and limbs.

Mixed lumbago

Sometimes there is a sudden attack of acute low back pain, increasing slowly during the subsequent few hours or days. This indicates that the protrusion is probably mixed, consisting of an annular crack, with some pulpy material oozing backwards between its edges.

The distinction between an annular and a nuclear protrusion is extremely important, for both treatment and prophylaxis. A hard fragment reacts very well to manipulation, whereas a soft protrusion is more difficult to reduce. In the maintenance of reduction and in prophylaxis, a patient with a history of recurrent annular protrusions has to be constantly on guard during specific movements (bending and lifting) but a nuclear protrusion only reappears after prolonged loading of a joint in flexion.

Clinical examination

During clinical examination the following are important.

Inspection

Deviation towards flexion is noted and the sacrospinalis muscles are seen and felt to be in contraction to maintain the adaptive posture. Because the flexed position places the upper trunk in front of the centre of gravity, the muscles contract to prevent further forward toppling. Lumbago is not caused by muscle spasm – as was maintained by some authorities for many years[36] – but is the result of a disorder at the posterior aspect of the intervertebral joint.

A lateral shift associated with acute lumbago is a common clinical event, undoubtedly associated with a disc protrusion.[37] The lateral shift can be either towards the dominant side of pain (ipsilateral) or away from the side of the pain (contralateral). The majority of affected patients have a contralateral shift.[38] Occasionally, the shift may change from side to side, which has been termed an alternating scoliosis. The lateral shift is explained as avoidance of compression or irritation of

the dura mater, either actively or reflexively through muscle spasm.[39,40]

When gross lateral deviation is present, a lesion at the fourth or third lumbar level should be suspected. Because of the stabilizing effect of the iliolumbar ligaments, fifth lumbar protrusions very seldom result in gross lateral deviation.

Alternating deviation is pathognomonic for central protrusions at the fourth lumbar level. At a given moment, the patient is deviated to the left but, after performing some lumbar movement, deviates to the right. This curious phenomenon is explained by the dura slipping to one or other side of a midline protrusion.

Spinal movements

There is gross but unequal degree of limitation in the four directions (the partial articular pattern), which indicates that one part of the joint is more affected than the others.

Extension

As a rule, extension is considerably limited (Fig. 33.6) on account of the posterior displacement of the disc causing a block at the back of the joint.

Side flexion

In one direction, side flexion is considerably more limited than in the other and is usually associated with visible lateral deviation on inspection. If side flexion towards the pain is more limited, manipulation seems to be less effective but, if pain is felt more on the side away from which the patient bends, manipulative reduction usually succeeds.

Alternatively, there is a gross painful arc when the trunk passes the vertical, on swinging from one side to the other. Both side flexions are then painless at the end of range. This phenomenon indicates a central bulge at the fourth lumbar level and corresponds with the alternating deviation seen on inspection.

Flexion

This is extremely painful in cases of acute lumbago and is usually the last movement to free up after a manipulative session.

Sometimes deviation becomes visible during flexion, despite its absence in the standing position, or an evident lateral tilt in the upright position disappears during flexion.

Dural tests

Neck flexion

In lumbago, neck flexion often hurts in the lower back, which proves the involvement of the dura mater in the origin of the pain[41] (see p. 502).

Straight leg raising (SLR)

We have discussed the evidence that SLR is a dural sign (see p. 427) and, just as neck flexion stretches the dura from above, so SLR stretches it from below. A lesion resulting in such a gross discodural interaction as acute lumbago, therefore, *must* influence SLR. Acute lumbago with full and painless SLR should make the clinician reluctant to accept the diagnosis of a displaced disc. If the acute pain in the back is so severe that the patient cannot move out of bed, but dural symptoms and signs – including a positive SLR – are absent, gross bony lesions such as osteomyelitis or metastases should be considered (see Ch. 39).

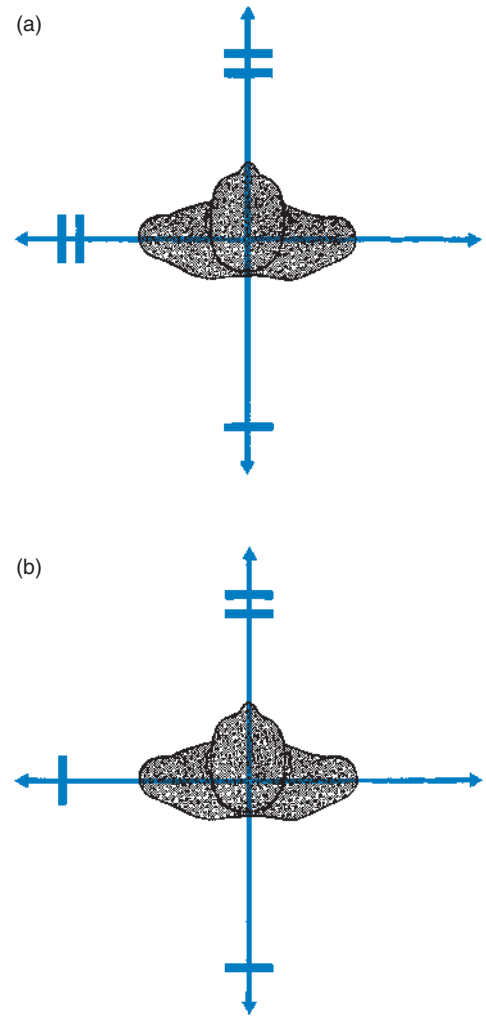

Fig 33.6 • Two examples of gross partial articular patterns. (a) Gross limitation of flexion and left side flexion, slight limitation of extension, normal right side flexion. (b) Gross limitation of flexion, slight limitation of extension and left side flexion.

Lumbago usually causes bilateral limitation of SLR: because the bulge and the dura mater both lie centrally, raising both legs pulls on the dura equally. In unilateral lumbago there will often be more limitation of SLR on the painful side. Occasionally this may be reversed, when the crossed SLR phenomenon is present (see p. 498).

The degree of limitation of SLR is an indication of the intensity of the discodural interaction.[42] In hyperacute lumbago, any attempt to move the straight leg upwards results in considerable pain, whereas in more moderate lumbago the SLR is limited at 45–60°. During recovery, when the reduction is almost complete, SLR will probably only be painful at the end of range or show a painful arc at mid-range. The progress of SLR is therefore a very sensitive clinical index in following the position of the protrusion during manipulation.

Tests of conduction

Neither muscle weakness nor cutaneous analgesia is present in cases of acute lumbago. Because protrusion is more or less central, nerve roots are not involved. Care should be taken, however, not to miss a compression of the fourth sacral root. Because it lies centrally, partly protected by the posterior longitudinal ligament, a central protrusion can endanger it, especially if the protrusion overstretches the ligament. Physical findings are non-existent and the diagnosis is made entirely on the history. If pain deep in the sacral area, pain and paraesthesia in the penis, vagina or rectum, numbness in the saddle area or problems with continence are mentioned, damage to the fourth sacral root should be considered and the patient immediately referred for further assessment.[43] A fourth sacral lesion occurs at a level proximal to the posterior ganglion and permanent interference with bladder function can result if decompression is not carried out.[44] Therefore its onset, however slight, is an indication for laminectomy. Cyriax[45] (his p. 284) recommends operation even when bladder function is returning after the attack of lumbago, because there is no guarantee that lasting incontinence may not follow the next attack.

Natural history

With, without or despite treatment, most cases of acute lumbago recover spontaneously and completely within 2–6 weeks (Dixon[46]; Chöler, cited by Nachemson[47]; Spitzer[48]). The tension in the posterior longitudinal ligament exerts counter-pressure on the bulge, which moves gradually anteriorly, until compression of the dura mater ceases and symptoms disappear. However, as cartilage has little tendency to reunite, a fragment that has moved backwards once will sooner or later move again, which implies that, although complete recovery after an attack of acute lumbago is the rule, recurrences are to be anticipated.[49]

Sometimes, however, a disc protrusion will not recede completely and chronic backache results. Although the patient largely recovers and most of the symptoms disappear, a continuous lumbar ache remains, especially during or after particular movements or in particular positions.

Alternatively, the lumbago disappears but there is simultaneous onset of root pain. As has already been discussed (see p. 442), the protrusion has moved from the centre to one side.

Treatment

Most cases of acute lumbago recover without treatment. MacNab put it well when he remarked that 'The physician must constantly remind himself that even if he elected to treat the patient by rubbing peanut butter on each buttock, in the balance of probabilities, the patient would get well fairly quickly.'[50] However, keeping the intradiscal pressure as low as possible will, of course, ease symptoms and hasten the reduction of the bulge. It is therefore wise to adopt the supine lying position from time to time, with the knees and the hips flexed to a right angle[51]; this decreases the load on the disc to about 30 kPa[52] (the 'psoas position'; Fig. 33.7). It is also sensible to avoid movements and positions that cause high intradiscal pressures, such as sitting or bending (Nachemson[53]: p. 708).

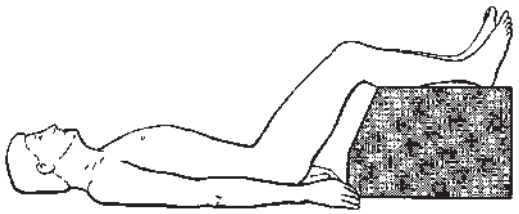

Fig 33.7 • The 'psoas position'.

Standard textbooks almost unanimously recommend bed rest as the first line of treatment for acute lumbago.[54,55] However, it has never been proven that complete and continuous bed rest decreases the time of recovery. In a comparative trial, statistically significant differences between bed rest, early mobilization and no treatment have not been found, although results tended to favour early mobilization.[56] Others have reported little difference between mobilization and rest,[57] and 2 days in bed was found to be even better than 7 days; put the other way around, 7 days in bed was more harmful than 2 days.[58,59] Also, a recent Cochrane review concluded that there is no difference in effect between advice to stay in bed and advice to stay active.[60] Therefore bed rest is only necessary if bed is the only place where the patient is comfortable. If, after a couple of days, walking around is possible without a considerable increase in pain, such a regime should be followed. Furthermore, a patient should never be forced to stay in bed against his or her will.

Annular lumbago

If acute lumbago is of the annular type, there is a good chance of early and complete reduction over the course of one or two manipulative sessions; instead of awaiting spontaneous recovery over 2 or more weeks, the patient can return to work from the second or third day.

Nuclear lumbago

In nuclear types of acute lumbago, classic manipulative reduction usually fails. A slow onset of symptoms usually indicates that the protrusion is too soft to be pushed back. Manipulation is also apt to fail in lateral deviation away from the painful side. A good alternative, then, is a sustained manual stretching technique. Positioning the patient in increasing but still comfortable lordosis (McKenzie technique) is another alternative in treating acute nuclear lumbago.[61,62]

Although effective in chronic nuclear backache, where the dural symptoms are much milder, traction should *never* be used in acute nuclear lumbago. Experience shows that, if traction is applied on a patient who mentions the presence of 'twinges', considerable worsening of the condition for several days may be expected. The reason for this is not completely understood. Presumably the size of the bulge increases when the hydrostatic and osmotic conditions within the disc change during traction (see p. 420).

Hyperacute lumbago

If the lumbago is really hyperacute, which means that the dural symptoms are so intense that repeated and agonizing twinges force the patient to lie motionless, any attempt at manipulative reduction is unthinkable. It is obvious that manipulation cannot be done when the patient can hardly move or when it takes some minutes to roll from a prone to supine-lying position on the examination couch. In these cases, the only alternative to several weeks of bed rest is epidural local anaesthesia, which affords immediate and complete relief of symptoms over 1 or 2 hours. Curiously enough, and although the anaesthesia only works for 2 hours, there is lasting relief from the next day on. The injection probably has some long-term effect on the inflamed dura, rendering it less sensitive. Once the immobilizing twinges have been abolished, the patient is capable of getting up and travelling for manipulative reduction of the residual displacement. This combination of epidural local anaesthesia and manipulation is rapidly successful in nearly all cases of hyperacute lumbago.[63]

Backache

About 80% of all cases of low back pain relate directly to the intervertebral discs.[64] Discodural backache presents a typical complex of symptoms and signs, both articular and dural. The mechanism of pain and dysfunction is exactly the same as described in lumbago, but the signs and symptoms are less acute because the discodural interaction is more moderate.

Mechanism

In a predisposed and slightly degenerated disc, a small posterior displacement occurs when the biomechanical factors are favourable: increased load in a flexed spine shifts the disc material backwards (towards the convexity). Contact with the dura mater then creates the pain.

If the displaced disc material is nuclear, the onset of the symptoms will be slow; if it is annular, the pain will appear suddenly. Because, in contrast to lumbago, the protrusion is rather small, the dura will not be stimulated continuously and therefore dural irritation remains moderate; the twinges and gross deviation typical of lumbago are absent. Sometimes dural contact occurs during particular movements of the spine only when an increase in load pushes the bulge in the direction of the dural tube. The protrusion may not be large enough to interfere with the dura when the latter is moved forwards during neck flexion or straight leg raising, and therefore dural signs are not always present. This explains why, in moderate backache, there can be articular signs only, even though the mechanism of pain is that of a discodural interaction.

History

The pain is usually located in the back, unilaterally or centrally, at the sacral region or in one buttock. Because the pain is of dural origin, it can spread to the iliac crest, the trochanteric area and the groin, although seldom beyond the gluteal folds. Occasionally it may be vaguely situated in the posterior or anterior aspect of the thigh.

Depending on which part of the dura is irritated, the pain is central or unilateral or shifts in location.[65] Shifting pain is a common history and indicates that the lesion has moved from one side of the intervertebral joint to the other. Shifting pain in the back is one of the most characteristic phenomena in discodural backache. An alternating ache in the buttock, however, suggests sacroiliac arthritis rather than a disc problem (see Ch. 41).

The localization of pain not only varies according to the site of compression of the dural tube but is also determined by the intensity of the stimulation. One of the rules of referred pain is that the stronger the stimulus, the further the pain will be referred. This has some practical bearings when it comes to evaluation of therapy: when the pain has originally been located in a buttock but, during a manipulative session, tends towards the centre and becomes paravertebral, this implies that the pain stimulus has been reduced and discodural contact is now less pronounced than it was. 'Centralization' of the pain is thus a good predictor of a successful outcome.[66,67] The reverse change – pain moving more and more distally – indicates that the situation has worsened.

The onset of the complaints is very important from a clinical point of view but cannot always be recalled. Especially in long-standing cases, the patient may have difficulty in remembering if the symptoms appeared suddenly – as would occur with an annular lesion – or if disability was progressive – a nuclear displacement. In an *annular* protrusion, the patient may describe a sudden sensation of something giving way in the back, which may have been accompanied by an audible click or 'thud' in the lower back, associated with a twinge of pain. From that moment the back has ached during particular positions and movements. The typical history of a *nuclear* protrusion is that the initial symptoms were slight, with little disability, the patient easily being able to continue normal activities, probably with only minor backache. The same evening, however, after sitting down to eat, read or relax, considerably increased discomfort will have been felt and the following day worsening will have become apparent from the moment an attempt was made to get out of bed.

Relation between posture/movement and pain is also important. In minor disc lesions, the ache probably depends entirely on the level of exertion. Any work involving stooping, lifting or sitting for too long is followed by pain, which may, however, be almost or completely absent at rest. In more advanced instances, particular positions are very painful or even impossible. It is obvious that contact will increase in positions and activities that increase intradiscal pressure and thus discodural contact. Bending forwards and lifting result in higher pressure than standing erect. To most patients with backache, walking around is more comfortable than sitting, because the latter imposes more load on the disc.[68] Sitting without support causes yet more load and consequently more pain than does sitting with a reclined back rest.[53]

Pain is influenced not only by position but also by particular movements. It is striking that in backache caused by disc problems one of the most consistent complaints is a temporary

increase in pain when the patient changes position. The aggravation of pain on standing after sitting for some time or the momentary increase in pain on sitting after walking is typical of a discodural interaction. Turning in bed and putting on footwear in the morning is often mentioned as being associated with an increase in pain. Dural symptoms, such as pain on coughing and sneezing, are often present.

A paradoxical symptom complex is sometimes encountered. The dynamics of the disc, described above (see p. 420), suggest that intradiscal pressure should decrease and any bulge become less prominent when the patient lies down. Yet some patients have more pain during and after bed rest, wake during the night and have to get out of bed before dawn. The explanation is probably an increase in swelling when the external load diminishes. Diurnal changes in disc hydration and pressure have been demonstrated both *in vitro*[69] and *in vivo*,[70,71] and it is estimated that around 25% of the disc fluid is expressed and re-absorbed during each diurnal cycle.[72] A small posterior bulge that becomes more hydrated swells to increase dural contact. This phenomenon is also mirrored in the diurnal changes in the range of the SLR; comparison of the range of SLR after recumbency and after 2 hours erect shows an increase in range of 10% or more.[73]

The characteristics of discodural pain are summarized in Box 33.2.

Clinical examination

Inspection

Lateral deviation or flexion deformity is present only in more marked cases of backache. As in lumbago, the lateral tilt may be either away from or towards the painful side. Some protective muscle spasm may be seen or felt.

In mild examples, inspection reveals nothing special; nor does the patient mention any pain in the neutral position.

Spinal movements

A partial articular pattern is present on the four active movements. The degree of limitation is unequal in different directions (Fig. 33.8); if there is no limitation, some movements are painful at their extremes and some not. All these findings are typical of internal derangement – some movements increase the annular or nuclear bulge, so increasing dural contact, while others reduce it.

Box 33.2

Characteristics of pain in discodural conflicts

- Dural reference
- Dural symptoms: on coughing, sneezing and pressing
- Shifting pain
- Pain increases during sitting/bending and when position changes
- (Pain worse in the morning)

Extension

This is painful in the centre of the lumbosacral area and, if the protrusion lies centrally, is also limited. Sometimes the lumbar spine is seen to shift slightly laterally during extension.

Side flexion

Usually this is unequally limited (Fig. 33.8a). Alternatively there is pain at the end of one side flexion only, the other being full-range and painless. If side flexion away from the pain is the more difficult to achieve, manipulative reduction will almost certainly succeed, but in the reverse situation quick and lasting relief by manipulation is more uncertain. Sometimes there is a painful arc (Fig. 33.8d): momentary pain is experienced on moving the trunk from one side to the other. The arc may be quite extensive and is only overcome with considerable effort. Therefore the patient should be encouraged to continue movement and not stop the moment pain is felt; otherwise, the presence of an arc could be missed. Sometimes both side flexions are full and painless. This does not eliminate a disc protrusion but probably indicates that it is too small and too centrally localized to come in contact with the dura during side flexions. Only extension or flexion will then influence the pain and asymmetry is probably only shown by some momentary deviation, a painful arc during flexion or unilateral localization.

Forward bending

As in acute lumbago, forward bending is usually the most painful and limited movement, because it not only acts on the intervertebral joint but also drags the dura forwards in the direction of the protrusion. During flexion the trunk may deviate, although in the upright position it was straight. The reverse may also happen: a lateral tilt in the erect position is lost during flexion. Sometimes the deviation is momentary: the spine shifts away from, then back towards, the midline as the movement proceeds. There may also be an alternating deviation: one way in forward flexion and the other way when the direction of movement is reversed.

Deviations, whether in the upright or flexed position or alternating, are all defensive mechanisms to avoid pain: the dura mater has to be held to one side or the other of the projection. Therefore the clinical finding of deviation, of whatever type, strongly suggests disc protrusion.

It is also possible for flexion to be of full range and only painful at the extreme. Or pain is only provoked when, at the end of range, active neck flexion is added.

Painful arc

Frequently, a painful arc is encountered, with a transient pain somewhere at mid-range (Fig. 33.8c, d). Alternatively, slight deviation may be seen at the midpoint of flexion. Careful observation is needed to detect this visible arc, of which the patient is usually unaware. A painful arc during flexion can be associated with a partial articular pattern but it can also be an isolated finding. It *always* means that a small fragment of disc tissue impinges momentarily against the dura mater. At the beginning of flexion, an increase in both intradiscal pressure and convexity of the posterior aspect of the intervertebral joint provokes discodural contact (Fig. 33.9). Flexion beyond the horizontal imposes more distraction than compression on the

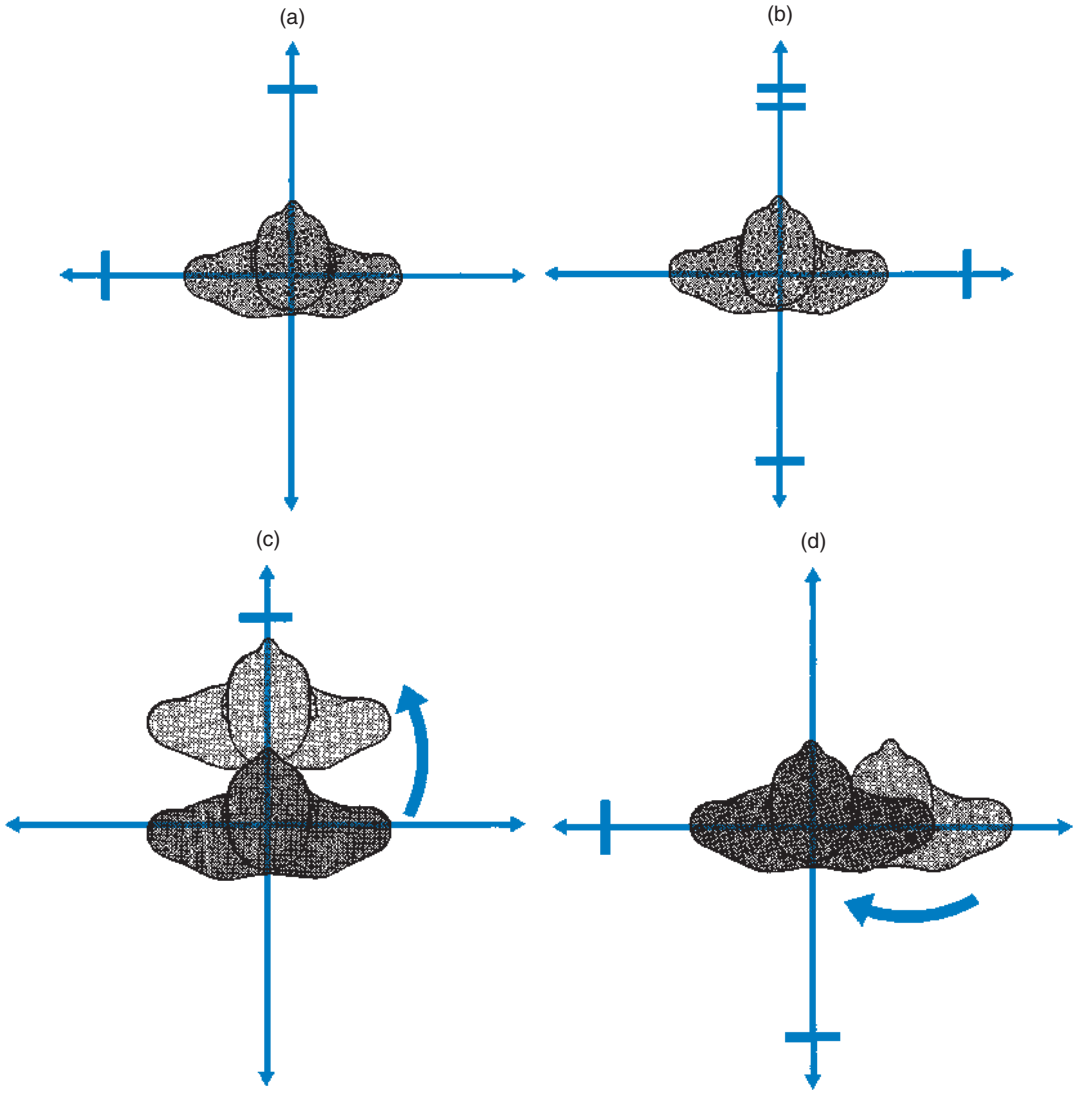

Fig 33.8 • Example of partial articular patterns. The lower figures are associated with a painful arc: (c) during flexion; (d) during side flexion.

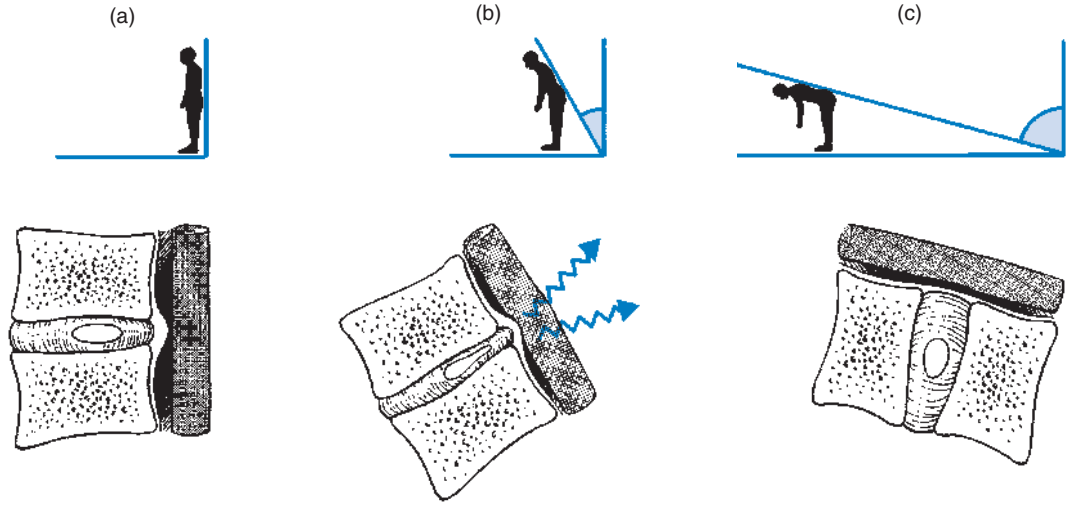

Fig 33.9 • Painful arc: (a) erect position, (b) 30° of flexion, (c) 60° of flexion.

intervertebral joint. The backward pressure on the disc then decreases and is replaced by a more centripetal force on the disc, which is supported by the tightening of the posterior longitudinal ligament. The small posterior displacement is then removed from contact with the dura and pain ceases.

Dural signs

Any hindrance to the normal mobility of the dura leads to a limitation of SLR or to pain during neck flexion. This is the normal finding in acute lumbago. In discodural backache SLR may be painful or limited but, should this not be the case, the disc cannot be automatically eliminated as a cause of symptoms. Especially in mild examples, displacement can be small and the impact of the bulge on the dura not continuous. In a supine-lying position the protrusion may not be large enough to cause interference with dural mobility, and so SLR remains negative. Contact between disc and dura then only originates when a momentary increase of intradiscal pressure moves the disc backwards, which happens during forward flexion while standing. In the course of manipulative treatment it is a common finding that SLR becomes negative before reduction is complete. Lumbar movements, tested while the patient stands, then still provoke pain because, in the erect position, the joint is subjected to axial pressure, which causes increased posterior bulging of the disc.

Root signs

In uncomplicated backache there are no root signs.

Natural history of discodural backache

It is extremely difficult to predict the natural history and therefore unwise to tell the patient that backache will very soon abate. Although it is true that most episodes are self-limiting,[74] the disability often becomes chronic.[75] Though an acute bout shows some tendency to spontaneous cure,[76] recent research shows that the course of back pain is merely episodic, with repeated recurrences following an acute episode.[77–79] A substantial minority of patients may not even experience resolution of their pain and disability, and suffer for years from chronic lower lumbar pain.[80–83]

Particular types of backache

Bruised dura

Sometimes a patient complains of a constant ache in the back, which is unaltered by position or movement. The onset takes the form of an attack of acute lumbago. Resolution usually took place within 2 weeks, except for persistent constant backache over months or years. Coughing and sneezing may aggravate the pain but other movements definitely do not; there may be increased pain during the night or in the morning.

Clinical examination reveals absolutely nothing: there is a full range of spinal movements and dural signs are absent.

One possible explanation for this type of backache is 'bruising' of the dura mater.[84] The acute lumbago has induced inflammation of the dura mater. Although the disc displacement has receded after some time, the dura has remained inflamed, which results in continuous pain. Obviously this type of backache – chronic pain unaltered by posture or exertion and with a negative clinical examination – can also exist as the result of pain referred to the back from other (visceral) structures.

When a bruised dura is suspected, an epidural injection with procaine 0.5% is indicated. A positive diagnostic response not only settles the differential diagnostic question but is also the treatment, because about half of those with backache attributed to a bruised dura are permanently cured by one injection.

Nocturnal or morning backache

Backache may be confined to night-time. The patient can do everything normally undertaken during the day, without the slightest discomfort, but every morning is woken in the early hours because of increasing and severe backache which forces the patient to get out of bed. The pain quickly eases, and once the patient has been upright for, say, half an hour, the disability has totally disappeared. A pain-free day follows, in spite of the level of exertion. Alternatively, unbearable backache after 2 hours of sleep forces the sufferer out of bed. The pain abates quickly and resumption of sleep is possible. During the day there is not the slightest discomfort, even on heavy work.

Clinical examination during the day is negative: there is a full range of movement and dural signs are absent.

This nocturnal backache often occurs in middle-aged people. It is best explained by an increase in intradiscal oncotic pressure at an early stage of degeneration. When the external load is diminished in the horizontal position, there is a considerable increase in water content. Expansion forces the disc against the pain-sensitive dura. Resumption of the upright position raises the hydrostatic pressure, water is extruded and the disc deflates, which alleviates the tension on the dura mater so that pain disappears.[72]

Because the pain is of dural origin, epidural injection is the treatment of choice and succeeds in about 70% of cases.[63] Should the injection fail, ligamentous sclerosis is used, in order to stabilize the lower lumbar segments.

Nuclear self-reducing disc

Sometimes the history obtained is the converse of that described in the previous section. Waking is comfortably pain-free and exertion does not cause symptoms. Backache starts after some hours upright, increases slowly as the day goes on, being worst in the evening, and varies in intensity according to activities. Lying down abolishes the pain, which has completely gone by the next morning.

Clinical examination in the morning is negative with a full range of movement and absence of dural signs. By the evening a partial articular pattern and pain on SLR are present. Clearly there has been protrusion of nuclear material as the result of axial loading of the spine. Recumbency during the night then results in spontaneous reduction.

Because this history indicates a reducible but unstable disc protrusion, treatment should be directed towards stabilization

of the intervertebral joint. This can be achieved by sclerosing injections, which usually give good results.

Treatment

Before specific treatment is given, a few questions must be answered:

- Is the backache caused by an activity-related spinal disorder?
- If this is the case, is the disorder a discodural interaction or not?

When there is a clear combination of both articular and dural symptoms and signs, the answer is obvious. In moderate discodural backache, however, when the patient presents with articular signs only, it may be more difficult to make a certain diagnosis of internal derangement. However, a partial articular pattern always indicates a disc lesion, except in a few cases (see Ch. 39). A deviation, whether in the upright position or in flexion, signifies a protrusion. Also, the presence of a painful arc, whether during side or forward flexion, is the sign of a small posterior bulge.

The therapeutic approach to discodural backache differs from patient to patient and depends largely on the data obtained from the history and clinical examination. Although most cases of backache are caused by an impingement of a subluxated disc against the dura mater, the size, structure, position, level and stability of the bulge differ considerably. Treatment therefore must be selective. A single definitive treatment for discodural low back pain does not exist. If a subluxated fragment of disc is believed to be the cause of the pain, further questions should be posed:

- What is the level of the lesion and what is the size and composition of the bulge?
- Is the subluxated fragment an acute and occasional event, or does the patient have recurrent attacks of backache? How long does the disability last? Does the pain disappear completely between bouts or is there a continuous ache?
- What is the degree of pain and how much is the dura inflamed?
- What attitude does the patient have towards the problem?
- Does the patient want to get better? Is there any compensation claim or does the patient show clear evidence of psychological disorder? (see online chapter *Psychogenic pain*).

If there is proof of a disc lesion and the patient is well motivated, conservative treatment consists of:

- Reduction of the displacement
- Maintenance of reduction
- Desensitization of the dura (in acute or gross inflammation of the dura, it is sometimes better to desensitize it in order to abate the pain instead of trying to move the disc back into place).

Reduction

Reduction is achieved by manipulation or traction. When a slight displacement of disc tissue is believed to be responsible for the symptoms, the obvious treatment is to restore its anatomical position.

If the displacement is annular, the treatment of choice is manipulative reduction. A nuclear displacement is an indication for sustained traction. Although the two techniques are, to some extent, interchangeable, some protrusions prove irreducible by traction, yet reducible by manipulation and vice versa. It is obvious that a protrusion composed of hard annular material will respond better to manipulation but that a soft nuclear bulge requires traction. Cyriax said[45]: 'You can hit a nail with a hammer, but treacle must be sucked.' If sufficient data on the onset of the complaints cannot be obtained and the choice of treatment is in doubt, manipulation should be tried first. If it fails, the patient should attend for traction from the next day on. If considerable improvement is achieved by manipulation but, despite further attempts, a residual displacement cannot be reduced, traction should be substituted so as to complete the process.

Manipulation

The indication for manipulation is a posterior annular displacement. Signs that favour the use of manipulation are a small painful arc or a small lateral deviation during flexion. Reduction is usually easy to achieve in patients whose pain is greatest when they bend away from the painful side. The chance of success of manual reduction is also greater in elderly patients.

The manipulation techniques used in this book tighten the posterior longitudinal ligament and create space at the posterior aspect of the joint. The increased distance between the two vertebral borders gives the fragment room to move, and the force exerted by the posterior ligament pushes it back in place.

Displacements at the third and fourth levels respond best to rotatory manœuvres, whereas at the fifth level extension manœuvres are usually more effective. Rotatory manœuvres are also chosen if deviation of any kind exists. Elderly patients tolerate prone extension techniques better than rotational techniques.

The simple and easy-to-learn manipulation measures are usually speedily effective. Overall, acute backache is relieved by one session of manipulation in 46–57% of patients.[85,86] As a rule, small annular displacements are cured by a single manipulative session. In larger protrusions, 2–4 sessions may be required. When the patient presents with a marked lateral deviation, up to four manipulation sessions are sometimes needed. Manipulation is successful after a small number of sessions or not at all. Hence, if the patient does not improve almost immediately and lastingly, it is unwise to continue treatment and daily traction should be used instead.

Young patients tolerate daily manipulation when repeated sessions are required. In the elderly, however, it is wise to manipulate on alternate days, for fear of increasing ligamentous pain.

Sustained daily traction

The indication for traction is a patient under 60 years old, who describes slow onset of pain in the back. Patients with a discodural conflict, in whom the consistency of the protrusion is uncertain and who do not improve immediately after

manipulation, should also be treated with daily traction. Experience also teaches us that, when trunk side flexion towards the painful side increases the pain, traction will succeed better than manipulation.

The intention of traction is to create negative pressure in the disc[87] and to tauten the posterior longitudinal ligament, which exerts a centripetal force on the nuclear material.[88] This results in a gradual reduction of the bulge and a release from the dura mater.

Maintenance of reduction

Once the displacement is reduced and the patient asymptomatic, the question of specific prophylaxis arises.

If the history is that of a nuclear protrusion, the patient should be careful about posture, especially during prolonged sitting or bending. Maintaining the spine in slight lordosis is beneficial and helps to prevent posterior bulging of nuclear material.

Occasional attacks of annular low back pain – say, once a year – can be managed by a good manipulator, provided one is available. More frequent recurrences call for attention to active prevention. The necessity for lowering intradiscal pressure and keeping the back hollow during daily activities should be explained during 'back school' sessions, where the patient is instructed in sitting, standing, bending and lifting. However, the back school is prophylactic and not therapeutic, and patients should never attend before they are completely asymptomatic.

Strengthening the muscles of the trunk does not increase the stability of the disc. Back muscles do not directly control the intervertebral content and in consequence stability will not depend on their strength but on the position in which they keep the body. Exercise and strengthening of the abdominal and sacrospinalis muscles are therefore futile and may make backache worse because intradiscal pressure increases significantly with prone-lying extension exercises[89] and sit-up and curl-up exercises.[90,91]

In recurrent backache, where the disc is unstable and the patient suffers repeated attacks despite maintaining good posture, sclerosing injections should be given to the posterior ligaments. The purpose is to induce inflammation at the inter- and supraspinous ligaments, the posterior capsule of the facet joints and the deep aspect of the lumbar fascia, at the fourth and fifth lumbar levels. In response to the inflammation, fibrous tissue and tissue contracture in the injected ligaments occur. Permanent shortening of the injected structures then decreases the mobility and increases the stability of the intervertebral joint. About 80% of patients treated by sclerosing injections benefit from them. Another indication for these stabilizing injections is nuclear self-reducing disc protrusion, for which no other treatment is effective. They are also indicated when nocturnal or morning backache does not respond to epidural local anaesthesia.

Epidural injection

In discodural interactions in which inflammation of the dura is more important than the actual disc protrusion, the treatment of choice is epidural injection of a local anaesthetic. This is the case in nocturnal backache, for instance, where a discal swelling only intermittently presses against the dura. When backache is brought on by a 'bruised dura', epidural local anaesthesia is also used.

When backache is clearly the result of a low lumbar disc displacement but proves refractory to both manipulation and traction, the next step is epidural injection. If it is impossible to correct the discal bulge, it is logical to try to desensitize the dural tube.

Definition, symptoms, signs and treatment of discodural backache are summarized in Box 33.3.

Sciatica

Since Mixter and Bar published their classic paper in 1934,[12] it has been generally acknowledged that lateral disc displacements are the main source of radicular pain. Pressure of the protruded disc against the nerve root causes mechanical nerve fibre deformation and changes in the nerve root circulation, which result in pain and functional changes.

Mechanism

A posterior disc displacement (Fig. 33.10a) usually remains more or less under the physical influence of the posterior longitudinal ligament. The resistance of the ligament keeps the bulge in place or tends to push the protrusion forwards again, as happens during the spontaneous or manipulative reduction of a disc in acute lumbago: the pressure exerted by the ligament is higher than the intradiscal pressure and moves the bulge gradually forwards.

Sometimes, however, when intradiscal pressure remains high, the displaced tissue is pushed more and more laterally towards the posterolateral edge of the disc – a zone of lesser resistance (Fig. 33.10b).[92,93] Moved laterally, and freed from the counterpressure of the strong central part of the posterior longitudinal ligament, the bulge enlarges, lifts or ruptures the lateral ligamentous expansion and herniates into the lateral compartment of the epidural space where it compresses the nerve root. This is the typical development of a secondary posterolateral protrusion leading to a classic attack of sciatica.

For a good understanding of the clinical picture, it is important to remember that the severity of the symptoms depends not only on the mass of protruded disc material[94] but also on other factors (Fig. 33.11). Among these, the distension within the mass – in other words, the softness or hardness of the bulge – plays an important role.[95,96] Furthermore, the relative fixation of the root to the bony elements of the intervertebral foramen can determine the degree of traction on it.[97–99] Finally the degree of inflammation of the nerve is a significant element in producing symptoms.[100] There can be a direct chemical injury to the nerve root,[101–105] or extra- and intraneural swelling,[106,107] with further compression.[108] Many experts have emphasized that pain is provoked mainly when the nerve root is the site of a chronic irritation,[109–111] and experimental confirmation of this has been obtained by inflating Fogarthy balloon catheters

Box 33.3

Summary of discodural backache

Definition

- Backache, sometimes with dural reference in buttocks or legs, which is caused by a posterior shift of disc material constantly or intermittently pressing against the dura mater

Symptoms

- Acute, chronic or recurrent
- Onset indicates the type of protrusion:
  - Acute onset: annular protrusion
  - Slow and gradual onset: nuclear protrusion
  - Acute onset, with slow worsening: mixed protrusion
- Pain is unilateral, central, bilateral or alternating (extrasegmental pain reference in buttocks and legs is possible)
- Pain is increased by particular movements: as a rule sitting, coming upright after sitting, and getting out of bed are the most painful
- Dural symptoms may be present
- Particular types of backache
  - Continuous pain, 'bruised dura'?
  - Nocturnal/morning backache
  - Self-reducing disc

Signs

- Articular
  - Partial articular pattern
  - Deviation: in upright position, in flexion or alternating
  - Momentary deviation during flexion
  - Painful arc
- Dural (not always present)
  - Neck flexion?
  - Positive straight leg raising
  - Painful arc during straight leg raising

Treatment

- Manipulation
  - Annular lesions
  - Small nuclear lesions
- Traction
  - Nuclear lesions
  - Disc lesions unaltered after manipulation
- Epidural injections
  - Intractable backache
  - Nocturnal and morning backache
  - Bruised dura
- Back school: only as a prophylactic measure
- Sclerosing injections
  - Recurrent discodural conflict
  - Self-reducing nuclear protrusions
  - Nocturnal and morning backache

placed around the roots, which produce sciatica only if the pressure is maintained long enough to set up an inflammatory reaction.[112] During operations using progressive local anaesthesia, sciatica can be produced only by direct pressure or stretch on an inflamed nerve root, whereas pressure on a normal root is painless.[65]

It should thus be clear that the severity of sciatic symptoms and signs is a function of the magnitude of the mass, the intensity of the discoradicular contact and the inflammatory responses around the nerve root.[113] For all these reasons, *sciatica is not simply the existence of a bulge*, demonstrable on CT. Judging the severity of sciatica therefore depends only on data obtained from the history and clinical examination. Technical investigations usually add little information.

Symptoms and signs, the consequence of the involvement of the nerve root in the pathological changes, are articular, dural and nervous. Nerve root sleeve and nerve root fibres give rise to two different sets of clinical findings: dural and parenchymal.

The dural sleeve

Symptom: segmental pain

The dural investment is first to be compressed and inflamed, and causes the appearance of radicular pain. Unlike extrasegmental pain from pressure on the dura, pain stemming from the dural root sleeve follows exactly the rules of segmentally referred pain[114] (see Ch. 1). However, an inexperienced examiner may sometimes find it difficult to differentiate segmental radicular pain from extrasegmental dural pain. The following features may then be of value. First, dural pain is never felt beyond the ankle, whereas radicular pain of L4, L5, S1 and S2 origin usually spreads to the foot and the toes. Second, dural pain is not restricted to precise dermatomes of which the patient can give an accurate description but is felt vaguely over a large area. The patient will therefore be more imprecise in describing the area.

Sign: alterations in mobility

The dural sheath of the nerve root moves in relation to the neighbouring structures. As the course of the nerve root is downwards and slightly anterior and the nerve root is loosely bound to the pedicle below by the lateral root ligament, it will be caught against the posterolateral aspect of the disc when downward traction is exerted[115] (Fig. 33.12).

During SLR, the L4, L5, S1 and S2 roots undergo a downward and anterior excursion of 2–4 mm at the level of the intervertebral foramen[116] (see p. 430). It is obvious that, in large posterolateral disc protrusions, the mobility of these roots is impaired and SLR painfully limited. Sometimes a painful arc rather than limitation is observed: pain appears during the movement but disappears when the leg is raised higher – an indication of a small projection, which the nerve catches against and then slips over.[117] Such a momentary pain is an encouraging sign for conservative treatment.

The third lumbar root continues into the femoral nerve, which remains relaxed during SLR. Therefore lack of pain with
